There are certain laws that determine, when two substances are rubbed together, which will take the positive, and which the negative electricity. In general, the surface whose particles suffer the greatest agitation or disturbance is the negative surface. Thus if two pieces of the same material are rubbed together, there will be no excitement if the surfaces are perfectly identical; but if one is rough, and the other smooth, the rough one will be negative, and the smooth positive. So if there is a difference in their temperature, the hot surface will be negative, and the cold positive. If we take two bits of ribbon, both from the same piece, and rub the one its whole length across the other, the friction will be most intense on the second, which has sustained, on a narrow surface, the action of the other's whole length; so that the stationary ribbon will be negative, and the other positive. If one ribbon is black, and the other white, the former is negative, and the latter positive; the black dye having the effect, partly of retaining the heat, and raising the temperature more than the white, and partly of bringing in a greater agitation of the atoms under the friction. It will sometimes happen that the same body is negative when rubbed on one kind of material, and positive when rubbed on another.

The metals may be arranged in a certain fixed order, such that each metal will be negative when rubbed on any one that follows it, and positive on any one preceding it. The order is as follows:—bismuth, platinum, lead, tin, copper, gold, silver, zinc, iron, arsenic, antimony. If bismuth is rubbed on antimony, the bismuth will be negative, and the antimony positive. If iron were rubbed on lead, the iron would be positive, and the lead negative. The above series is not an isolated random arrangement of the metals, but is the order of their radiating powers for heat. The worst radiators are at the beginning of the list, the best radiators are at the end; that is, bismuth, platinum, and lead, when once heated, radiate off their heat very slowly; and, on the other hand, when they are exposed to a fire, or any other source of radiant heat, they absorb it very slowly, or they take a long time to acquire the heat. Iron and antimony, however, are good radiators; they give off their heat rapidly, and take it in rapidly. But if two metals be very near one another in such a series, their action might be reversed, if one of the two surfaces were well polished, and the other made very rough. Thus if lead were rubbed on tin, the lead ought to be negative, and the tin positive; but if the surface of the tin were very rough and very hot, while the lead is smooth and cold, the latter might become the positive element. See *Thermo-Electricity*, p. 234.

In rubbing metals to produce electricity, it is necessary to rub with large sweeps, to prevent the two electricities from joining together at the place where they are rubbed. The conducting power of the metals is such, that the excitements produced on the touching surfaces are very apt to run together, and neutralise each other on the spot.

ELECTRICAL INDUCTION.

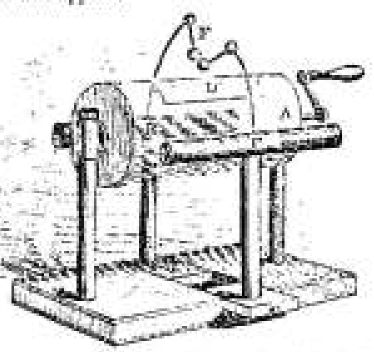
If a body is charged with electricity, and insulated so perfectly as to prevent the escape of the electricity which it contains, it nevertheless tends to produce an electrical state of the opposite kind in all the bodies around it. Thus the vitreous induces the resinous, and the resinous the vitreous, electricity in a body that is situated in the vicinity of either of them, and this to a degree proportioned to the distance which separates the bodies. The electricity is in this case said to be induced, and the phenomenon is called *electrical induction*. The operation of this law is a key to the principal phenomena of electricity. In illustration of it, we shall quote an able writer upon the subject:—'If an electrified body, charged with either species of electricity, be presented to an unelectrified or neutral body, its tendency, in consequence of the law of induction, is to disturb the electrical condition of the different parts of the neutral body. The electrified body induces a state of electricity contrary to its own in that part of the neutral body which is nearest to it; and, consequently, a state of electricity similar to its own in the remote part. Hence the neutrality of the second body is destroyed by the action of the first; and the adjacent parts of the two bodies, having now opposite electricities, will attract each other. It thus appears that the attraction which is observed to take place between electrified bodies, and those that are unelectrified, is merely a consequence of the altered state of those bodies, resulting directly from the law of induction; and that it is by no means itself an original law or primary fact in the science.

'The effect of induction will be in proportion to the facility with which changes in the distribution of electricity among the different parts of a body can be effected, a facility which corresponds with the conducting power of the body. Hence the attraction exerted by an electrified body upon another body previously neutral, will be much more energetic if the latter be a conductor than if it be an electric, in which these changes can take place only to a very small extent. This is confirmed by the following experiment:—Suspend, by fine silk threads of equal length, two small balls of equal dimensions, both made of gum-lac, but one having its surface covered with gold leaf. Place these two pendulums, as they may be called, at a little distance from one another, so as to admit of a comparison of their motions; and then present to them an excited electric, which may be either a tube of glass, or a cylinder of sealing-wax. It will at once be seen that the ball with the metallic covering, which readily admits of the transfer of electricity from one side to the other, will be much more readily and powerfully attracted than the other ball, which allows of no motion in its electricity. The latter ball will, by slow degrees, however, assume electrical states of the same kind as the gilt ball, and will be fully attracted. As this change is very slowly effected, so it is more permanent when once produced; and the plain ball adheres for a considerable time to the electric which has attracted it. The gilt ball, on the contrary, is sooner repelled, by its readily receiving the charge of electricity imparted to it by the electric. A degree of permanent electricity, however, is also induced on this ball, in consequence of its gradual penetration into the substance of the gum-lac.'

Electrical phenomena are generally accounted for by supposing that there is an extremely subtile and highly elastic fluid which pervades all material substances, but is itself devoid of any sensible gravity. It is supposed to move with various degrees of facility through the pores or actual substance of various kinds of matter. Hence, in proportion as they admit of the fluid passing through them with ease or difficulty, bodies have been divided into conductors and non-conductors. According to the doctrine of there being but one species of fluid, it is supposed that the electrical equilibrium which constitutes the natural state of matter is disturbed by friction, and that one of the two bodies brought near to each other attracts to itself a surcharge of the fluid, and is *over-saturated*, whilst the other is left in a deficient state, and is *under-saturated*. For this view of the subject we are indebted to Franklin; and hence the terms of positive or plus, and negative or minus, have arisen. But as some of the appearances cannot easily be reconciled to the hypothesis of a mere excess or deficiency of one fluid, there is another theory which supposes the fluid to be a *compound*, susceptible of decomposition by friction and other means; hence the origin of the terms vitreous and resinous electricities. With respect to the intensity of the electric force, it resembles that of gravitation, by being inversely as the square of the distance. Like gravitation, also, it acts at all distances, and it is not impeded by any intervening body, provided it be not in an active electrical state. But whilst the particles of each fluid repel those of the same kind, they exert, as we have seen, a high attractive power over those of an opposite kind. The intensity of this attraction also, like that of gravitation, increases with a diminution of distance. It is evident, therefore, that from the powerful attraction which they have for each other, they would always flow towards each other, and coalesce, were it not that the non-conducting properties of electrics offer an impediment to their motion.

ELECTRICAL MACHINES.

Rubbing or friction, it will be perceived, is always requisite to produce an artificial display of electrical phenomena. Thus in rubbing the back of a cat, in rapidly drawing off a silk from a woollen stocking, or in performing any similar action with suitable, and in all cases dry, substances, we evolve electric sparks, of lesser or greater intensity. For the purpose of producing powerful electrical results, the aid of mechanism has been found essential. We here offer a representation of the machine most commonly used, in our description of which, the essential parts constituting such instruments will appear:—



A B represents a hollow cylinder of polished glass, which revolves upon a horizontal axis, and is from eight to sixteen inches diameter, and from one to two feet long. For the purpose of insulation, it is supported on two upright pillars of glass, which are fixed in a wooden stand. Two hollow metallic conductors, equal in length to the cylinder, and about one-fourth of its diameter, are placed parallel to it, one on each side, upon two insulating pillars of glass, which are cemented into two separate pieces of wood, that slide across the base, so as to allow of being brought within different distances of the cylinder. To one of these conductors the cushion is attached, which is of the same length with the conductor C. The cushion is usually made of soft chamois leather, stuffed with hair or wool, so as to be as hard as the bottom of a chair, but yet sufficiently yielding to accommodate itself, without much pressure, to the surface of the glass to which it is applied. The prime conductor is a cylindrical tube, each end terminating in a hemisphere. As the electricity is only contained at the surfaces, it is made hollow, generally of thin sheet brass, copper, tin, or pasteboard covered with gold leaf or tinfoil. It must be carefully freed from all points and asperities; and if perforations are made in it for the purpose of attaching wires and other kinds of fixtures, for the purposes of experiment, they should be made about the size of a quill, and should have their edges well rounded and smoothed off. The pressure of the cushion against the cylinder is regulated by an adjusting screw, adapted to the wooden base at E, on which the glass pillar that supports the conductor is fixed. From the upper edge of the cushion there proceeds a flap of thin oiled silk D, which is sewed on the cushion about a quarter of an inch from its upper edge. It extends over the upper surface of the glass cylinder to within an inch of a row of metallic points, proceeding, like the teeth of a rake, from a horizontal rod, which is fixed to the adjacent side of the opposite conductor. The motion of the cylinder, which is given by a single handle, or by a multiplying wheel, must always be given in the direction of the silk flap. That part of the cushion which comes in contact with the glass cylinder should be coated with an amalgam composed of a little tinfoil and mercury, mixed like a paste by means of hogs' lard. The amalgam should be placed uniformly over the cushion, until level with the line formed by the seam which joins the silk flap to the face of the cushion. No amalgam should be placed over this line, nor on the silk flap; and it is even requisite to wipe the silk flap clean whenever the continued motion of the machine shall have soiled it, by depositing dust or amalgam on its surface.

This machine acts in the following manner:—When the cylinder is driven round by the handle, the friction of the cushion upon it produces a transfer of the electric fluid from the latter to the former; that is, the cushion becomes negatively, and the glass positively electrified. By the revolution of the cylinder, the fluid adhering to the glass is carried round, and its escape is at first prevented by the silk flap which covers the cylinder, until it arrives near to the metallic points, which absorb most of the electricity, and convey it to the prime conductor. This being positively electrified, the conductor connected with the cushion being deprived of this electricity, is negatively electrified; so that light balls suspended by threads at F, being oppositely electrified, will attract each other. After the action has gone on for some time, the cushion and its conductor become exhausted of their electricity; so that a new supply must be brought from the earth, the great reservoir of the fluid. This is easily done, by establishing a communication between the cushion and the ground by means of a metallic chain or wire. In this manner a constant stream of positive electricity flows to the prime conductor. Negative electricity is obtained by insulating the conductor to which the cushion is attached, and connecting the prime conductor with the ground, so as to carry off the fluid collected from the cylinder. If the person who works the machine be supported upon a stool having glass legs, and connected with the conductor by means of a metallic rod, or if he touch it with his hand, he is found to be in the same state of electricity; and another person standing upon the ground can draw sparks from him by presenting his knuckles to his body.

By using the electrical machine in the above manner, we are enabled to collect a considerable quantity of electricity, and thus perform experiments upon an ample scale. A pith ball, or a fragment of gold leaf, is very strongly and immediately attracted by the electrified conductor; and the instant after it has come into contact with it, it is repelled; but it is now attracted by the other bodies in its neighbourhood, to which it communicates its own electricity, and then is again in a state to be influenced by the conductor, and to be again attracted; and this alternation of effects will continue as long as the conductor remains charged. This alternation of attractions and repulsions accompanying the transferring electricity by movable conductors, is also illustrated by the motions of a ball suspended by a silk thread, and placed between two bells, of which the one is electrified, and the other communicates with the ground: the alternate motion of the ball between the bells keeps up a continual ringing.

The intensity of the electricity which bodies may contain is measured by a delicate instrument called an *Electrometer*, of which there are several invented by various distinguished individuals. Our limits, however, will not admit of our giving a minute account of them. They all depend upon the repulsive property of electrified bodies; the distance to which the one is repelled by the other being indicated by an index.

We have already observed, that upon the extent of the surface of a body its capacity for receiving electricity principally depends. Electricity is therefore supposed not to spread throughout the whole mass of a body, at least equally, but to remain principally, if not altogether, at the surface. This has been proved by experiments for trying the distance to which the electricity extended beyond the coating of the Leyden jar.

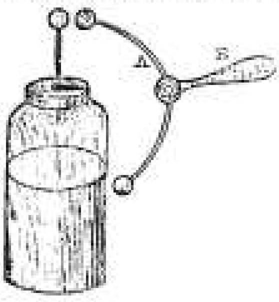
Several remarkable phenomena occur when electricity is drawn off by means of a conductor from those bodies in which the electrical equilibrium has been destroyed. A sharp snapping sound is heard, accompanied by a vivid spark, whilst intense heat is evolved in the path which the electric fluid takes. A perfect conductor offering no impediment to its course, it is unattended with light during its passage through such a body, light only appearing when there are obstacles in its path, such as imperfect conductors. Of the velocity with which it is transmitted we have already spoken. It is so great, that in experiments performed with a chain of considerable length, each link became apparently instantaneously luminous. There are various methods of showing the intensity and colour of electrical light. Conductors having a rounded form give the longest and most vivid sparks, which are sometimes seen to take a zig-zag course, similar to that of a flash of lightning. This deviation in its course is supposed to be occasioned by the fluid darting to minute conducting particles, such as those of moisture floating in the air. Electrical light is similar to light obtained from other sources, and its brilliancy depends upon its intensity. Sir David Brewster found that it was capable of polarisation.

An interesting question arises—Whence comes the light—is it the electric fluid which thus renders itself visible? This was really supposed to be the case by the early electricians, but later philosophers have substituted other theories to account for the phenomena. That of M. Biot, a celebrated French philosopher, is, that electric light has the same origin as the light disengaged from air by mechanical pressure; 'and that it is purely the effect of the compression produced on the air by the explosion of electricity.' This hypothesis has been objected to, however, on the ground that electrical light is produced in the best vacuum that can be formed; and although he has replied to the objection, that no perfect vacuum can exist, yet his arguments, though they carry weight, do not bring conviction.

We have already observed that various sounds accompany the various modes of transference of the electric fluid: a peculiar odour has also sometimes been felt near a machine which has been sharply wrought; but whence its origin, is unknown. All sharp-pointed bodies concentrate most of the electric fluid at their apex, from whence it has a powerful disposition to escape; and every discharge is accompanied by currents of air. Upon this principle many ingenious experiments are founded. An apparatus, consisting of wires terminating in points, and having balls annexed to them to represent the planets, may be constructed so as to revolve when electrified, and thus to imitate the planetary motions. We cannot enter further into this subject, but may state in general terms, that the appearances of the electric spark depend upon the nature of the surface from whence it issues, and towards which it is directed. When it escapes *from* a pointed body, the luminous appearance is that of diverging streams, resembling the filaments of a brush, and forming what is termed a *pencil of light;* but when the fluid goes to a point, the light concentrates at the point itself, and assumes the appearance of a star.

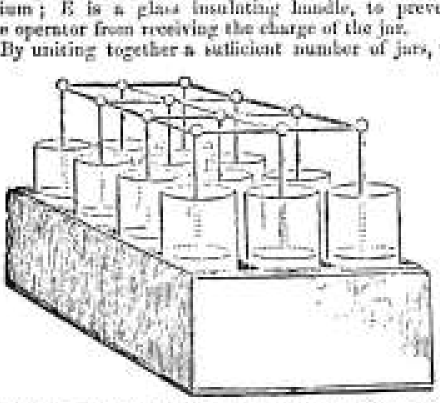
The most convenient mode of obtaining an accumulation of electricity arising from induction, is by the employment of coated glass; that is, of a plate of glass on each side of which is pasted a sheet or coating of tinfoil. Care must be taken to leave a sufficient margin of glass uncovered with the metal, to prevent the transfer of electricity from one coating to the other; and all sharp angles or rugged edges in the coatings should be avoided, as they have a tendency to dissipate the charge.

The form of coated glass best adapted to experiments is that of a cylindric jar; this is coated, within and without, nearly to the top. The cover consists of baked wood, and is inserted with sealing-wax, to exclude moisture and dust. A metallic rod, rising two or three inches above the jar, and terminating at the top in a brass knob, is made to descend through the cover till it touches the interior coating. The name of the *Leyden phial*, or *jar*, is applied to this instrument. It is used in the following manner:—The outer coating being made to communicate with the ground, by holding it in the hand, the knob of the jar is presented to the prime conductor when the machine is in motion; a succession of sparks will pass between them, while at the same time nearly an equal quantity of electricity will be passing out from the exterior coating, through the body of the person who holds it, to the ground. The jar, on being removed, is said to be charged; and if a communication is made between the two coatings, by a metallic wire extending from the external one to the knob, the electric fluid which was accumulated in the positive coating rushes, with a sudden and violent impetus, along the conductor, and passes into the negative coating; thus at once restoring an almost complete equilibrium. This sudden transfer of a large quantity of accumulated electricity is a real explosion; and it gives rise to a vivid flash of light, corresponding in intensity to the magnitude of the charge.



The effect of its transmission is much greater than that of the simple charge of the prime conductor of the machine; and it imparts a sensation, when passing through any part of the body, of a peculiar kind, which is called the *electric shock*. In the foregoing figure, A is a bent *discharging rod*, for establishing a direct communication between the inner and outer coating of the jar, and restoring the electrical equilibrium; E is a glass insulating handle, to prevent the operator from receiving the charge of the jar.

By uniting together a sufficient number of jars, we



are able to accumulate an enormous quantity of electricity. For this purpose, all the interior coatings of the jars must be made to communicate by metallic rods, and a similar union must be established among the exterior coatings, as shown in the annexed engraving. When thus arranged, the whole series may be charged, as if they formed but one jar; and the whole of the accumulated electricity may be transferred from one system of coatings to the other, by a general and simultaneous discharge. Such a combination of jars is called an *electrical battery*.

If we wish to send the whole charge of electricity through any particular substance which may be the subject of experiment, we must so arrange the connecting conductors as that the substance shall form a necessary part of the *circuit of the electricity*, as it is termed. With this view, we must place it between two good conductors, one of which is in communication with the outer coating; and the circuit may then be completed by connecting the other conductor with the inner coating by means of a discharging rod, to one branch of which, if necessary, a flexible chain may be added.

In forming arrangements for directing the passage of accumulated electricity, it should be borne in mind that the electric fluid will, on these occasions, always pass through the best conductors, although they may be more circuitous, in preference to those which are more direct, but have inferior conducting power; and it must also be recollected that when different paths are open for its transmission along conductors of equal power, the electricity will always take that which is the shortest. Thus if a person holding a wire between his hands discharges a jar by means of it, the whole of the fluid will pass through the wire without affecting him; but if a piece of dry wood be substituted for the wire, he will feel a shock; for the wood being a worse conductor than his own body, the charge will pass through the latter, as being easier, although the longer circuit. During its transit through the human body, in like manner, the shock is felt only in the parts situated in the direct line of communication. If the charge be made to pass through a number of persons, who take one another by the hand, for example, and form part of the circuit between the inner and outer coatings of the jar, each will feel the electric shock in the same manner and at the same instant; the sensation reaching from hand to hand, directly across the breast.

By accurate experiments, it appears that the force of the electric shock is weakened, or its effects are diminished, by employing a conductor of great length for making the discharge. A retardation in the passage of electricity also takes place if the conductor is not of a sufficient size; and when this is the case, as well as in those instances where the conductor is not a good one, the discharge will not be effected so instantaneously or so completely. It has also a tendency to diverge from the direct line of its course, being drawn towards conducting bodies which may attract it. The motion of electricity through perfect conductors is attended with no perceptible alteration in the mechanical properties of the conducting bodies, provided they be of sufficient size for the charge of the electric fluid transmitted. On the contrary, very considerable effects are produced when a powerful charge is sent through a wire which is too small to allow the whole quantity to pass with perfect freedom, or through an imperfect conductor, though of large size, as is proved when a tree is struck by lightning.

ELECTRICITY APPLIED TO INORGANIC BODIES AND ANIMALS.

The effects of electricity passing through various substances are both of a mechanical and chemical nature. The former resemble those which would be produced by a material agent driven with great velocity through the substance of the body. But there are many changes induced by electricity, such as cannot be attributed to mechanical agency, and are undoubtedly of a chemical nature. Some of the mechanical effects have already been noticed. Dr Priestley discovered that it expanded bodies. This is proved by passing a stream of the fluid through a capillary or thermometer tube filled with mercury; the latter will be so much expanded, as to break the glass to shivers. The tendency to expand will of course be greater as the conducting power of the body which transmits it is less. Although we know nothing of the nature of electricity, yet it has been found convenient to speak of it as a fluid. Its action upon bodies, which either obstruct its motion, or afford it a ready passage, renders its analogy with a fluid very striking, and the laws of its equilibrium are just those of an imponderable fluid. Solid bodies are capable of being diffused into vapour by passing electricity through them, as is shown by the following experiment:—Take three strips of window-glass, each about three inches long and one wide, and having placed two narrow strips of gold leaf or leaf brass between them, so that the ends of the gold leaf project a little beyond the glass, transmit the charge of a large Leyden jar through the gold leaf. The gold leaf will be found to be melted by the shock, and driven into the pores of the glass. The outer plates of glass are generally broken in this experiment, and the middle one, which frequently remains entire, has an indelible metallic stain upon each of its surfaces.

The metallic colours thus obtained have been employed for impressing ornamental figures upon paper or silk. In order to do this, trace the outline of the figures on thick drawing-paper, and having cut it out as in stencil plates, place it on the silk or paper intended to be ornamented. When a gold leaf is laid upon it, and a card above the gold leaf, the whole is placed in a press, or beneath a weight, and an electrical charge sent through it; the metallic stain is limited to the portion of the drawing-paper that is cut away, and consequently any outline figure may be readily impressed upon the ground employed to receive it.

The effects of electricity as a chemical agent are strikingly displayed in its power of evolving heat, and consequently of inflaming and fusing bodies, and its power of promoting chemical composition and decomposition. Combustible bodies, such as a common candle, can be lighted in various ways, by passing the electric fluid through them. The heat evolved by electricity, like most other of its effects, is in proportion to the resistance opposed to its passage. Nor is its heating power in the smallest degree diminished by its being conducted through any number of freezing mixtures which are rapidly absorbing heat from surrounding bodies. Sparks taken from a piece of ice are as capable of inflaming bodies as those from a piece of red-hot iron. Amongst the more striking chemical effects of electricity, or electro-chemistry, are the decomposition of water, the oxidation of metals, and the restoration of the oxides to their metallic state.

Many experiments have been made for the purpose of ascertaining the changes effected in *phosphorescent* bodies by electricity; and the results are not without importance. It has been discovered, for instance, that substances not naturally phosphorescent, such as statuary marble in its natural or calcined state, were not only rendered phosphorescent by heat after being strongly electrified, but acquired this property with a beauty, a variety, and an intensity of colour, superior to those which occur in specimens that possess natural phosphorescence. It has also very recently been discovered that electricity exercises a curious influence upon odoriferous bodies. When a current of the fluid is made to traverse camphor, the odour gradually disappears. After being withdrawn from electrical influence, it remains odourless for some time, and then slowly resumes its former properties.

There are certain mineral bodies which, from being in a neutral state at ordinary temperatures, acquire electricity simply by being heated or cooled. This property is possessed only by regularly crystallised minerals; and of these the most remarkable is the tourmalin. It is a stone of considerable hardness, and the form of its crystals is generally that of a nine-sided prism, terminated by a three-sided pyramid at one end, and by a six-sided pyramid at the other. When heated to between 100 and 212 degrees, the latter extremity becomes charged with positive electricity, whilst the former remains negative. On cooling, the electric states are generally reversed, that end becoming positive which was formerly negative. Other gems possess similar properties, such as the topaz, some species of diamonds, &c. There are a great many substances which become electrified by passing from the liquid to the solid form, such as sulphur, gum-lac, and in general all resinous bodies. The conversion of a body into the aëriform state is also generally attended by some change in its electrical condition.

There are some bodies which are rendered electrical by pressure. The substance which possesses this property in the most remarkable degree is that variety of the carbonate of lime known by the name of Iceland spar. Cork, bark, hairs, paper, and wood, also possess the property of producing electricity by compression. A number of substances, when reduced to powder, exhibit electricity, if they are made to fall upon an insulated metallic plate. The relation subsisting between electricity and the chemical properties of matter is the most important branch of this inquiry. It is observed by Sir Humphry Davy, that most of the substances that act distinctly upon each other electrically, are also such as act chemically when their particles have freedom of motion; this is the case with the different metals, with sulphur and the metals, with acid and alkaline substances. Of two metals in contact, the one which has the greatest chemical attraction for oxygen acquires positive electricity, and the other the negative. There is little doubt, indeed, that electricity is not only elicited by, but is intimately connected with, all chemical action; and there is every reason to believe that electricity is essentially concerned in the processes carried on in the living system both of animals and vegetables.

The influence of electricity upon the human frame—whether it is administered in small quantities, so as to excite and surprise us, or in the more powerful and awful form of a stroke of lightning—must be well known to every one. When the human frame forms part of the electric circuit, or when the charge of a Leyden phial is made to enter the body at one hand, and pass out of it at the other, a violent concussion or shock is felt along the line of its passage across the breast and through the arms. If the charge is increased, the patient falls down paralysed, suffering a temporary cessation of vital action; and if it be increased to a still greater extent, it produces instantaneous death. This is frequently exemplified in the cases of individuals who are killed by the lightning stroke. It is upon the nervous system that electricity produces the most powerful influence. A strong charge passed through the head gives the sensation of a violent but universal blow, and is followed by a transient loss of memory and indistinctness of vision. If a charge be passed through the spine, the person who receives it loses his power over the muscles to such a degree, that he either drops on his knees, or falls prostrate on the ground. Different persons are affected in very different degrees by electricity, according to their peculiar constitutional susceptibility. Small animals, such as mice and sparrows, are instantly killed by a shock from thirty inches of square glass.

M. Rousseau has suggested a means of 'ascertaining the purity of certain substances, and of detecting any adulterations in them, by measuring their conducting power for electricity. Some years ago, he described a simple apparatus by means of which the purity of olive-oil might be tested on similar principles. He now states that, by these means, any adulterations in chocolate or coffee may be readily detected: he finds that pure chocolate is a non-conductor or insulator of electricity, but that in proportion to the quantity of farina or fecular matter with which it is adulterated, the more easily does it conduct electricity; and in the same way he states that coffee is an insulator, whilst chicory, with which it is often mixed, is an excellent conductor: hence the presence of only a small quantity of that substance is easily detected in coffee by its increased conducting power.'

Electricity is exhibited in a remarkable degree in various living animals; for example, we find in certain fishes a regular system of electrical organs, by which they either defend themselves from the attacks of their enemies, or seize the prey nature has provided for their use. Amongst the most remarkable of these is the *raia torpedo*, which is capable of giving a great many shocks to a number of individuals connected together, in the same manner as in the experiment with the Leyden jar. Another is the electric eel, *Gymnotus electricus*, which, when provoked, discharges its electricity, and the shock is experienced if the hand be dipped in the water containing the fish.

Although many ingenious electrical experiments have been made upon *vegetables*, some of which seem to indicate that the fluid exercises considerable influence over vegetable life, yet the subject is still involved in too great obscurity to admit of its being treated as a branch of electricity.

ELECTRICITY OF THE ATMOSPHERE.

The resemblance between the electric spark, and more especially the explosive discharge of the Leyden jar, and atmospheric lightning and thunder, struck the mind of Franklin with so much force, that he determined, if possible, to verify their identity by experiment. Having constructed a kite, by stretching a large silk handkerchief over two sticks in the form of a cross, on the appearance of an approaching storm he went into a field in the vicinity of Philadelphia, and raised it, taking care to insulate it by a silken cord attached to a key, with which the hempen string terminated. No sooner had a dense cloud, apparently charged with lightning, passed over the spot, than his attention was arrested by the bristling up of some loose fibres on the hempen string: he immediately presented his knuckle to the key, and received an electric spark. The rain now fell in torrents, and wetting the string, rendered it a conductor throughout its whole length, so that electric sparks were now collected from it in great abundance. This discovery soon engaged the attention of the philosophers of Europe; and the truth of the theory, that lightning and electricity are the same fluid, was put beyond all question. In like manner, falling-stars, and other meteoric phenomena, can only be satisfactorily accounted for by regarding them as the results of certain electrical conditions of the atmosphere.

The atmosphere is very generally in an electrical state. This is ascertained by employing a metallic rod, insulated at its lower end, elevated at some height above the ground, and communicating with an electroscope. In order to collect the electricity of the higher regions of the air, a kite may be raised, in the string of which a slender metallic wire should be interwoven. The atmosphere is almost invariably found to be positively electrified; and its electricity is stronger in the winter than in the summer, and during the day than in the night. From the time of sunrise, it increases for two or three hours, and then decreases towards the middle of the day, being generally the weakest between noon and four o'clock. As the sun declines, its intensity is again augmented till about sunset, after which it diminishes, and continues feeble during the night. In cloudy weather, the electrical state of the atmosphere is much more uncertain; and when there are several strata of clouds moving in different directions, it is subject to great and rapid variations, changing backwards and forwards in the course of a very few minutes. On the first appearance of fog, rain, snow, hail, or sleet, the electricity of the air is generally negative, and often highly so; but it afterwards undergoes frequent transitions to opposite states. On the approach of a thunder-storm, these alternations succeed one another with remarkable rapidity.

The protection of buildings from the destructive effects of lightning, is the most important practical application of the theory of electricity. The conductors for this purpose should be formed of metallic rods, pointed at the upper extremity, and placed so as to project a few feet above the highest part of the building they are intended to secure; they should be continued without interruption till they descend into the ground below the foundation of the house. Copper is preferable to iron as the material for their construction, being less liable to destruction by rust or by fusion, and possessing also a greater conducting power. The size of the rods should be from half an inch to an inch in diameter, and the point should be gilt or made of platina, that it may be more effectually preserved from corrosion. An important condition in the protecting conductor is, that no interruption should exist in its continuity from top to bottom; and advantage will result from connecting together by strips of metal all the leaden water-pipes, or other considerable masses of metal in or about the building, so as to form one continuous system of conductors, for carrying the electricity by different channels to the ground. The lower end of the conductor should be carried down into the earth, till it reaches either water, or at least a moist stratum.

For the protection of ships, chains made of a series of iron rods linked together are most convenient, on account of their flexibility. They should extend from the highest point of the mast some way into the sea, and the lower part should be removed from the side of the ship by a wooden spar or outrigger.

VOLTAIC ELECTRICITY, OR GALVANISM.

About the end of last century, an Italian named Galvani discovered that, by arranging two rods of different metals so that they touched one another at one end, and included between their other ends the leg of a recently-killed frog, a convulsive contraction of the limb was produced. It is necessary that one of the metals should touch the nerve, and the other the muscles, in order to produce the effect. The action thus caused by the contact of two metals, or by a triangular circuit formed of two metals and a frog's leg, was found to be the very same as a shock of electricity from the common machine. A new source of electricity, independent altogether of friction, was consequently brought to light. Volta, who followed up the experiments of Galvani, was the first to construct an apparatus for obtaining the excitement in this new principle; hence the kind of electricity so produced is now called *voltaic electricity, or galvanism*.

Although the electricity of Volta is undoubtedly the same natural agency as the electricity of the common machine, it has nevertheless some characteristics that distinguish it from machine electricity, besides its peculiar mode of development. It is found to be of feeble *strength* or *intensity*; that is to say, it can never be excited to such a stretch as to inflict the severe blows upon animate or inanimate things that the other can give. The most powerful voltaic machine that has ever been constructed could not strike a man dead, or shatter a resisting obstacle. On the other hand, the voltaic electricity can be produced in much greater *quantity* or amount than we can obtain from friction. The distinction between *intensity* and *quantity*, which is of great importance in reference to the whole of the present subject, may be familiarly illustrated by the case of heat. The *intensity* of heat is its temperature; the *quantity* depends partly on the temperature, but chiefly on the extent of the heated substance. A red-hot poker is of a very high temperature or intensity; but it does not contain so great an amount of warmth as the water of a single hot bath. The quantity of heat is measured by the amount of coal necessary to produce it; and it may be expended either in heating a small body to a very high temperature, or a larger extent of material to a moderate temperature. The electricity of friction may be compared to a red-hot iron, that of Volta to a vast volume of warm water.

Now there are certain purposes that are best served by the high intensity; and others that require merely a great quantity, no matter how feeble the intensity. The chemical and magnetical effects of electricity are dependent on quantity alone; hence these were not produced in a very high degree till after the discoveries of Volta.

The term *current electricity* has also been given to the present branch of the subject, because the excitement arises in a constant stream, and can hardly be said to exist if it is not continually evolved. A Leyden jar may be charged, and may remain in that state, without requiring a continual supply to be poured into it; hence the common electricity has been called *statical*, or reposing electricity, or electricity in equilibrium. But the other kind must be kept in constant motion, in order to appear at all. This is owing to its feebleness, or its inability to give a high charge. If it is insulated, it soon ceases; because it cannot go on adding to the intensity of a limited surface: hence the voltaic machine must always be formed into a circle of conductors, where the electricity may flow round and round without interruption; in which case it is produced without ceasing.

It was supposed by Volta that the electricity arose from the simple fact of two different metals touching each other; or that there is a virtue in mere contact similar to the active rubbing of two surfaces. A crown-piece laid on a copper penny would, according to him, evolve electricity; and the one would be positively, and the other negatively charged. But there is no sufficient reason for believing that the simple contact of two bodies, apart from all other influences, is able to disengage electricity. There may be circumstances attending the contact that will render it a source of excitement; the one substance may have a strong chemical affinity for the other, as when a piece of soda is dipped into an acid; or the one may be much hotter than the other, and cause a rapid communication of heat to arise; or they may be unequally susceptible to some common influence, as when the flame of a lamp is applied to the joining; but in all these cases a power is present over and above contact, which may serve to give forth electricity.

The more common belief as to the source of voltaic electricity is, that it is due to *chemical combination*, or the union of two substances having a chemical affinity for each other. Such unions commonly produce heat in great abundance; for it is well known that the warmth of a fire proceeds from the union of coal with the oxygen of the air. When two substances combine together to produce a third substance different in its qualities from both, there is always a disengagement of heat, and the action is of the kind called *chemical*. A quantity of brimstone united in this way with a mass of copper filings, results in a new material, different in every respect from either brimstone or copper; they are yellow; it is black: it is neither a combustible like the one, nor a metal like the other. The production of this new substance is an act of chemical combination; and while the union is going on, an intense heat is given forth.

Now the prevailing theory is, that the kind of action that transforms two substances into a third substance having new and distinct properties, which takes place in uniform and fixed proportions, and which causes sensible heat, is the action that gives birth to the electricity of Volta. It can be proved that in most cases of chemical action electricity is always developed. When an acid combines with an alkali, the acid acquires positive, and the alkali negative excitement. So when an acid acts on a metal—as when zinc is plunged into oil of vitriol—the acid is positive, and the metal negative. The action of water in rusting metal would also render the metal negative.

Dissolutions without chemical action bring forth the electrical excitement. When acids are dissolved in water, they become positive, and make the water negative. When alkalies are dissolved in water, they become negative, and make the water positive. When acids are mixed with one another, there is no action beyond mere solution; electricity, nevertheless, arises. If nitric and muriatic acid are mixed, at the moment of mixture excitement may be detected—the nitric acid being the positive ingredient.

The action of the machinery that is used for producing voltaic electricity may now be understood without much difficulty. This machinery generally consists of two metals, and a liquid capable of acting upon metallic bodies by chemical affinity. One of the metals should be acted on as strongly as possible, and the other as weakly as possible. The liquid is commonly an acid, or a corroding salt dissolved in water. Water alone will serve the purpose; but its chemical affinity for metals being faint, compared with acids, it produces feeble effects.

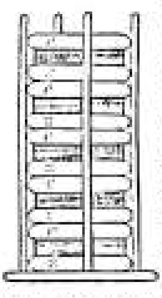
Let the adjoining fig. represent a vessel containing an acid, or other corrosive liquor. Immerse in the liquid a plate of zinc (Z): a chemical action will immediately arise; the surface of the zinc will be attacked, and gradually converted into a new substance, which will be some compound of zinc. In the meantime the zinc will be acquiring a charge of negative electricity, and the liquid an equal charge of positive electricity; which could be made apparent by the instruments adapted to show this kind of electricity, or by what is called a voltaic electrometer. But let us next immerse a copper plate (C), face to face with the zinc plate. Copper is much less readily acted on than zinc, but it is still liable to be corroded by an active liquor.

Accordingly, the copper surface would be gradually combined with the liquid, and a coating would be formed on it which would consist of a compound of copper. Thus, then, we should have two metallic plates—one undergoing a quick, and the other a slower corrosive action or chemical combination. Electricity would arise in both cases; the metals would be negative, and the liquid positive. But take now a wire (W), and solder it to the edges of the two plates that are outside the liquid; a circle is then formed, containing four portions—namely, a plate of zinc, a mass of corrosive liquor, a plate of copper, and a wire bridging from the copper to the zinc. The actions formerly described are now greatly modified. The action upon the zinc plate, which is the more corrosive of the two, is very much quickened; the compound formed on its surface is deposited more rapidly. But *the corrosion of the copper entirely ceases.* The production of electricity is therefore now confined to the surface of the zinc; and this electricity is found to circulate steadily round and round the fourfold circle of zinc, liquid, copper, and wire: it may be easily detected at any place in this circle. In other words, a permanent electrical excitement is maintained in every point of four connected substances. If all the excitement existing in the apparatus were taken off and discharged at any one instant, it would be found renewed again the next; hence the reason for speaking of this excitement as a *current*, or as being in a current state. The principle already laid down for determining the kinds of electricity that arise when an acid acts on a metal, informs us of the directions taken by the positive and negative currents. Thus the zinc (Z) is negative, while the liquor adjoining, or intervening between the plates, is positive; and as the action goes on, more and more negative electricity passes upon the zinc, and more and more positive electricity upon the liquid. Accordingly, the negative charge of the zinc, being driven away from the surface of contact of zinc and liquor, can go in only one direction. It cannot pass to the liquid, and thence to the copper; it must therefore pass upon the wire, and round to the copper by the outside portion of the circuit. So the positive electricity, originating at the surface of corrosion, and passing thence upon the intercepted liquor, must make its way through the liquor to the copper plate, and from that to the outside wire, and round to the zinc in this direction. That is to say, the negative charge is conducted from the zinc by the outside wire to the copper, and through the liquid to the zinc again; while the positive charge is conducted in the opposite course, or through the liquid to the copper, and thence by the wire to the zinc. All the four portions of the circle are conducting substances, so that the charge will readily pass round and round. We have thus two opposite currents—a positive current circulating in one direction, a negative current circulating in the contrary direction. The two currents are always of equal intensity and quantity, and they always move in the directions now described. The zinc plate is called the negative pole of the circle, and the copper plate the positive pole; because a body touching the one would take on a negative charge, and a body touching the other, or the copper, would be made positive.

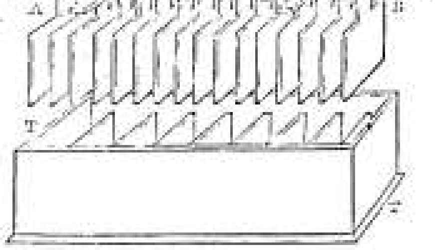
It appears, therefore, that chemical action is the origin of the electricity; and, on the other hand, that the electricity produced has some control over the chemical action; for one of the two affinities—namely, that between the liquid and the copper, is entirely suspended by it, and the other is made more intense. How this happens, we shall have to explain when we come to speak of the theory of the voltaic circuit, after describing the most usual forms of its construction.

VOLTAIC PILES AND BATTERIES.

The first form of the apparatus for evolving chemical electricity was called the *pile of Volta;* because it was constructed by Volta from a great number of round pieces of metal, like crown pieces, piled up in a column. If a round piece of zinc is taken, and a similar piece of copper, and if a moist cloth is laid between them, a voltaic circle will be formed when an outside conductor is carried from one plate to the other. All the four elements of the circle will be present—the zinc; a corrosive liquor in contact with it, and extending to the copper; the copper; and the outside conductor from the copper to the zinc. The cloth merely serves the purpose of containing the liquid. Thus, let an upright stand be formed, with glass or wooden rods fixed into a piece of wood for a bottom. Place on the bottom a disk of zinc, Z; above that a piece of woollen rag, soaked with corrosive liquor, of the same size as the zinc, and upon the cloth a disk of copper. On the copper lay another piece of zinc, a wet cloth, and another piece of copper; and repeat the same process until the pile is built up to a sufficient height, being careful to observe the same order throughout. The pile will terminate in a disk of copper above, and in a disk of zinc below; and when a conducting communication, such as a piece of wire, is carried from one end to the other, a circle will be formed, and a pair of currents will be carried round and round in opposite courses, exactly as in a single circle. Commencing at the lowest zinc plate, there will be a chemical action between its surface and the liquor touching it; electricity will be developed, the negative charge will pass upon the zinc plate, and the positive will be conducted through the liquid to the first copper disk, and from it to the zinc lying upon it, and thence to the place of action between the second zinc and the second cloth, where it will be reinforced by the excitement produced at this contact, and a double charge will pass through the second cloth to the second copper, and thence to the third zinc, to be reinforced again, and pass on as before. In this way all the actions of the pieces of zinc upon their adjoining liquid will conspire into one great positive current, passing from the bottom upwards; and at the same time the negative charges arising on the zinc plates will join together in one great negative current passing downwards, and going off at the lowest plate by the outside conductor, and proceeding by it to the top, to move downwards again. The general course of the process will be the very same as in a single circle: the zinc end will be the positive, and the copper end the negative pole of the pile. The intensity of the pile increases with the number of plates. If these are few, but large, the intensity is not great, but the quantity is considerable. That is to say, such a pile would not give severe shocks, but it would have powerful magnetic and chemical effects, which, as stated, depend upon quantity, without regard to intensity.

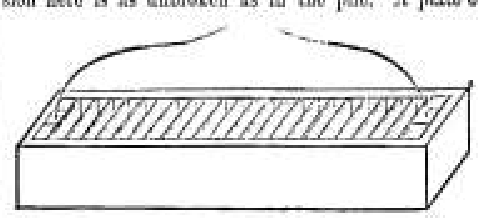


The pieces of cloth employed in the pile being of no use but to contain the liquid, they may be dispensed with, and instead of them, vessels may be used to contain both the liquid and the plates. Volta himself made an arrangement of this sort; and all the usual forms of the voltaic battery are constructed on the principle of immersing the plates in the corroding liquor. The *trough battery* is a porcelain trough (TT), divided by partitions into separate compartments or cells, each compartment being intended to receive a pair of plates



and contain the acting liquor. The plates are suspended from a piece of wood (AB), at the proper distances for being immersed in the separate cells, and they are connected with one another by metallic slips; it being necessary that each plate of copper should have a conducting connection with the next plate of zinc, in order to complete the circle. No communication of any kind is allowed to take place between one cell and another; with this view the partitions are made not only water-tight, but of an insulating material, like porcelain. The battery of the Royal Institution, by which Sir Humphry Davy effected the decomposition of the alkalies and earths, was of this construction, and consisted of 2000 pairs of plates, with an acting surface amounting to 128,000 sq. inches.

Another kind of trough battery is represented below, where the partitions themselves are the acting plates; each partition being made up of a plate of zinc and a plate of copper soldered together. The succession here is as unbroken as in the pile. A plate of

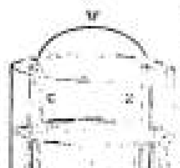


zinc, a portion of liquor, and a plate of copper, follow each other, and are repeated from one end to the other. The liquid is of course poured into the cells. A wire is soldered to the last zinc plate at one end, and another wire to the last copper plate at the other end; and when these wires are brought together, or connected by any conductor, the circle is completed, and the currents pass into active circulation.

THEORY OF THE VOLTAIC CIRCUIT.

Various imperfections of a practical kind occur in the working of the piles and batteries above described, the most serious of which is, that the action, although ever so strong at first, becomes rapidly weaker and weaker, and in no very long time entirely ceases. The materials formed by the chemical action of the liquid and the zinc gradually accumulate, and stand between the fresh zinc and fresh liquor, and thus prevent the process from going on. But to remedy this and the other imperfections of the battery, it is necessary to understand clearly what the circumstances are that add to its strength, and what causes contribute to weaken and obstruct it.

Let us consider again a single pair of copper and zinc plates, immersed in a vessel containing liquid: and in the first place, let the liquid be pure water, which, though feeble in its effects, is an exciting substance. Let Z and C be the two plates, supposed to be seen edgeways, and to face one another, and connected outside by the wire W. It has been known for the last seventy years that water is not a simple, but a compound body, formed by the chemical union of other two elements—oxygen and hydrogen. Each ultimate particle of water must therefore be supposed to be a compound particle, or an atom of oxygen adhering firmly to an atom of hydrogen. It is as a compound body that water acts in the voltaic circle, and as such we have to look upon it.



Let the double circles 1, 2, 3, 4, stand for atoms of water, or compounds of oxygen and hydrogen; the oxygen atom being marked *o*, and the hydrogen atom *h*. An oxygen atom is supposed to be in contact with the zinc plate; and the process pursued is the following. The zinc has, from its nature, a strong affinity for oxygen; this affinity is more powerful than the affinity of hydrogen for oxygen; and in such an arrangement as the present, the superior affinity of the zinc draws the oxygen atom to itself, dissolves the attraction between it and its hydrogen atom, sets the hydrogen free, and makes a new compound atom called oxide of zinc. Along with this transference of the oxygen particle, there is a quantity of free electricity evolved: the oxide of zinc has a negative charge, and the disengaged hydrogen atom a positive charge. But this charge possessed by the hydrogen increases its affinity for oxygen, or makes it more powerful than a particle that has no such extra excitement. Accordingly, it approaches the oxygen end of the second particle of water, overpowers the affinity of the two atoms, combines with the oxygen, and sets the hydrogen free, charged in like manner with positive electricity. This free and charged hydrogen comes up to the third atom of water, and decomposes it in the same way; and a series of decompositions goes on till the copper plate is reached, and the action interrupted. Thus the free hydrogen appears at the copper plate, and communicates to it by contact its positive charge, rendering the copper positive, and enabling it to transmit positive electricity round the outside wire towards the zinc. The particles of free hydrogen rise up to the surface from the copper plate. The reason why the copper is not acted on in the closed circuit is, that the currents derived from the zinc overpower its own attraction for the oxygen of the water. The copper would of itself attract water particles by their oxygen end, and decompose them; but the zinc being much more powerful in its attraction, it begins a series of decompositions that end in presenting hydrogen instead of oxygen to the copper, and in suspending its power to decompose the water. The transmission of electricity is thus effected by loosening the bonds of every compound atom that stands in its way, and by making up new combinations, where different atoms are brought together. The carrying round of the currents to the place of action, quickens the energy of the combination at the surface of the zinc.

Such a circle formed out of zinc, copper, and pure water, would in a short time entirely cease, owing to the zinc becoming coated with oxide, which stands between the water and the particles of metallic zinc. But if a small portion of oil of vitriol, called also sulphuric acid, is poured into the water, it combines with and carries off the coating of oxide from the zinc plate, and leaves a clean surface; the action then goes on again with renewed energy. The acid continues to take up the oxide as fast as it is formed, and the circle is thereby rendered much more active.

When sulphuric acid combines with oxide of zinc, it forms a new substance, called sulphate of zinc, which remains dissolved through the liquid. But this new substance acquires, like the hydrogen, a positive excitement, and goes in consequence towards the copper, and is apt to form a deposit that mars the conducting power of the plate. Moreover, the hydrogen itself, by its attraction for the copper, is apt to remain stagnant in the surface, and prevent the evolution of new particles, in which the continuance of the action depends. This is remedied by pouring nitric acid into the cells, which has the power of absorbing the hydrogen as fast as it is formed at the copper; and to prevent the sulphate of zinc from going on to the copper conductor, a porous or permeable partition is interposed between the plates. This partition is called the *diaphragm*.

The power of a battery is increased by substituting for the copper a metal still less corrosive, such as silver, gold, or platinum. Platinum is, of all metals, the least acted on by acids; hence it is well adapted for the positive plate of the battery. A further improvement is made by amalgamating the zinc plates, that is, coating them with mercury, which, from a cause not well understood, serves to diminish their waste.

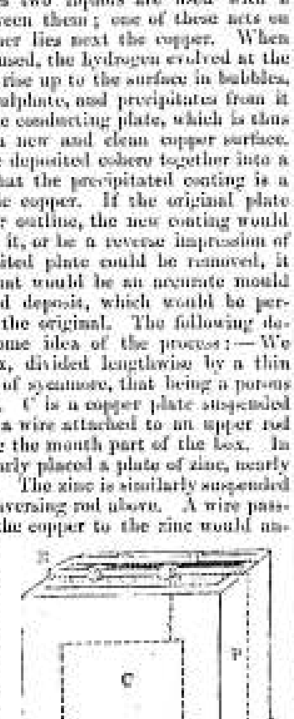
The voltaic battery produces effects similar to those of common electricity. It has the power of decomposing chemical compounds; it evolves heat sufficient to burn combustibles and heat metallic wires to redness. Its magnetical effects will be described afterwards. With respect to its physiological effects, it may be observed that the shock received by the human body from the voltaic pile is similar to that resulting from a large electrical battery very weakly charged. Twenty pair of plates are generally sufficient to give a shock which is felt in the arms. With a hundred pair, it extends to the shoulders. A continued flow of the current through the body is accompanied by a continued aching pain. The impression made upon some of the nerves of the face when they form part of the circuit, is accompanied by the sensation of a vivid flash of light. When the current is made to pass along a nerve distributed to any of the muscles of voluntary motion, they are thrown into violent convulsive contractions. The susceptibility of some animals is very great; and if the battery be powerful, small ones (birds, mice, &c.) may be easily killed by the shock. Striking effects are produced by galvanism in the muscles of an animal after death, as long as they retain their contractility.

APPLICATIONS OF VOLTAIC ELECTRICITY.

The first practical application of voltaic electricity to the arts, was the protection of the copper bottoms of ships from the destructive action of sea-water. Sir Humphry Davy suggested that nails or wires of zinc should be fastened, at intervals, on the copper plates, which would cause a circuit to be formed of copper, zinc, and salt water. In this case the copper would cease to be acted on by the water, and would serve as a conducting plate to the zinc, which would be the substance wasted. Thus a small expenditure of zinc would come in place of a great expenditure of copper. A piece of zinc equal to the head of a small nail was found sufficient to protect between forty and fifty square inches of the ship's bottom.

The value of the device was, however, neutralised by a consequence that had not been foreseen: the protected copper bottom rapidly acquired a coating of sea-weeds and shell-fish, whose friction on the water became a serious resistance to the motion of the ship; and it was discovered that the bitter poisonous taste of the copper surface, when corroded, acted in preventing the adhesion of living objects. The principle, however, has been applied with success to protect the iron pans used in evaporating sea-water.

The greatest application of the voltaic circuit is the *electrotype*, or the process of multiplying impressions of medals, coins, engraved plates, busts, &c. which was invented about the same time by M. Jacobi of Petersburg and Mr Spencer of Liverpool. It is founded on the action of the circuit upon sulphate of copper, commonly called blue vitriol, when this is dissolved in the liquor adjoining the copper plate. We have seen that in improved batteries two liquors are used with a porous partition between them; one of these acts on the zinc, and the other lies next the copper. When sulphate of copper is used, the hydrogen evolved at the copper plate does not rise up to the surface in bubbles, but decomposes the sulphate, and precipitates from it metallic copper on the conducting plate, which is thus constantly receiving a new and clean copper surface. The particles that are deposited cohere together into a firm solid mass, so that the precipitated coating is a plate of good metallic copper. If the original plate had a certain shape or outline, the new coating would exactly correspond to it, or be a reverse impression of it; and if the deposited plate could be removed, it would have a face that would be an accurate mould for receiving a second deposit, which would be perfectly identical with the original. The following description will give some idea of the process:—We take a trough or box, divided lengthwise by a thin partition P, composed of sycamore, that being a porous and durable material. C is a copper plate suspended in one of the cells by a wire attached to an upper rod of metal R, traversing the mouth part of the box. In the other cell is similarly placed a plate of zinc, nearly the size of the copper. The zinc is similarly suspended by a wire from the traversing rod above. A wire passing over direct from the copper to the zinc would answer the same purpose of communication; but the plan of an intervening rod with attaching screws is found to be more convenient. Into the cell containing the copper we put as much water as will about four-fifths fill it; then into this we place crystals of sul-



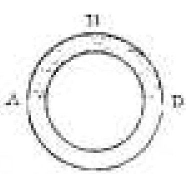
phate of copper, which soon dissolve and form a solution. Into the other cell, containing the piece of zinc, we place a similar quantity of water, into which pulverised sal ammoniac is put, so as to form a solution likewise. The preparatory process may now be said to be complete; but unless the copper has been previously prepared to receive the deposition on one part only, the deposition would take place all over it. To guard against this, the copper, before being placed in the trough, must have been coated on the back and edges with a moderately thick varnish of sealing-wax dissolved in spirits of wine, and which must be allowed to harden before it is put into the trough. The wire of the copper must likewise be varnished; but no varnishing is necessary on the zinc.

We have now described all that requires to be done in the first instance; and the trough may be put aside to allow the process time to operate. This operation will consist of voltaic currents, commencing with the action of the sal ammoniac upon the zinc, and going round the circuit. As the action proceeds, it will be observed that an effervescence is going on in the zinc cell; and this indicates that the deposition of metal from the sulphate of copper is taking effect on the plate. The length of time occupied in perfecting the process will vary from four to six days; but during this interval it will be necessary to add fresh material, both sulphate of copper and sal ammoniac. In some boxes a small shelf is put, to contain the sulphate of copper during its dissolution. The copper plate may be occasionally examined, to ascertain the extent of the deposition; and when this deposition is as thick as a shilling, it may be separated from the plate. We have now procured a fac simile of the engraved copper plate *in relief*—in point of fact, a substantial piece of copper formed from a solution. The copy in relief is of no value in the arts; and to be of use, it must be subjected to a fresh process, in which *it* receives the deposition. This second deposited cake of metal is a *fac simile* or duplicate of the original plate; and by thus using the relief plate again and again, we may obtain any number of engraved copper plates of the same subject that we may think proper.

In this way a deposition may be made on any metallic surface whatsoever, and an exact copy in reverse of that surface taken. But the process is not confined to metallic surfaces. A coating can be precipitated on wood, sealing-wax, plaster of Paris, or any other plastic material, by first covering it over with a film of black lead. The black lead renders the surface a conductor of electricity, and, as such, it may form part of the voltaic circle, and cause a metallic deposit to take place. Copies may be taken in silver, gold, and platinum, as well as in copper, by using solutions of the salts of these metals. So the processes of plating, gilding, and platinising can be performed by electrical deposition—that is, an article made of iron, copper, or any cheap metal, can receive a coating of silver, gold, or platinum, to whatever thickness may be desired. Even baskets and wickerwork may be enveloped in a metallic surface.

THERMO-ELECTRICITY.

In the voltaic circuit, chemical combination is the source of the electricity, and this electricity produces a great many different effects, the most prominent being—chemical decomposition, *heat*, and magnetism. Now, as electricity can produce heat, so, on the other hand, heat can produce electricity, as we formerly had occasion to mention. But it was only in 1822 that the method was devised of procuring a permanent current by the application of heat, in the same way as a current is maintained by chemical combination in the voltaic circle. The discovery was made by Professor Seebeck of Berlin. Hence arose a new branch of the subject, termed *thermo-electricity*, or *heat-derived* electricity. A thermo-electric circle is formed by choosing two metals, whose power of radiating heat is unequal, and soldering them together; then if the joining is heated by a lamp, currents of electricity are evolved, which will pass round and round when a metallic circle is completed. Thus in the figure; if ABCD be a metallic circle, the one-half ABD being bismuth, and the other half copper; and if a lamp is applied at A, one of the joinings, it will heat both metals, and cause electric currents to flow round the circle. A positive current will pass from the bismuth to the copper, or round in the direction ACDB, the negative taking the opposite direction; so that when two metals differently disposed in regard to the reception of heat are heated together, the discrepancy shows itself in rendering the metals electric.



If, instead of bismuth and copper, bismuth and antimony are soldered together, the effect will be greater, the disparity of the metals being greater. The following table exhibits the order of the principal metals in regard to thermo-electric combinations:—

Bismuth	Lead	Gold
Mercury	Tin	Zinc
Nickel	Copper	Iron
Platinum	Silver	Antimony.

The metals at the top of the table—bismuth, mercury, &c.—are the worst radiators of heat; that is, if they are raised to a high temperature, they give off their heat slowly; and on the other hand, they take in radiant heat slowly. If exposed to a fire at the same distance as metals at the lower end of the table—such as iron and antimony—they would be much longer in being heated to a given pitch than these would be. Accordingly, antimony, iron, and zinc, are good radiators of heat, and good at taking in radiant heat. The farther asunder two metals are in the list, the greater the difference of their radiating power, and the better they answer as a thermo-electric couple. Hence bismuth and antimony surpass all others; next to these would be bismuth and iron. Each metal causes a positive current to pass upon any metal beneath it, and a negative upon any metal above it; that is, the bad radiating and receiving metal is rendered negative, and the good radiator positive, by the application of heat to their junctions.

Compound thermo-electric circles, or batteries, are formed by soldering any number of rods, end to end, in a line; in this case the heat will have to be applied to every second joining. Thus we must take first a bar of bismuth, and solder it to a bar of antimony; then to the free end of the antimony we solder a second bar of bismuth; and so on as long as we please. Then if the first, third, fifth, &c. joinings are heated, currents will be produced all in the same direction, and augmenting each other. If, while these joinings are heated, the other joinings—that is, the second, fourth, sixth, &c.—are cooled, by being laid in ice, the effect will be increased. Cooling has the same action as heating; but the currents arising from it are in opposite directions. Such a line of bars as we have described may be so doubled up into a bundle, as that the odd joinings shall be at one end (the first, third, fifth, &c.), and the even joinings (the second, fourth, sixth, &c.) at the other end. Such is the usual form of the thermo-electric battery. A wire connected with the last rod of bismuth makes the negative pole; a wire attached to the last rod of antimony is the positive pole. If either end of the bundle is heated, currents will be produced; if both are equally heated at the same time, there would be no excitement; if one were heated, and the other cooled, the excitement would be doubled. The thermo-electric battery is found to be a very delicate measure of radiant heat; and it is therefore adopted as a new kind of thermometer.

MAGNETISM.

Anciently, there was found in Magnesia, in Asia, a certain kind of iron ore, in which the remarkable property was discovered of attracting other kinds of iron or steel; this ore afterwards received the name of *loadstone;* but from Magnesia, the place in which it was originally found, we derive the terms *magnet* and *magnetism.* Latterly, loadstone ore has been discovered in Siberia, Sweden, Piedmont, the kingdom of Naples, and various places in North America. This magnetic iron ore, which is of an excellent quality for making steel, is of a dark colour, and generally occurs crystallised in the form of regular octahedrons; its attractive quality is strengthened by exposure to the air. It has likewise been found that meteoric stones, which are composed of iron and nickel, possess a strong magnetic virtue resembling the loadstone of the earth.

Besides attracting iron, the loadstone is found to have the remarkable property named *polarity;* that is to say, if a loadstone is freely suspended by a string, or lies on a pivot, it will not rest till it has settled in one position, which is a nearly north and south direction; or one end points to the north, the other to the south. If it is moved out of this position, it returns to it again. The term *polarity,* which has now such a wide usage in the sciences, originated in this fact. The end of the loadstone that pointed to the north pole of the earth was called its north pole, and the other end its south pole; and the loadstone was thus said to be *polar* in a new sense; for the old meaning of poles, as when we speak of the earth's poles, was the ends of the axis of revolution.

But the loadstone, besides attracting iron, and pointing to the north and south poles of the earth, has the power of communicating its virtue to steel. If a bar of steel is repeatedly rubbed from end to end by a loadstone, the steel is permanently endowed with all the magnetic properties; that is, it is able to attract iron, and it arranges itself in the north and south direction. A piece of steel thus acted on is called an *artificial magnet,* the loadstone being designated the *natural magnet.* A magnet will attract iron in all its forms; but it is only iron made into steel that can take on the power of magnetising upon itself.

If we suspend a magnet till it come to rest in its north and south position, the north end is always reckoned its north pole; and this is a test for discriminating the poles. If, now, we take two magnets whose poles are known in this way, and if we present the north pole of the one to the north pole of the other, we will find that they repel one another; if the first magnet is held in the hand, and the second suspended on a string, the north end of the second will fly away the moment the north end of the first comes near it. And if we present south pole to south pole, the very same repulsion will take place. But if we bring the *north* pole of the first near the *south* pole of the second, they attract each other, and clink together, end to end, and the one will draw the other after it. So if the south pole of the first is placed near the north pole of the second, a like attraction ensues. Hence are deduced the two general facts, or general laws of magnetic polarity—namely, *like poles repel each other; unlike poles attract each other.* We have seen that electrical attractions follow the same laws. Had we been able to go into the detail of chemical decomposition by the voltaic battery, we should have found it also to be governed by these laws. The negative atom of a chemical compound goes to the positive pole of the circuit, or to the wire issuing from the copper; while the positive atoms gather around the negative wire, which proceeds from the zinc. Wherever polarity occurs—that is, whenever bodies have opposite forces residing in their opposite sides—it is on these principles that the attractions and repulsions take place. All electric and magnetic forces have this character; chemical affinities are of the same nature; and cohesion, when it causes the particles of bodies to assume the forms of crystals, is a polar cohesion.

Another property of the loadstone, and of the magnets formed from it, is that termed *magnetic induction;* which means that magnets have the power of communicating a temporary polarity to soft iron. When a magnet attracts a piece of iron wire, it renders the wire a magnet for the time, or so long as the two touch each other. This is proved by the fact, that the bit of wire, while it hangs by the magnet, is able to attract another piece of iron to itself; but the moment that the connection with the magnet is broken, the second attraction ceases. Such a power is called *induction.* The magnet is said to *induce* polarity upon the iron that it attracts. This induction, however, is ruled by the law of opposites; that is, the north pole of the magnet renders the end of the iron, touching it a south pole, while the other, or free end of the iron, is a north pole. So the south end of the magnet attracting the end of an iron rod makes it north, and the far-off end south.

South joins north, and north south, in all cases of attraction. In fact the reason why a magnet attracts soft iron at all is, that it has the power of making it for the time a magnet, and of attracting it as it would another magnet. It is a general rule that a polar body can act only upon a polar body; and if a body destitute of polarity is acted on, it is in consequence of its first receiving a temporary polarity by induction.

If one piece of iron in contact with a magnet attract a second piece, it will render this also magnetic, and enable it to attract a third, and the third a fourth, and so on till the strength of the magnet can bear no more. Each new piece has its two invariable poles, and each of these poles always joins the opposite pole of the next piece. On this principle a magnet can sustain a long string of iron filings, each particle being attached to another by its temporary magnetic power. This action is exactly analogous in its nature to what takes place in common electricity; so that the principle of induction also pervades more or less all polar phenomena.

A straight bar of steel, magnetised by rubbing, is called a bar magnet. But it is more convenient to twist magnets into the form of a horse-shoe, as in the annexed figure. M is the magnet, R the ring for suspending it, and K a piece of soft iron lying across the two poles, and called the *keeper*, and sometimes the *armature*, or arming of the magnet. It is also called the *lifter*, because when the magnet is made to show its attractive power by supporting weights, they are suspended from it. In the horse-shoe, the two poles of the magnet are brought so near, that they can be joined in this manner by a single piece of iron; and they attract it by their combined force. The keeper is itself made a magnet by induction, with its opposite poles lying to the opposite poles of the horse-shoe. The closing of the magnet by the keeper preserves its strength; and if a scale is suspended by it, and weights added by little and little, the power may be very much increased.

The earth itself is found to be a huge magnet, having its two opposite poles, which, however, are not situated in its proper poles, or the ends of its axis of rotation, but at a considerable distance from these. Still the magnetic poles are in the neighbourhood of the poles of revolution; and the one is called the north, and the other the south, *magnetic pole*. This is the reason why magnets and magnetised needles point in a north and south direction. These magnetic poles are gradually shifting; and seem to be describing a circle, which it takes hundreds of years to accomplish.

The *mariner's compass*, which shows the direction that a ship is sailing at sea, when all other landmarks are wanting, is a small magnetic bar resting on a pivot in the centre of a card, and acted on by the earth's magnetism, so as always to point to the north and south magnetic poles. Allowance is made for the deviation of these poles from the true north and south points, and thus the mariner can always tell in what direction he should steer.

In order to observe the state of the earth's magnetism for scientific purposes, as, for instance, to determine the precise shifting of the poles, other instruments are used. The *dipping needle* is a magnet that shows the direction of the pole downwards in the depths of the earth. The *intensity needle* is an apparatus to show if the earth's polarity has always the same strength. Observation has shown that there are daily and yearly variations in the state of terrestrial magnetism; besides sudden changes, called *magnetic storms*. These storms always appear along with earthquakes; they also accompany the *aurora borealis*, rendering it likely that the northern lights have a magnetic origin.

ELECTRO-MAGNETISM.

This branch of electricity was created in 1820, when Professor Oersted of Copenhagen discovered that a voltaic current has the power of magnetising an iron bar, so as to give to it all the properties of the loadstone. This discovery, taken along with thermo-electricity, completes the proof of the identity of the various natural agencies known by the names of chemical affinity, heat, electricity, and magnetism. All these influences are nothing more than modifications of one grand power pervading material bodies, and most probably derived from the sun. It is not necessary that they should be supplied separately to the earth; for out of any one of them all the others can be produced. Supposing that the sun's ray contained nothing but heat alone (in addition to light), electricity, magnetism, and chemical force could all be obtained from it by making the proper arrangements. The sun's heat causes electric currents to circulate round the earth, and these electric currents are sufficient to make it a magnet exactly as we find it to be. But it is to be carefully observed, that although chemical power, electricity, magnetism, and mechanical force (as derived from heat), are all so far identical with one another, and with the sun's heat, that out of any one all the rest can be formed, yet from all that appears, the other portion of the solar ray—namely, *light*—is perfectly distinct from these, although often appearing in their company, and dependent upon them for its manifestation. It is something more refined and subtile than the other ethereal powers, being, as it were, an agency superadded to these, with laws and functions of its own. When heat is converted into electricity, it disappears as heat: a certain measure of the one is consumed in producing a certain measure of the other. But when heat makes a body luminous, it loses nothing of its heating power; there is no expenditure of substance in yielding the light. So, on the other hand, if pure light were taken in ever so great quantity, it could not yield the smallest portion of heat. Light and heat, therefore, are not *convertible*. Hence they can never be considered to stand in the same relation to each other as the five agencies of chemistry, electricity, magnetism, heat, and mechanical force.

It had been long observed that electricity was capable of producing magnetical effects. The needles of ships' compasses, when struck with lightning, always underwent a change in their magnetic character: on some occasions their poles have been reversed—what was the north before becoming the south. Disturbances of needles have also been caused by shocks from Leyden batteries. But the exact way that the electricity acted in such cases was difficult to discover, and very singular when actually discovered.

If we take the conducting wire of an active voltaic battery—that is, when the electric currents are moving along it—and bring a magnetised needle, or small bar, near the wire, the needle will be affected in such a way, that it will tend to lay itself right across the wire. In other words, the electric wire has an attraction for a magnet; but this attraction is not in the direction of its length, but in the direction of its breadth, or at right angles to the line of the currents. The conductor is electric along its length, and magnetic across. If the needle is held in all positions, close by the wire, we shall find that the magnetic tendency circulates round and round, there being two magnetic currents moving in opposite circles, corresponding to the two electric currents passing along the conductor. If a needle is pointed to the side of the wire, the end will either dip or rise, according to the pole presented; supposing it to dip, the opposite end, when pointed in the same way, would rise. So that while the electricity passes from particle to particle of the copper wire, each particle is made a magnet, with its poles lying across the electric poles, having electricity at its two ends, and magnetic currents moving round its middle, or round what would be called its *equator*.

The conducting wires of two active voltaic circuits, laid side by side, and free to move, attract or repel each other like two magnets. If the directions of the currents are the same in both—that is, if the positive currents both move one way—they will repel each other, by the law of like repelling like. If the currents are opposite, or if the positive of the one moves in the same course as the negative of the other, they will attract each other.

A piece of soft iron laid across the wire of a battery is made a magnet by induction, just as if suspended from the loadstone. If the wire is taken and coiled round and round the soft bar, the action will be very much increased, from the contiguity of a greater amount of electric and magnetic matter. Hence, for showing the magnetism of electricity in its highest energy, the method of coiling is always adopted. Such a coil, spiral or cork-screw, is technically called a *helix*. Sometimes it is formed of thick wire, with few turns, in the exact resemblance of the cork-screw; in other arrangements small wire is used, covered with silk thread, and coiled as close as it can lie, and in a great number of layers, one above the other. The silk covering is necessary to insulate the wires, or prevent the electricity from passing from one to another by the contact of their sides, which would confuse and destroy the whole action. If a bar of soft iron is inserted into one of these coils, connected with a voltaic battery in full operation, it is made for the time a magnet, and receives the name of the *electro-magnet*. When it is taken out, its magnetism disappears. And when the connection of the wire with the battery is cut off, or when the circle is broken, the magnetic action ceases. Such a bar lying in a coil, where electricity is circulating, can be made to show all the effects of the loadstone magnet. By employing a powerful voltaic battery, or a series of circles producing the currents in *large quantity*, very powerful attractions are developed. The *quantity battery*, as distinguished from an intensity battery, is formed of a few very large single circles; that is, of pairs of large plates, or large cylinders, according to the shape employed. Electro-magnets can easily be made to support a hundredweight; and with a compound battery of six or eight large cylinders, the keeper could not be dragged off by the whole strength of a draught horse. The electro-magnet, like the common magnet, is often made in the horse-shoe form, and the wire coiled all along both legs.

The *voltaic electrometer*, or the instrument for showing the existence of a voltaic current, and measuring its quantity, is an electro-magnetic coil or helix, with a magnetised needle attached to it, which moves across the direction of the wires when a current is passed along their length. A wire from each end of the coil is made to connect with the apparatus that is producing the electricity to be tested, and thus a circle is completed; and if any excitement is present, it will pass in a double current through the whole length of the coiled wire, and render it magnetic in its cross direction, and thereby act on the needle, and thus make evident to the eye the presence of what excitement (however feeble) there happens to be.

MAGNETO-ELECTRICITY.

The relation of magnetism to electricity was finally established in the most triumphant manner when Faraday succeeded in causing the loadstone, or common magnet, to produce a current of electricity of exactly the same kind as that produced by the chemical actions of the voltaic circle; so that a magnet could, as it were, take the place of the apparatus of zinc, copper, and corrosive liquid. This discovery is analogous to the thermo-electric pile, in so far as it shows that what formerly appeared as an effect of electricity, is also a cause of it. The current had always been known to have a heating power; but it was not till 1822 that heat could be made to produce an electric current; so whereas Oersted showed that electricity could yield magnetism, Faraday pointed out the means of making magnetism yield electricity. This, with some other researches of Faraday, completed the proof of the convertibility of any one kind of the polar agencies here treated of into any other kind.

It was from believing in the likelihood of deriving electricity from a magnet, after a magnet had been formed by electricity, that Faraday made the attempt, by placing a powerful permanent magnet, in all conceivable ways, in contact with a circle of wire connected with the electro-magnetic electrometer. For a long time, however, no effect could be traced. But at last the circumstance was discovered that was essential to the transference sought for—*the magnet must be in motion* across the wire, or, what is the same thing, the conductor must be in motion across the magnet. This condition being complied with, the electric currents are actually manifested, or a circle of wire can be made alive with electricity the same as if an active pile of volta were in its course: so that the magnet does really contain within itself both the magnetic and the electric virtues; or it possesses a power that can show itself either as a magnet, or as an electric current, according to the circumstances it is placed in. If iron is in the neighbourhood, it appears as a magnet, and draws the iron to itself: if a wire formed into a complete circle is in the neighbourhood, and is moved in the direction of its length across the bar, the magnet puts forth the very same energy as a voltaic circle. The magnet at rest lying by the wire at rest has no influence; but any movement of the transverse kind, corresponding to the difference of direction previously discovered to belong to the two powers, makes the wire an active circle. On this principle machines have been constructed for showing electrical effects, called

ELECTRO-MAGNETIC MACHINES.

The discovery of electro-magnetism showed how electricity might be employed as a mechanical agency, or a prime mover of machinery. When powerful currents circulate around the wire enveloping the body of an electro-magnet, it can draw any piece of iron to itself with very great force. This attractive energy may be turned to account in machinery as well as the expansive force of steam. Hence many persons have occupied themselves in devising electro-magnets with the view of maintaining by their means a constant motion. It is essential that every motive power should be able to turn a wheel, in order that it may be serviceable in the mechanical arts: and if once a wheel motion is produced, every other kind of motion can be derived from it. Electro-magnetic attraction acts in a straight line, and for a short way; and its strength increases as the keeper approaches the end of the magnet, where the motion ceases. The character of the action, therefore, is a straight movement of limited range and increasing power. The attempts which have been made to produce a wheel motion out of such a power have been in part successful. Mr Davidson of Aberdeen has succeeded in moving a turning-lathe, and in propelling a wheel carriage, which was carried forward like a locomotive; and of course any other whirling machinery could be moved by the same means. The principle of his apparatus was to have four magnets arranged so as to act upon the four iron spokes of a wheel, and to have only two acting at a time. When two spokes came up opposite the ends of two of the bars, their magnetism was suspended, and the other two rendered magnetic. These carried forward the wheel another stage, and were then suspended, and the others again brought into action. The defect of the machine was, that the whole power of the magnets was not brought into play. Until the machinery employed be such as to give effect to the total energy of the attraction, we cannot expect that an electro-magnet will be made an economical prime mover.

The electric telegraph is the most successful application of electro-magnetism that has yet been made. Proceeding upon the principle that an electric current can pass along a conducting wire to a great distance, and can move a magnetic needle at any point of its course, the contrivers of this astonishing machine have been able to convey signals from one end of the country to the other with the speed of lightning; and these signals being sufficiently varied in their appearance to stand for all the letters of the alphabet and the ten figures, verbal communications can be made from one place to another hundreds of miles distant.

The machinery of the telegraph consists, in the first place, of a *line of conducting wire*, suspended on poles, and reaching from station to station. A single wire serves for one circle of electric currents, it being found that the earth is a conductor of electricity; and if a current pass along a wire above ground, it will return again under ground, provided the wire at each end is carried to the earth and attached to a mass of metal buried there; so that every wire will make a separate circle, and carry a distinct set of signals. The wire is formed of iron coated with zinc, called galvanised iron wire. It rests on the poles in earthenware tubes, which serve to insulate the passing electricity.

The second part of the telegraph is the *battery*, which maintains the electric current that moves along the wire and returns by the earth. The form of battery that answers best is the partitioned trough battery, with a pair of copper and zinc plates in each cell. The cells are filled first with dry sand, and into this is dropped dilute sulphuric acid, in sufficient quantity to moisten the sand all through, and form both a corrosive agent and a liquid conductor of the electricity from the zinc to the copper. The bottom of the battery is porous, and the liquor gradually oozes through, and carries away with it the sulphate of zinc formed by the action, and new liquor is constantly dropped in above. The battery is thus constant. It requires to be large or small in proportion to the distance between the extreme stations. A line of a hundred miles must have a much stronger current than a line of twenty.

The third portion of the telegraph machinery is the *needles*. These are what the signals are made by. If a magnetised needle lie side by side with a portion of conducting wire, when the circle is closed, and the currents set on, the needle is deflected, or lies across the wire, so that the circle cannot be completed without the fact being known along the line, wherever we attach properly a needle to the conductor. In the same way, when the circuit is broken, the return of the needle will indicate the change. Or if there be such an arrangement as to reverse the current, or connect with the copper pole the end of the wire that formerly joined the zinc pole, a deviation of the needles will again take place, but in an opposite direction. This reversing of the current is easily produced by a piece of simple machinery. Thus, then, each wire can make two distinct signals; and by using several wires at the same time, a great variety of signals can be given. Thus, for example, if there were two wires, four signals could be made by using one needle at a time. Then by using both in all possible combinations, other twelve signals would be produced. By repeating the deviations of the needles two or three times, the variety can be still further extended. Thus one letter may be signalled by moving both needles once to the right; another by moving one to the right and the other to the left; another by moving one twice to the right; and so on. The needles stand over a coil, in order to receive the strength of a concentrated or multiplied current. But the needle system is not the only signalling apparatus that has been contrived, although it is the most extensively used at present. Its defect is the slowness of the working. The most expert operator can signal only fifty or sixty letters in a minute, which is very much slower than ordinary speaking. It being desirable to communicate intelligence with as little loss of time as possible, other schemes have been proposed of quicker operation than the needles.

The fourth part of the machinery is the apparatus for making and breaking the metallic contact that completes the circle, and for passing the currents either way. The external instrument for this purpose is a handle that may be moved to one side or the other, and in so doing closes the circuit. When it stands in an up and down direction, the circuit is broken, and no action is manifested; the needle corresponding is then seen to hang likewise in a perpendicular direction. When the handle is moved to one side, the circuit is closed, and one end of the needle deviates to the same side. When the handle is moved to the other side, the current is arrested, and put on in the reverse direction, and the needle moves to the other side. See No. 26.

The galvanic principle has also been applied to the movement and regulation of clocks, as will be explained under TIME AND TIME MEASURERS.

ANIMAL ELECTRICITY.

This branch of the subject refers to the production of electricity by living bodies. It includes also what is known of the effects of electricity on the animal system.

We have already adverted to the production of electricity by the torpedo and gymnotus. In these animals the electrical organ is something superadded to the ordinary structure of fishes, and is quite independent of the other vital organs, except in so far that it requires to be supplied with nerves and blood-vessels. But apart from the possession of special apparatus, the operations of the animal body are such as to evolve electricity in many ways. The chemical processes of digestion and respiration, the constant passage of heat to and fro, the mechanical movements, may all generate electricity. It is probable, however, that a large portion of what is thus produced is expended or consumed in other operations. Observation seems to show that in the whole the state of the body, when healthy and vigorous, is *positive*, or that a surplus of positive electricity tends always to appear on the surface, from the actions of the vital organs. But after severe labour, hard exercise, and exhaustion, the state of the free electricity generally changes to *negative*.

This observation, when connected with the electrical states of the atmosphere, has an important bearing upon human health and vigour. If the positive state of the body is its natural state when sound and strong, a positive atmosphere, and the contact with positive surfaces, will be favourable, and a negative atmosphere unfavourable, to its wellbeing. Now it is found that the regular and ordinary state of the atmosphere is positive, and the state of the earth negative. In clear, dry, steady weather, this is the uniform character of the atmospheric and terrestrial charges. The contact of the air will therefore be healthy, and the contact with the earth, by a good conducting substance, unhealthy—that is, to stand upon an iron floor, or in water, with the naked feet, even in a fine day, must tend to carry off the body's positive electricity, and communicate to it the charge, associated with weariness and exhaustion. In foggy weather, the air is generally negative, and envelopes the body with a charge hostile to its own; it is therefore inevitable that such weather should have a depressing effect on the system. Even within doors, where the air is rendered dry and warm by fires, the absence of the congenial electricity must be felt. During rain and storms, the state of the atmosphere often fluctuates, and passes in a few minutes from positive to negative, and from negative to positive. Such changes are very distressing to many people. The sensibility to alternations of the electrical state of the atmosphere enables us to feel the approach of storms, or changes from dry to moist weather.

When the actions of electricity on the animal system are better understood, it may be possible to use artificial methods of maintaining, under all circumstances, the charge that is identical with health and activity. We have acquired, by means of our houses, clothing, and fires, an almost perfect command of the element of heat; and it is to be hoped that we may some day attain an equal command over the element of electricity, and keep at a distance the deleterious negative charge, as effectually as we defy the winter cold.

CHRONOLOGY—HOROLOGY.

THE general relation of events and successive existences to each other we denominate *Time*—a thing of duration, involving the past, the present, and the future. It is evident that for the measurement of time we can have no standard of the same tangible nature with a pound, a yard, or a pint measure. We must have recourse to the space or duration involved in some continued or reiterated motion, as to which we have all the proof possible in the nature of the thing, that it requires the same period for its recurrence on one occasion as on every other. The motions of the heavenly bodies are of such a nature, and present the surest standard of reckoning time on a large and comprehensive scale. For periods, however, less in duration than a single day, or day and night, there are no explicit natural standards; hence the utility and necessity of mechanism of human invention, the motions of which, mathematically adjusted and numbered, shall measure and record more brief and arbitrary divisions.

In accordance, therefore, with what is the common practice of mankind in applying such a scale of time to the general routine and business of life, especially in its more civilised condition, we purpose to treat—*first*, of the measurement of time by days, months, years, and cycles, considered with special reference to their respective natural and artificial subdivisions and accumulations; and *secondly*, of those instruments and machines which have been invented for dividing the leading astronomical unit, or day, into seconds, minutes, and hours. The former of these departments may be termed *Chronology*, or the science of time in general; the latter *Horology*, or an explanation of the various contrivances which have been devised for marking and measuring its arbitrary subdivisions.

CHRONOLOGY.

Chronology—from *chronos*, time, and *logos*, discourse—is literally the doctrine of time—the science which treats of its various divisions, and of the order and succession of events. The chronologist has thus a threefold duty to perform—namely, to assign a measure to the interval which elapses between the recurrence of any natural event; to determine certain points or epochs from which to date occurrences, whether preceding or succeeding that epoch; and lastly, dating from any given epoch, to arrange in due order all facts and phenomena which may be considered of importance. Adopting this course, we shall treat in the first place of the division of time into

DAYS AND HOURS.

The day is that portion of time which elapses while the earth turns once completely round on its axis—one half of its surface being exposed, alternately, to the light of the sun on the one hand, and to the darkness of the starry heavens on the other—thus producing to those carried round with it the succession of day and night, and the apparent phenomenon of a diurnal revolution of the sun from one point in the illuminated atmosphere back again to the same point, or nearly so, as explained under ASTRONOMY.

The succession of day and night would undoubtedly constitute the first great natural period reckoned by the human race—involving, as it does, not only the most familiar and most strikingly-contrasted phenomena within the bounds of man's experience, but phenomena peculiarly adapted to the great necessities of his nature—those of vigilance and sleep. Yet the precise point at which the day should be held to begin and terminate, must have been a matter much less easily settled; and accordingly we find, that while, amongst ancient nations—the Babylonians, Persians, Syrians, Greeks, and almost all the nations of Asia—the day began at sunrise, and was held to last throughout the whole of the ensuing daylight and darkness (an arrangement better adapted to countries near the tropics than elsewhere, as the sun there rises more nearly about the same time throughout the year), the Jews, Turks, Austrians, and others, with some of the Italians and Germans, have begun their day about sunset; the Arabians theirs at noon, as do astronomers and navigators of all nations; the ancient Egyptians, and most of the modern Europeans and Americans, on the other hand, as well as the modern Chinese, beginning theirs at midnight, which is evidently the most convenient method, since it throws all the waking and active portion of the day under one date.

The subdivision of the day into morning, forenoon, mid-day, afternoon, evening, and night, is natural, though somewhat indefinite, and may be conceived to have always been more or less marked by man, even in his rudest state. At all events, the ancient Chaldeans, Syrians, Persians, Indians, Jews, and Romans, divided the day and the night into four parts; but there is nothing obvious in the natural changes or motions of the sun, moon, earth, or stars, which could point out the division of days into hours, hours into minutes, or minutes into seconds. These divisions are entirely artificial and arbitrary, unless, indeed, we conceive the second to represent that minutest portion of time which, to the human mind, constitutes its natural unit or rudiment, as particles constitute the units of a mass; but even seconds have been subdivided into thirds; and still it is evident that, after all, these are no more the minutest elements of time than are molecules the minutest elements of masses.

In the civilised part of the world, it is now customary to divide the day, and reckon the minuter portions of time, by instruments to be afterwards described, in seconds, sixty of which constitute a minute; in minutes, sixty of which constitute an hour; and in hours, twenty-four of which constitute a day. Most nations have these instruments marked for only twelve hours, the computation being twofold, like the day itself; but the Italians, Bohemians, and Poles, run them on from the first to the twenty-fourth—from one o'clock to twenty-four o'clock. The Chinese, on the other hand, divide the day into twelve hours only, each being, therefore, twice the length of ours. When the decimal system was adopted by the French, the day was necessarily divided into ten hours.

The length of time which elapses while any given point on the earth's surface passes from a similar point in the starry firmament, and returns to the same point, is called the *sidereal* day, and is found, when measured by the motions of the ordinary instruments invented for the purpose of pointing out its subdivisions—namely, time-keepers—to consist of, or be equal to, 23 hours 56 minutes 3 seconds, and (to be still more exact, as astronomers require to be) 4 thirds—a third being the sixtieth part of a second. But although the distance of any fixed star in the firmament is so immense, that the whole orbit of the earth is but, as it were, a point itself in comparison, and the motion of the earth in that orbit, therefore, cannot alter or affect the length of the sidereal day to any appreciable extent, it is otherwise with the *solar* or natural day, which is that portion of time elapsing between the arrival of the sun at the meridian, or mid-day, on two consecutive days. The mean length of this period of time is 24 hours; nearly 3 minutes 56 seconds on the average being required, in consequence of the earth's motion in its orbit, to bring the sun up to the same meridian on every successive day. The present inclination of the plane of the earth's equator to the plane of its orbit, however, which is diminishing, though with extreme slowness, and the unequal rapidity of the motion of the earth in its orbit, which is also diminishing as slowly, with the diminution of the eccentricity of the orbit, really cause the solar or natural days to be of unequal length; so that, though averaging 24 hours each, they sometimes fall short, and sometimes exceed that average.* It is the former of these causes, too, which gives rise to the difference in the relative length of night and day, according to the seasons of the year. This average of twenty-four hours is what we denominate a *civil* or mean solar day, and is the time employed by the earth in revolving on its axis, as compared with the sun, supposed to move at a mean rate in its orbit, and to make 365.2425 revolutions in a mean Gregorian year.

We have thus three species of day—the sidereal, or that time which elapses between two successive culminations of the same star, and which is now universally adopted by astronomers in their observatories; the solar, natural, or apparent day, being the time that elapses between two consecutive returns of the same terrestrial meridian to the centre of the sun, and which consequently commences at noon; and the civil or mean solar day, which is the mean or average of these meridional returns, and which most modern nations have adopted, placing the commencement and termination at mean midnight.

It is here necessary to observe, that as the earth rotates from west to east, every meridian has its own natural day; and any place east or west of that meridian has a corresponding earlier or later sunrise. The earth, of 360 degrees of longitude, turns in twenty-four hours; consequently every hour is equal to 15 degrees; and every degree equal to four minutes of time. Thus, taking Greenwich as the normal meridian, Alexandria being 30 degrees E., is two hours earlier, or 12 o'clock when 10 at Greenwich; Bengal is 90 E., and it is there 12 at noon when only 6 in the morning at Greenwich. So New York is 74 degrees W., or four hours fifty-six minutes; and consequently, when noon at Greenwich, it is only 4 minutes past 7 in the morning at New York. As with these large distances, so with every other difference of longitude, however minute; and it is thus that we speak of our clocks being earlier or later than Greenwich time, according as we are situated east or west of that meridian. Ipswich, for example, being east of Greenwich, is about 5 minutes before, or earlier; Edinburgh being west, is about 12½ minutes behind; and Dublin being still farther west, is about 25 minutes late. Hence the necessity, in these days of rapid transit, of keeping by one uniform standard of time, or at least of having a table of differences for the principal stations throughout the country. In most cases, it would be preferable to have our clocks furnished with two minute-hands — one to indicate Greenwich time, and the other the natural time of the locality.

MONTHS AND WEEKS.

After the day, the next distinct natural measure or division of time marked out by the heavenly bodies in their time-keeping revolutions is the month. The lunar month is the period during which the moon revolves once round the earth, and is equal to 29 days 12 hours 44 minutes 3 seconds. The solar month is the period during which the sun appears to pass through a twelfth part of his annual course, or through one of the twelve arbitrary signs of the zodiac, and is equal to 30 days 10 hours 30 minutes: it is not so distinctly pointed out by nature as the lunar month. The month came ultimately to be disconnected from the lunar and terrestrial revolutions, as will be afterwards more particularly noticed, and civil or calendar months, accommodated to the year, were substituted; these also, as well as the names given to them in their annual order, will fall to be noticed while treating of the year itself and its subdivisions.

The subdivision of the month into weeks of seven days is very ancient, having, from the most remote period of history, been in use among the Hindoos and other nations in the East, including the Chaldeans and Jews. The week did not enter into the calendar of the Greeks, who divided the civil month into three periods, of ten days each; and it was not introduced at Rome till the time of the Emperor Theodosius. The Roman month was anciently divided into three periods—*Calends*, *Nones*, and *Ides*. The calends were invariably placed at the beginning of the month; the ides at the middle of the month, on the 13th or 15th; and the nones (*novem*, nine) were the ninth day before the ides, counting inclusively. From these three terms the days were counted backwards in the following manner:—Those days comprised between the calends and the nones were denominated *days before the nones*; those between the nones and ides, *days before the ides*; and those from the ides to the end of the month, *days before the calends*. The Greeks had no calends; hence the Roman phrase 'Græcæ calendæ,' or 'never,' corresponding to the English 'Latter Lammas,' and the Scotch 'Morn come never.'

The use of weeks is supposed by some to be a remnant of the tradition of creation; by others, as suggested by the phases of the moon; while a third class refer its origin to the seven planets known in ancient times. The latter hypothesis explains the circumstance, that the days of the week have been universally named after the planets in a particular order. Thus the French, at the present day, following the practice of the ancients, name the days from Mercury, Jupiter, Venus, &c.; while the English adopt Saxon appellations, derived from the deities of northern Europe, and from the Sun and Moon. Hence our term Sunday is from the *Sun*; Monday, the *Moon*; Tuesday, *Tuesco*; Wednesday, *Woden*; Thursday, *Thor*; Friday, *Friga*; and Saturday, *Seater*. (See SUPERSTITIONS.) In England, the Latin names of the days are still retained in legislative and judiciary acts. The Quakers, or Society of Friends, do not use the name of the week-day, but call each day, as they do the months, by its proper number—reckoning Sunday the 1st, Monday the 2d; and so on.

YEARS AND SEASONS.

The year, properly so called, or the solar or astronomical year, is that portion of time which elapses while the sun passes through the twelve signs of the zodiac, or rather while the earth revolves once completely round the sun in its orbit; and while, from the parallelism of the axis of the earth's rotation to itself, combined with its inclination to the axis of the orbit, each hemisphere is turned alternately, once toward, and once from the sun; thus constituting, at least in the extra-tropical regions, the distinction between summer and winter. (See ASTRONOMY.)

It would undoubtedly be this marked alternating distinction which would first lead the attention of every rude but progressing nation not inhabiting tropical countries to calculate their time by years, for in these would even the most savage nation feel an interest, analogous to that with which they had come to contemplate the alternating distinction between day and night. The spring and autumn, too, would soon be stamped with the impress of their sensibilities as natural periods, respectively, of hope and fruition. But it is rather remarkable that the only distinctions in the seasons made by the most ancient nations known, were those of summer and winter; as if these had been so extreme, as to absorb all other distinctions.

The distinction of the seasons would soon be found to depend upon the alternate approach and departure,

* A combination of both causes renders necessary an equation of time (see ASTRONOMY, p. 14), by which clocks ought to be kept earlier or later than the meridian sun or sun-dial. A clock so adjusted is said to keep *true* or mean time, in contradistinction to solar or *apparent* time. Equation tables are given in most almanacs, along with the hours of sunrise and sunset.

or elevation and depression, of the sun in the heavens at stated and regularly-recurring intervals; but the exact division of time into solar years could not have been effected till astronomy had made some progress; when it would immediately appear, in the endeavours at length made to measure the year by revolutions of the moon, that as an exact number of days, or times of the earth's rotation, is not contained in 'a moon,' or lunar month, so an exact number of moons, or even of days, is not contained in a year, or revolution of the seasons. Such observations as these led to methods of accommodating the one period to the other; or in other words, to the

ADJUSTMENT OF THE CALENDAR.

The Chaldeans, Egyptians, and Indians, and indeed almost all the nations of antiquity, originally estimated the year, or the periodical return of summer and winter, by 12 lunations; a period equal to 354 days 8 hours 48 minutes 36 seconds. But the solar year is equal to 365 days 5 hours 48 minutes 49 seconds; or 10 days 21 hours 13 seconds longer than the lunar year, an excess named the *epact*; and accordingly the seasons were found rapidly to deviate from the particular months to which they at first corresponded; so that, in 34 years, the summer months would have become the winter ones, had not this enormous aberration been corrected by the addition or intercalation of a few odd days at certain intervals. Thus was the calendar first adjusted, and the solar year estimated to consist of 12 months, comprehending 365 days. But no account was taken of the odd hours, until their accumulation forced them into notice; and a nearer approximation to the exact measurement of a year was made about 45 years before the birth of Christ, when Julius Cæsar, being led by Sosigenes, an astronomer of his time, to believe the error to consist of exactly 6 hours in the year, ordained that these should be set aside, and accumulated for four years, when of course they would amount to a day of 24 hours, to be accordingly added to every fourth year. This was done by doubling or repeating the 24th of February; and in order to commence aright, he ordained the first to be a 'year of confusion,' made up of 15 months, so as to cover the 90 days which had been then lost. The 'Julian style' and the 'Julian era' were then commenced; and so practically useful and comparatively perfect was this mode of time-reckoning, that it prevailed generally amongst Christian nations, and remained undisturbed till the renewed accumulation of the remaining error, of 11 minutes or so, had amounted, in 1582 years after the birth of Christ, to 10 complete days; the vernal equinox falling on the 11th instead of the 21st of March, as it did at the time of the Council of Nice, 325 years after the birth of Christ.

This shifting of days had caused great disturbances, by unfixing the times of the celebration of Easter, and hence of all the other movable feasts. And accordingly, Pope Gregory XIII., after deep study and calculation, ordained that 10 days should be deducted from the year 1582, by calling what, according to the old calendar, would have been reckoned the 5th of October, the 15th of October 1582. In Spain, Portugal, and part of Italy, the pope was exactly obeyed. In France, the change took place in the same year, by calling the 10th the 20th of December. In the Low Countries, the change was from the 15th December to the 25th, but was resisted by the Protestant part of the community till the year 1700. The Catholic nations, in general, adopted the *style* ordained by their sovereign pontiff; but the Protestants were then too much inflamed against Catholicism in all its relations, to receive even a purely scientific improvement from such hands. The Lutherans of Germany, Switzerland, and, as already mentioned, of the Low Countries, at length gave way in 1700, when it had become necessary to omit *eleven* instead of ten days. A bill to this effect had been brought before the parliament of England in 1585, but does not appear to have gone beyond a second reading in the House of Lords. It was not till 1751, and after great inconvenience had been experienced for nearly two centuries, from the difference of the reckoning, that an act was passed (24 Geo. II., 1751) for equalising the style in Great Britain and Ireland with that used in other countries of Europe. It was enacted, in the first place, that eleven days should be omitted after the 2d of September 1752, so that the ensuing day should be the 14th; and in order to counteract a certain minute overplus of time, that 'the years 1800, 1900, 2100, 2200, 2300, or any other hundredth year of our Lord which shall happen in time to come, except only every fourth hundredth year of our Lord whereof the year 2000 shall be the first, shall not be considered as leap-years.' A similar change was about the same time made in Sweden and Tuscany; and Russia is now the only country which adheres to the *old style*; an adherence which renders it necessary, when a letter is thence addressed to a person in another country, that the date should be given thus:—April $\frac{1}{13}$ or $\frac{\text{June 26}}{\text{July 9}}$; for it will be observed, the year 1800 not being considered by us as a leap-year, has interjected another (or twelfth) day between old and new style.

The twelve calendar or civil months were so arranged by Julius Cæsar, while reforming the calendar, that the odd months—the first, third, fifth, and so on, should contain 31 days, and the even numbers 30 days, except in the case of February, which was to have 30 only in what has been improperly termed leap-year, while on other years it was assigned 29 days only; a number which it retained till Augustus Cæsar deprived it of another day. The names of the twelve months are strictly Roman;—Thus *January* is said to be derived from Janus, a divinity who presided over the commencement of all undertakings, whence his name was appropriately applied to the first month in the year; *February* from *februo*, 'I purify,' because in that month funeral lustrations were performed at Rome; *March* from Mars, the reputed father of Romulus; *April* probably from *aperire*, 'to open,' in allusion to the opening or budding of vegetation; *May* from Maia, the mother of Mercury, to whom sacrifices were offered on the first day; *June*, according to some, either from Junius, Juno, or Juniores; *July*, in honour of Julius Cæsar; *August*, in honour of Augustus; *September*, *October*, *November*, and *December*, signifying respectively seventh, eighth, ninth, and tenth, are the names which were employed when the Roman year consisted only of ten months, and began with March.

The commencement of the year, till a comparatively very recent period, was the subject of no general rule. The Athenians commenced it in June, the Macedonians in September, the Romans first in March, and afterwards in January, the Persians on 11th August, the Mexicans on 23d February, the Mohammedans in July, and astronomers at the vernal equinox. Amongst Christians, Christmas day, the day of the Circumcision, the 1st of January, the day of the Conception, the 15th of March, and Easter day, have all been used at various times, and by various nations, as the initial day of the year. Christmas day was the ecclesiastical beginning of the year, till Pope Gregory XIII., on reforming the calendar, ordered it, in 1582, to begin thenceforward on the 1st of January. In France and England, the same practice commenced about the same time; but in the latter country, it was not till 1752 that legal writs and instruments ceased to consider the 25th of March as the beginning of the year. In Scotland, New-Year's Day was altered, both for historical and legal purposes, from the 25th of March to the 1st of January, by a proclamation of King James VI., in the year 1600. The English plan was found exceedingly inconvenient; for when it was necessary to express a date between the 1st of January, which was the commencement of the historical year, and the 25th of March, which opened the legal one, error and confusion were sure to occur, unless it were given in the following awkward fashion—January 30, 1648-9, or 164 8/9. Even this was apt to lead to mistakes; and it is perhaps even to this day a matter of doubt with some intelligent persons whether the execution of Charles I., of which the above is the usual appearance of the date, occurred in the year 1648 or 1649: it in reality occurred in the year which, by our present uniform mode of reckoning, would be called 1649.

The present mode of reckoning time has experienced no interruption in its leading features for many years, except under the French Republic. In September 1793, the French nation having resolved that the foundation of their new system of government should form their era, instead of the birth of Christ, whose religion they had in a great measure shaken off, resolved also that a calendar should be adopted on what was termed philosophical principles. The Convention, therefore, having decreed, on the 24th November 1793, that the common era should be abolished in all civil affairs, and that the new French era should commence from the foundation of the Republic—namely, on the 22d September 1792, on the day of the true autumnal equinox—ordained that each year henceforth should begin at the midnight of the day on which the true autumnal equinox falls. This year they divided into twelve months of thirty days each, to which they gave descriptive names, as follow:—From the 22d of September to the 21st of October was *Vendémaire* (Vintage Month); to the 20th November was *Brumaire* (Foggy Month); to the 20th December was *Frimaire* (Sleety Month); this completed the autumn quarter: to the 19th January was *Nivose* (Snowy Month); to the 18th February was *Pluviose* (Rainy Month); to the 20th March was *Ventose* (Windy Month), which completed the winter quarter: to the 19th April was *Germinal* (Budding Month); to the 19th May was *Floréal* (Flowery Month); to the 18th June was *Prairial* (Pasture Month); here ended the spring quarter: to the 18th July was *Messidor* (Harvest Month); to the 17th August was *Fervidor* or *Thermidor* (Hot Month); to the 16th September was *Fructidor* (Fruit Month), which terminated the period of summer. In ordinary years there are five extra days—namely, from the 17th to the 21st of our September, inclusive: these the French called *Jours Complementaires*, or *Sans-culottides*, and held as festivals; the first being dedicated to Virtue, the second to Genius, the third to Labour, the fourth to Opinion, and the fifth to Rewards. At the end of every four years, forming what they called a Franciade, occurred a leap-year, which gave a sixth complementary day, styled *Le Jour de la Revolution*, and employed in renewing the national oath to live free or die.

The *week*, though not exclusively a Christian or Jewish period of time, they also abjured. The thirty days of the month were divided into three parts, of ten days each, called *Decades*; of which the first nine (called Primidi, Duodi, Tridi, Quartidi, Quintidi, Sextidi, Septidi, Octidi, Nonidi) were working or common days, while the tenth, styled Decadi, was observed as a kind of Sabbath, though not exactly in the Jewish sense of the word. The French, however, in indicating any particular day, either by word or writing, generally mentioned only the number of the day of the month. The Republican Calendar was first used on the 26th of November 1793, and was discontinued on the 31st of December 1805, when the calendar used throughout the rest of Europe was resumed.

CYCLES.

A cycle, from a Greek word signifying *circle*, is a perpetual round or circulating period of time, on the completion of which, certain phenomena return in the same order; the end being thus, as it were, brought back to the beginning. Under such a definition, the common practice of accumulating years into centuries has of course no title to be classed: it is merely an arithmetical computation, like the equally common mode of counting by tens—forming, indeed, part of the same system.

The *Solar Cycle* is a period of 28 years, during which the day of the month, in every succeeding year, falls on a different day of the week, from the first, till the cycle is completed; when the days of the month and week meet as at first, one cycle corresponding to another. By this cycle, which has no relation to the sun's course, we find 'the Dominical letters,' or those letters amongst the first seven in the alphabet (used to represent the days of the week) which point out the days of the month on which the Sundays fall during each year of the cycle. If there were 364 days in the year, the Sundays would happen every year on the same days of the month; if 365 exactly, every 7th year; but because the additional fractional period contained in the year makes an alteration of a day in every 4th year, the cycle extends to four times seven, or 28 years.

The first solar cycle in the Christian era having begun 9 years before the commencement of that era, to discover what year of the cycle the year 1848 forms, we must add 9, and divide the sum 1857 by 28, the period of the cycle, and the quotient 66 is the number of solar cycles that have passed during that era, the remaining 9 being the year of the cycle corresponding to 1848.

The *Lunar Cycle*, also called the 'Golden Number,' from its having been written in letters of gold by the Greeks, and the 'Metonic Cycle,' from its having been discovered by Meton, an Athenian astronomer, is a period of 19 years, at the end of which the phases of the moon occur on the same days of the civil month as in a previous lunar cycle, and within an hour and a half of the same precise moment of time.

The first lunar cycle in the Christian era having begun one year before the commencement of that era, to discover what year of the cycle 1848 forms, we must add 1, and divide the sum 1849 by 19, the period of the cycle, and the quotient 97 is the number of lunar cycles that have passed during that era: the remainder, 6, corresponding with 1848, being the sixth year of the next lunar cycle.

The *Dionysian Period* is a combination of the solar and lunar cycles, forming, by the multiplication of 28 by 19, a period of 532 years, at the expiration of which it is again new moon on the same days of the week and month as before: chronological events are compared and tested by such a calculation.

The *Indiction* may here also be noticed; though, were it not for severing it from the other cycles with which it is connected in the Julian period, it might perhaps more properly appear under the head of epochs and eras. This was a Roman period of 15 years, the first of which commenced in the year 312 after the birth of Christ. It was appointed merely for the regulation of certain payments by the subjects of the empire; but it came to be observed by the Greek church and the Venetian senate, as well as the court of Rome.

The *Julian Period* is a combination of the solar and lunar cycles with the Indiction; the respective periods of 28, 19, and 15 years being multiplied by each other, and the product, 7980 years, being what is called the Julian period, during which there cannot be two years having the same numbers for the three cycles; but at the termination of this period they return in the former order.

The year 1848 is the 6561st of the Julian period: hence it began about 709 years previous to the date vulgarly assigned to the creation of the world, and has been used instead of that era, to obviate the disputes of chronologers, and to reconcile their systems; for all agree as to the year in which the Julian period began.

The *Precession of the Equinoxes*, on the supposition that the motion on which it depends is uniform, is a cycle of 25,920 years, during which the points whereat the sun crosses the equator at the equinoxes retrograde along the whole circle of the ecliptic, and return to their former position. The present rate of this motion, which depends on the solar and lunar attraction of the quantity of matter heaped up along the region of the equator, is 50 seconds of a degree yearly, or a whole degree in 76 years. (See ASTRONOMY.)

Sir Isaac Newton endeavoured to fix the period of the Argonautic expedition by this cycle, and it has given rise to some curious and interesting speculations regarding the period when the signs of the zodiac were invented.

The *Ecliptical Cycle* is an unknown period of time, during which the angle between the ecliptic and the equator, or the obliquity of the ecliptic, has completed all its changes. The present rate of the diminution of the obliquity is estimated at about 48 seconds of a degree every century. The extent of this change on either hand, like the length of the period in which it is accomplished, is at present unknown, though astronomers, founding on elements with regard to which there admittedly exists 'great uncertainty,' suppose the extent of the 'oscillation' to be very limited. The degrees of ecliptical obliquity at present existing in the *different* planets, however, so far as known, vary from a state in which it almost vanishes in the entire coincidence of the ecliptic with the equator, as in Jupiter, to one in which it is almost 'wide as the poles asunder,' as in Uranus. The ascertainment of the extent of this movement, in the case of the earth, is of great practical importance, especially in geological chronology. The changes of the seasons are occasioned by the obliquity of the ecliptic, being more or less extreme, according to the greater or lesser degree or extent of that obliquity; and, from certain recent discoveries in geology, which seem to imply the former increase of these extremes, coincidently with the former increase of the obliquity of the ecliptic, it appears highly probable that the hitherto hopeless problem of *a geological chronology*, in its most comprehensive sense, by a 'conversion of astronomical into geological periods'—a problem proposed some years since as the subject of a prize essay by the Royal Society of London—will receive its complete solution from the movements of this great ecliptical pendulum.

EPOCHS AND ERAS.

The principal difficulty which must have presented itself to nations desirous of preserving the memory of events, as they might occur, in their annals, from day to day, from month to month, and from year to year, and for long periods of years, would be to obtain a starting-point from which to number these days, months, years, and periods of years; and as no very marked astronomical event (unless, perhaps, eclipses) could render one of these starting-points preferable to another, such starting-points came practically and generally to consist, in early times, when nations had little mutual intercourse, of some event, important or known, perhaps, only to the nation dating from it. This event would form *an epoch*, so named from a Greek word signifying to stop. The enumeration and series of years computed from an epoch is called *an era*; and accordingly of epochs and eras there have been almost as many as there have been of nations. As the eras of ancient nations, however, have become obsolete, it would be useless, as it is here impossible, to enumerate all that we know of, or even any great number of them. But we shall notice a few of the most important in the meantime, reserving the names of all the other principal eras to be afterwards presented together in a tabular form.

The *Era of the Olympiads* is the first on record, and it also became the most celebrated of the ancient methods of computing lengthened periods of time. It took its rise amongst the Greeks 776 years before the birth of Christ. Public games had been instituted at Olympia, a city in Elis, which took place every fifth year, at the recurrence of the full moon after the summer solstice—namely, about the beginning of our July. As this festival made a great impression on the public mind, the people began to reckon by Olympiads, or recurrences of the Olympic games, an Olympiad comprising four years. The computation by Olympiads ceased after the 364th Olympiad, in the 440th year after the birth of Christ, as usually computed, though the epoch of the birth of Christ is not a point of time exactly fixed. The Greeks latterly adopted a new era, called

The *Era of Seleucus*, or the *Seleucidæ*, sometimes also called the era of Alexandria. This era commenced twelve years after the death of Alexander the Great, at the first conquest, by Seleucus Nicator, of that part of the west which afterwards formed the immense empire of Syria. This era has also prevailed, and still exists, amongst the people inhabiting the Levant. The Jews reckoned by it till the fifteenth century of the Christian era, when they substituted the supposed era of the Creation, to be afterwards noticed; and they still begin their year according to it, in the months of September or October.

The *Roman Era* was reckoned by the Romans from the epoch of the foundation of their famous city Rome, an epoch now precisely ascertained to have corresponded to the 753d year before the birth of Christ. The computation of time by the Roman era ceased in the sixth century of the Christian era.

The *Christian Era*, of which we now live in the eighteen hundred and forty-eighth year, was not adopted as a mode of time-reckoning immediately after the commencement of Christianity. That religion existed long in a very obscure way; and the date of the birth of its founder did not, for several centuries, become a sufficiently important event in the eyes of enlightened nations to cause them to make it an era. The era of the Olympiads, the Roman era, the era of Seleucus, and the dates of ecclesiastical councils, and other events then considered of importance, were the common modes of reckoning, and continued partially to be so till a period less remote than many people suppose. Even in Italy, and its celebrated capital, Rome, which became the chief seat of Christianity at a very early period, this era was not used till the sixth century. It was introduced into France in the seventh, but not fully established till the eighth century. In Spain, though occasionally adopted in the eleventh, it was not uniformly used in public instruments till after the middle of the fourteenth century, nor in Portugal till about the year 1415. Now, however, all nations professing Christianity have abandoned other eras, and confined themselves to this; using the Latin words *Anno Domini*, 'the year of our Lord,' or their initial letters, A. D., to distinguish it; while for all dates previous to the generally-received epoch of the era, the words *Anno ante Christum*, 'the year before Christ,' their abbreviation A. A. C., or even more usually the letters B. C., signifying 'before Christ,' are used.

The *Era of the Hegira* commences at the epoch of the flight of Mohammed from Mecca to Medina, which took place on the 16th day of July, A. D. 622. The Mohammedan year is regulated by this event; hence it is used by the Turks, Arabs, and other Mohammedans, comprising a large portion of the modern population of the world.

The *Mundane Era*, or era of the creation of the world, has been the subject of much controversy. As many as 300 different opinions, according to Kennedy, in his 'Scriptural Chronology,' have been entertained regarding the period which elapsed between the creation and the incarnation. Some have made it 3616 years; others 6484. From the creation to the deluge, the computation of the Hebrew text makes a lapse of 1656 years; the Samaritan version only 1307; the Septuagint 2262. No ancient chronologist attempted to fix the epoch of the creation: some conceived it impious to do so. In modern times, the impiety has been supposed to lie all the other way. But some enlightened commentators have been bold enough to return to the ancient orthodox idea, so far at least as to maintain that the Scriptural epoch of the creation is indefinite, being merely cursorily alluded to in the words, 'In the beginning God created the heavens and the earth.' Geologists, in general, also adopt this wide interpretation. In the authorised version of the Bible, however, the chronology usually given places the epoch of the creation in the year 4004 B. C. Thus, A. D. 1 is A. M. 4004; the letters A. M. being used as an abbreviation of *Anno Mundi*—'year of the world.'

Years of Principal Eras Correspondent to 1848.

		YEARS.	ABBREV.
Era of Creation (Constantinopolitan account),		7356	A. M. Const.
Era of Creation (Alexandrian account),		7340	A. M. Alex.
Era of Creation (Jewish account),	7th Tisri,	5608	A. M.
Julian period,		6561	Jul. Per.
Caliyug (Hindoo),	Poos or Margaly,	4949	Cal.
Era of Abraham,	4th month of	3863	Ær. Abr.
Olympiads,	7th month 1st year of	660	Olymp.
Era of Rome,		2600	A. U. C.
Era of Nabonassar,	8th month of	2596	Ær. Nab.
Egyptian era,	24th Cohiac,	2301	A. Æg.
Era of Death of Alexander,	3d month,	2171	A. Mort. Alex.
Spanish, or era of the Cæsars,		1886	A. Cæs.
Diocletian, or era of Martyrs,	24th Cohiac,	1564	Ær. Diocl.
Hegira,	7th Regeb.	1264	A. H.
Chinese year,	45th year of 71st cycle of 60 years.		

MISCELLANEOUS PERIODS.

Besides these major periods, we have others of less significance, but still useful to be known, as they are frequently alluded to in works of a historical nature. Thus a *lustre* (Lat. *Lustrum*) is a period of five years; or, more properly, the completion of fifty months, at the end of which term a census was taken of the Roman population. A *generation* is the interval of time elapsed between the birth of a father and the birth of his son, and is generally used in computing considerable periods of time both in sacred and profane history. The interval of a generation is consequently of uncertain length, and depends on the standard of human life, and whether the generations are reckoned by eldest, middle, or youngest sons. Thirty years are usually allowed as the mean length of a generation, or three generations for every hundred years. A *reign* is the interval that elapses between the accession and demise of a monarch or supreme governor, and is a term in frequent use by historians. It is a period, however, of very uncertain duration, and differs in different countries, according as the sovereign may be liable to assassination, deposition, and the like. Dr Hales has, however, shown that the average standard of reigns is about twenty-three years, reckoning from a series of 454 kings in 10,105 years. A *century* (*centum*, a hundred) is a period of one hundred years, reckoning from the commencement of the first year in any given century; thus the current century is the nineteenth of the Christian era.

TABULAR CHRONOLOGY.

Under this head the leading events, phenomena, or facts recorded in history are arranged in the order of time in which they have occurred—that is, in chronological order. When we look back, however, over the lapse of three or four thousand years, and consider the imperfect modes of record, the changes and transcriptions through which these records have passed—or even the absence of all record, save undated monuments and vague tradition—it will not be surprising that the tabular arrangements of chronologists should be so frequently inaccurate and contradictory. A perfect tabular chronology is what mankind can now never hope to attain: a full record—even reckoning only such events as are of medium general interest—would be too vast either for compilation or perusal. All that we can reasonably hope to attain, is an approximation to the leading facts in the early history of our race, and a brief indication of the more important occurrences in later times. Referring the reader to the systematic chronologies of Newton, Blair, Playfair, Sir Harris Nicolas, and others, we shall merely remark, that the best mode of tabulating events is that which exhibits the dates in bold characters, and endeavours to arrange in juxtaposition the leading occurrences in the principal countries of the world. By these means reference is greatly facilitated, and a notion of civil progress more intelligibly conveyed. Particular chronologies, as of meteorology, agriculture, ecclesiastical history, and the like, are most advantageously constructed in separate tables; that is, by tabulating, in consecutive order, the leading incidents in the progress of the individual science or subject. The language of tabular chronology should always be concise, elliptical rather than expletive—a mere indication rather than an account of the event recorded.

HOROLOGY.

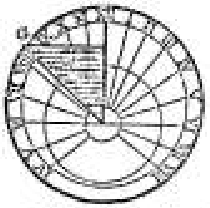
Reference has already been made to the heavenly bodies and their motions as the most primitive and natural, as well as most perfect time-keepers. Our attention here, therefore, must be confined to those artificial machines which have been invented chiefly for the purpose of adding to the convenience of these, by dividing the unit of astronomical time-keeping—namely, the day—into fractional parts, such as hours, minutes, and seconds; there being no such convenient and desirable measurement obvious in nature. The science which explains the methods of so measuring and marking the fractional parts of the day is termed *horology*, from two Greek words, signifying *hour* and *discourse*—a term comprehensive of every time-keeping contrivance, from the simplest sand-glass to the most perfect chronometer. The instruments to which we shall here advert are dials, depending upon the shifting shadow of an object illuminated by the sun; clepsydræ, depending upon the equable flow of a liquid; and clocks and watches,* whose movements are determined by weights and springs.

SUN-DIALS.

Long before the invention of any artificial time-keeper, the interval between sunrise and sunset was really divided, with no little accuracy, even amongst the rudest nations, simply by the shortening, turning, and lengthening of the shadows of trees, rocks, and mountains; and it was this primitive mode of dividing the day which no doubt naturally suggested the first idea of sun-dials. The earliest time-measurer of this description of which we have any historical notice is the dial of King Ahaz, who lived about 742 years before the birth of Christ. According to Herodotus, the Greeks learned the use of them from the Chaldeans, probably through the Babylonian priest and astronomer Berosus, who taught and expounded in Athens about 540 years before Christ. Mention is made of the hemisphere or dial of this philosopher; and the octagonal Temple of the Winds, which is still standing, shows on each side the lines of a vertical dial, and the centres where the gnomons were placed. In Rome, sun-dials were not known till B. C. 293, when one was erected near the temple of Quirinus—the rising and setting of the great luminary being the only standards of reckoning previous to this period. The Romans at this time were not aware that a dial made for Rome is not suited to other places. The ancients used hemi-

* Although modern machines for measuring time are designated by the general appellation of clocks and watches, they are also distinguished by peculiar names arising from certain modifications in their construction, or from certain particular purposes they are intended to serve. By the term *clock* is understood an instrument which not only shows, but also strikes the hours; a *time-piece* is one which shows the hours without striking them; a *quarter-clock* is one which strikes the quarters as well as the hours; an *astronomical clock* is one which shows sidereal time; a *watch* is a portable or pocket time-piece; a *repeater* is one having a contrivance, by means of which it can be made to repeat the hours; a *chronometer* is a watch of the best kind, or one fit to be employed for astronomical purposes.—*Brande's Dictionary of Science.*

spherical dial-plates, and placed the radius, which throws the shade, in the direction of the north polar star. Subsequently, vertical plane dials came to be the usual form, as may be seen on the fronts and gables of many of our old mansions. At present, the most common construction is the horizontal dial, or that in which the plane of the dial-plate is parallel to the horizon. In this form the style or gnomon G, the edge of the shadow of which determines the hour-line, runs in the plane of the meridian—that is, due north and south; while its sloping edge forms an angle with the horizon, or plane of the dial, equal to the latitude of the place in which the instrument is situated, and hence parallel to the earth's axis.



Although a sun-dial may certainly be adjusted so as to point out the time of day within a few minutes, it is needless here to dwell further on the details of an instrument now of little use. The most perfect of sun-dials being only available in sunshine, and not at all through the night (in which, by the way, moon-dials were sometimes used), they were partly superseded, even at a very remote period, by

CLEPSYDRÆ AND SAND-GLASSES.

It has been thought that the regular motion of the dropping of water, and the simpler forms of clepsydræ, or water-clocks, were used for the measurement of time even previous to the invention of sun-dials. They certainly were known in very remote antiquity, and were then used in various parts of Asia and Europe; in China, India, Chaldea, Egypt, Italy, and Greece; into the last of which countries they were introduced by Plato. Julius Cæsar found them even in Britain. It was by them that he discovered some of the nights to be shorter or longer in this country than in Italy, which is nearer the equator, or line of equal days and nights. The Romans themselves had clepsydræ 100 years before Cæsar's invasion; and it is supposed that the Phœnicians had introduced them into Britain through Cornwall, where they traded for tin. The clepsydra, invented by Ctesibius of Alexandria, B. C. 145, consisted of a jar containing water, which slowly escaped by a hole at the bottom, while the oar of a miniature boat on the surface, as it sank with the fall of the water, pointed out the hours, which were marked on the side of the jar. It is even alleged that toothed wheels were applied to clepsydræ by Ctesibius. Such instruments, however, though brought to great perfection in the ninth and tenth centuries, and indeed still used in India, have never been made to measure time with great accuracy. The principal defect is the unequal dropping of the water, caused by the varying depth or weight of the liquid in the containing vessel, the increase or decrease of temperature, or change of barometric pressure. Very ingenious attempts have been made to remedy this defect, but the greater complexity and delicacy thereby occasioned, render the instruments of very little practical value. As time-keepers, clepsydræ may therefore be considered as superseded by ordinary clocks and watches.

In one instance, however, the revival of their principle has been proposed—namely, for the accurate measurement of very short intervals of time by the flowing of mercury from a small orifice in the bottom of a vessel kept constantly filled to a fixed height. 'In this case,' says Brande, 'the stream is intercepted at the moment of noting an event, and diverted aside into a receiver, into which it continues to run till the moment of noting any other event, when the intercepting cause is suddenly removed. The stream then flows into its original course, and ceases to run into the receiver. The weight of mercury received, compared with the weight of that which passes through the orifice in a given time, observed by the clock, gives the interval between the events.' This ingenious application of the principle of the old clepsydræ is due to the late Captain Kater.

The running of fine well-dried sand through a tube, or from an orifice in a containing vessel, was another obvious species of regular motion, very analogous to the flowing or dropping of water. Accordingly, sand-glasses, still in use in this and other countries, were of very early invention. We have evidence of their employment in the East about a couple of centuries before the Christian era. Though now used only for rude and trivial purposes—the half-minute glass being still employed on ship-board, and the two and a half or three minute egg-glass by the housemaid—some centuries ago, in western Europe, they were the almost universal measurers of brief intervals; and hence the numerous allusions of our poets, and the symbolical representations on our monuments and sculptures.

PLANETARIUMS OR ORRERIES.

It is rather a curious circumstance, that, long before the invention of clocks or watches, artificial machines were constructed, imitative of the motions of the sun, moon, and planets—the natural time-keepers.

Of the planetariums of modern times, the first in England was one made for Lord Orrery, whose name has since been given to such machines. The talented and self-taught astronomer, Ferguson, who was originally a poor Scottish herd-boy, made several orreries, and used chronometers to keep them in motion. But though the accuracy with which wheels and pinions can be made to represent different revolutions is beautifully illustrated by the best of these machines, they can give no just conception of the relative size, distance, or velocity of the planets, or hence of the periods of their revolution. 'As to getting correct notions on this subject (the magnitude and distances of the planets),' says Sir John Herschel, 'by drawing circles on paper, or still worse, from those very childish toys called orreries, it is out of the question.' A verdict so decided, and from such a source, renders any attempt at description or illustration unmeaning and superfluous.

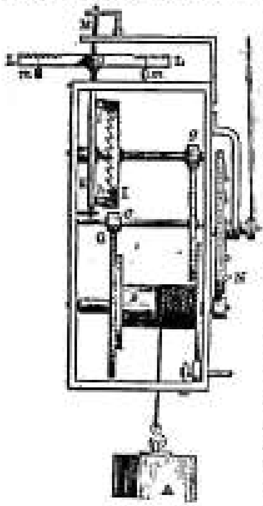
CLOCKS.

The strong hold which the planetary motions appear to have taken on the minds of our forefathers, as the great antitypes of all true time-keepers, is also curiously manifested in the fact, that even when a more detailed measurement of time became necessary, in the intellectual progress of nations, these motions still continued to be represented, so that the very first clock of which we have any perfectly authentic account—that, namely, invented by Wallingford, abbot of St Albans, in 1326—not only showed the hours, but the apparent motion of the sun, the changes of the moon, the ebb and flow of the tides, &c. This, however, was by no means the first clock ever constructed; instruments with weights, wheels, pinions, and a balance, for the measurement of time, having been long previously known, though by whom invented, appears to be a subject of much controversy. Doubtless they required more than the intellect of a single mind. Be this as it may, the most ancient clock of which we have any description, is that of Henry Vic, or De Wyck, a German, erected in the tower of the palace of Charles V., king of France, in 1379; and rude and imperfect as it was, the analogy of modern invention, especially in watches, would lead us to think that it must have been the fruit of several centuries of thought and improvement.

A portrait of this parent of modern time-keepers may be interesting to our readers; and, from its comparative simplicity, will be well adapted as a groundwork for further explanation of the mechanism of clocks and watches in their more complex and intricate forms. It will, moreover, show the general mode of construction adopted in the fourteenth century, including the balance with weights, by which the motion was then regulated, instead of as now by a pendulum.

General Movement and Regulation of Clockwork.

Without requiring to enter into any very minute detail of the manner in which motion in a clock or watch is successively communicated from one toothed wheel G or I, or pinion *e* or *g*, to another, which, indeed, would in some instances only tend to perplex the mind of the general reader, it will be readily understood that the weight A below the clockwork, wound up by a cord on the cylinder B, in its constant tendency to fall to the ground, will cause the cylinder to turn round on its axis as it falls, and as the cord uncoils; and thus one toothed wheel or pinion will set another in motion, till the movement be communicated to the crown wheel, escapement wheel, or wheel of rencounter (I), the teeth of which so act on the two small levers or pallets (*i h*) projecting from, and forming part of, the suspended upright spindle or vertical axis (K M), on which is fixed the regulator or balance (L L), that an alternating or vibratory instead of a circular motion of the balance itself will be the result. The rotatory motion of the wheelwork, in short, will be converted into a vibratory motion by the alternate catching of the levers by the teeth of the crown or escapement wheel, and their alternate escape from them.



De Wyck's Clock.

Now, it will at once appear manifest that a heavy weight, such as that here represented, operating on a few wheels thus arranged, unless it have some counteractive weight, or other check, to modify and balance its operation, will rapidly run down even to the ground, if the height of the clockwork, and the length of the cord attached to the cylinder, permit it, causing the wheels to rotate, the balance to vibrate, and the hands to revolve on the face of the clock, with similar rapidity, increasing every moment, till the weight be fairly run down. It is this rapid motion of the wheelwork which begins in a *modern* clock whenever the *pendulum* is taken away, while the weights are still attached to the cylinders; and the rapid ticking then heard is the uncounteracted operation of the crown wheel, moved by the falling weight upon a piece of mechanism similar in purpose to the levers and spindle in the above figure. To prevent this rapid unwinding of the clockwork, then, and to adjust it to the more deliberate measurement of time, we have, in De Wyck's clock, the balance, *loaded with two weights* (*m m*); and the farther these are removed from the axis or spindle (K M), the more heavily will they resist and counteract the escapement of the levers, and the rapidity of the rotation of the escapement wheel, till the clock be brought to go neither too quick nor too slow; when, of course, it would be improper to remove them further towards the ends of the balance, as the clock would then go too slow for correct time-keeping.

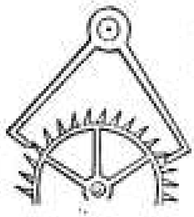
Pendulum and Escapement.

What the balance and the weights attached to it in De Wyck's clock were to clocks of an ancient date, the pendulum is, in general, to modern clocks; the oscillations of the pendulum, and the vibrations of the balance, being completely analogous in purpose and effect, both being kept up or sustained by the 'escapement,' while both require, or, as it were, demand, by the law of gravity, a certain time for their performance; and thus, by reaction, check and equalise the exercise of those very powers and movements by which they are kept in play. The measurement of time being thus regulated by the oscillations of the balance or the pendulum, this part of the mechanism of a clock, including the escapement, is of primary interest and importance; and we shall find this also to be the case in the numerous contrivances, chiefly by English artists, to effect the same object to the best advantage in the still more delicate and ingenious mechanism of watches. We may here also remark, that so invaluable is the principle of *regulation*, whether by oscillation or rotation, and so generally and extensively useful in other respects, that, from the smoke-jack to the steam-engine, it has, in one form or other, been called into practical operation.

Galileo, the great astronomer, when a student at Pisa, happened to discover, while engaged in the cathedral there—not in meditating on the imposing ceremonial of the Catholic church, which was then in progress, but in what, to many a good Catholic, would undoubtedly have seemed the vacant, idle, and profane contemplation of the lamps which swung from the roof—that the oscillations of a pendulum, whether great or small, are performed in equal times in each pendulum—an important fact, the truth of which he tested, not by the beats of his watch (for no such instrument then existed), but by the beats of a natural time-keeper to which we have not yet alluded—namely, the pulse. He afterwards discovered, what was ultimately demonstrated by Newton—that 'the shorter the pendulum, the less is the time of its vibration;' or, in other words, that the number of oscillations performed by a pendulum in a given time depends on its length—four times the length producing twice the number of oscillations. A pendulum, the length of which, from the point of suspension to the centre of the weight attached to its lower extremity, is 39 inches 2 tenths, will oscillate once precisely every second in the latitude of London; not in any other latitude, however, as has been found by experience; the number of oscillations with the same length of pendulum diminishing towards the equator, where oscillations equal in length to 2 minutes 15 seconds a day will be lost; while, on the other hand, they will increase towards the poles, where a proportional number of oscillations will be gained. Thus, as already explained under the Laws of Matter, the pendulum of a clock, made and adjusted to time in London, requires to be lengthened if taken nearer to the poles, or shortened if taken towards the equator. The greatest possible nicety, indeed, is required in the adjustment of the length; for a difference, if in extent amounting to the 1000th part of an inch, would cause an error of about one second a day; therefore, to make a pendulum *go slower* by one second a day, it must be lengthened by the 1000th part of an inch; and to make it go quicker, it must be shortened in the same proportion. The following are the result of some measurements of the seconds' pendulum at different latitudes in the northern hemisphere:—

Spitzbergen,	79°	49′	58″	N. Lat.,	39·2146	inches.
Edinburgh,	55	58	40	...	39·1554	...
London,	51	31	08	...	39·1390	...
Jamaica,	17	56	07	...	39·0350	...
Sierra Leone,	8	29	28	...	39·0195	...

The first use which Galileo, then a medical student, made of his valuable discovery, was to ascertain the rate and variations of the pulse; and its application to clockwork was an afterthought. It is even denied that he did more than suggest such an application; or, as has been also alleged, that at all events his son put his suggestion into execution; and accordingly the merit of the invention of pendulum clocks is very generally attributed to Huygens, a learned Dutchman, about 1657. This celebrated philosopher, in adapting the pendulum to the mechanism previously invented, had little more to do than simply to add a new wheel to the movement, so as to enable him to place the crown wheel and spindle in a horizontal instead of a perpendicular position, that the lower arm of the balance—then of course perpendicular, instead of horizontal, as in De Wyck's clock—might be extended, as it were, downwards, and thus, in fact, be converted into a pendulum. The principle thus adopted, however, from the peculiar action of the levers and spindle, required a light pendulum and great arcs of oscillation; and the consequence was, as Mr Thomson, a recent popular author, tritely remarks, that 'Huygens's clock governed the pendulum, whereas the pendulum ought to govern the clock.' About ten years afterwards, the celebrated Dr Hooke invented a better method, which was introduced by Clement, a London clockmaker, in 1680, and enabled a less maintaining power to carry a heavier pendulum, which also making smaller swings or arcs, was less resisted by the air, and therefore performed its motion with greater regularity. This was called the *anchor escapement*, and it is still in use, together with the practice to which it gave rise of suspending the pendulum by a thin flexible spring instead of a cord, which was liable to change its length



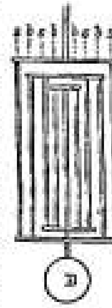
by moisture; an evil, however, perhaps fully equalled by the variation of the elasticity of the spring by heat and cold. The seconds' pendulum, with the anchor escapement, was called the *royal* pendulum. As this plan, however, was found to cause a reaction or retrograde movement of the wheels, and has hence been called the *recoil* escapement, a further improvement was made about the beginning of the eighteenth century by George Graham, another English artist, who invented the repose or *dead* escapement.

The wheels are kept by this escapement in a state of repose or rest during the whole oscillation of the pendulum, except at the moment when it receives its impulse from the crown-wheel. Requiring smaller arcs, too, even than before, the oscillations are made in more equal times. A still more perfect modification of the escapement is the free or *detached*, but it is more difficult to execute. The *half-dead* escapement, also, has been introduced as a mean between the dead escapement—an increase of power with which causes a clock to lose time—and the recoil escapement, with which a similar increase of power causes one to gain. For the purposes of ordinary clocks, this mode of escapement has been found to answer very well.

Compensation Pendulums.

Pendulum rods, which are usually made of metal, though sometimes of wood, especially in church clocks, were next found to vary in length by variations of temperature, according to that law of nature by which every body increases in volume or in actual size by heat, and diminishes or contracts by cold. The inevitable consequence of the influence of such variations on the length of the pendulum will at once be seen, from what has been already said, to be an increase of the number of its oscillations in a given time while in cold temperatures, and hence shorter than its mean length, as in winter, or even at night, or in cold situations; and a diminution of them while in warm temperatures, and hence longer, as in summer, or even during the day, or in warm situations: and a pendulum with a metal rod will cause a clock to vary several seconds in a day from such changes alone. To insure, therefore, a still greater accuracy and uniformity in the measurement of time than had previously been obtained, various ingenious but simple devices have been put into practice, wherein the very cause of the inaccuracy has been made subservient to the end desired. And here the talent of the artist Graham again displayed itself, and led the way to every other modification of the primitive *idea*, however dissimilar in detail, and whether applicable to pendulums or balances, to clocks or watches. Indeed the first method of 'compensation' adopted for pendulums has, with some little improvement, ultimately superseded all its more recent modifications. This method Graham called the *mercurial compensation*, and it consists simply of a tube or cylindrical glass jar containing quicksilver or mercury, and attached to the lower end of a steel rod in the arc of its oscillation. As the steel rod lengthens by heat, the mercury expands in volume, and rises in the tube; while, as the rod shortens by cold, it contracts, and sinks or falls. Thus the arc of oscillation remains ever at the same distance from the point of suspension, or upper extremity of the pendulum; or, in other words, the pendulum, in fact, remains ever of the same length.

Graham also conceived the notion of another compound pendulum, composed of different metals, so arranged, as to compensate each other by their *difference* of expansion or contraction. This modification of the idea of a compensating pendulum was more fully developed by John Harrison, another celebrated artist, who in 1726 invented the gridiron pendulum, composed of five rods of steel and four of brass, so arranged, that the rods which expand the most raise the weight or bob as much as the rods which expand the least depress it. In the annexed fig., the bars marked *a* are of steel, those marked *b* are of brass; the centre rod of steel is fixed at the top to the cross-bar connecting the two middle brass rods, but slides freely through the two lower bars, and bears the bob B. The remaining rods are fastened to the cross-pieces at both ends, and the uppermost cross-piece is attached to the axis of suspension. It is easy to see that the expansion of the steel rods tends to lengthen the pendulum, while that of the brass rods tends to shorten it; consequently, if the two expansions exactly counteract each other, the length of the pendulum will remain



unchanged. The relative lengths of the brass and steel bars are determined by the expansions of the two metals, which are found by experiment to be, in general, nearly as 100 to 61. If, then, the lengths of all the five steel bars added together be 100 inches, the sum of the lengths of the four brass bars ought to be 61 inches. When the compensation is found on trial not to be perfect, an adjustment is made by shifting one or more of the cross-pieces higher on the bars. This pendulum has been greatly improved by Troughton, who substituted for the two pairs of brass rods two cylinders of brass, sliding the one within the other, to which the steel rods are attached.

Unfortunately, however, this compensation changes, as all metals do, not continuously and gradually, under the influence of heat or cold, but by jerks. The mercurial pendulum, therefore, under certain improvements by Thomas Reid, a talented Edinburgh artist, and by others, has of late been frequently resumed; and it has been found that time-keepers provided with this pendulum and a dead escapement do not vary, on the average, more than a quarter of a second daily—a degree of accuracy wonderful, indeed, when contrasted with the fact, that down to the middle of the sixteenth century clocks were incapable of going nearer to accurate time than about 40 minutes within the 24 hours, and were nevertheless held to be precision itself compared with all other methods of measuring time then known.*

* Before quitting the subject of pendulums, it is worthy of remark that their mutual action or sympathy, while oscillating near each other on the same wall, so long as they are mutually connected by a rail or shelf common to both, or so long as the cases of the clocks to which they belong are either fixed to each other or standing on the same flooring plank, is a very singular phenomenon, observed by Huygens, Elliot, De Luc, Reid, and many other artists. One pendulum will even stop another, it is said, in such circumstances, and will again cause it to resume its

Other Improvements.

While improvements were effecting in the escapement and pendulum of clocks, the ingenuity of artists was not confined to these alone. Till the beginning of the sixteenth century, clocks were of great bulk, and only fit for turrets or large buildings; and although after this period they were made small enough to be introduced into apartments, there could be no such thing as a really portable clock, far less a watch, till weights and pendulums were got rid of altogether. The substitution of a mainspring for a weight, therefore, constituted a great era in horology, or the science of time-keeping; and this took place about the middle of the sixteenth century, and was shortly afterwards followed by the invention of the *fusee*, a very necessary appendage to the mainspring. But as these inventions completely altered the form and principles of horological machines, and, together with that of the spiral escapement spring, and other improvements, which soon followed that of the pendulum, rather constitute peculiar features of the watch than of the clock (although they were mostly applied at first only to portable timepieces of the nature of clocks, in which they are, indeed, still used), we shall reserve the explanation of these ingenious pieces of mechanism till we come to treat of watches. Meantime, there is another part of the works which requires to be here noticed; namely, the

Mechanism for Striking the Hours.

It is not known when the alarum or when the striking mechanism of the clock was first applied. The alarum was adopted for the use of the Romish priesthood, to arouse them to their morning devotions. The first striking clock probably announced the hour by a single blow, as they still do, to avoid noise, in most, if not all, of the Scottish churches. In De Wyck's clock, the wheel N, with its projecting pins, served to discharge the striking part, which it has not been thought necessary to illustrate. Like other old clocks, it locked against an interrupted hoop, fixed on what was called the *hoop-wheel*; and the eleven notches on the edge of the plate-wheel determined the hours, or particular number of blows which the hammer should give. During the seventeenth century, there existed a great taste for striking clocks, and hence a great variety of them. Several of Tompion's clocks not only struck the quarters on eight bells, but also the hour after each quarter; at twelve o'clock, 44 blows were struck; and between twelve and one, no less than 113! Many struck the hour twice, like that of St Clement Danes, in the Strand, London, first on a large bell and then on a small one. Others, again, were invented so as to tell the hours with the least possible noise, also by the aid of two bells, each blow on the small one indicating five hours.

vibrations till it stop, alternately, itself. It has also been found that two clocks with pendulums of nearly equal length and power, or weight, though differing in their measurement of time while apart, will so vibrate in unison when thus connected, as to keep time together with the most surprising accuracy, till they are again separated, or till the plank connecting them be sawn asunder. This singular but not altogether unaccountable influence appears to be not unlike that sympathy of sound between two musical instruments tuned in unison, wherein, when a chord of one is struck, the other, placed in a proper situation, though untouched, responds or echoes back the sounds at first called forth. And as in the combinations of certain medical substances, or in various other combinations, the general result of all the elements is obtained as a steady mean to be depended on, without the special failure, fault, or disadvantage of any one element in the combination, accuracy of time-keeping, of a remarkable kind, might readily be obtained by this singular mode of bringing out, by a combination of pendulum clocks, an average rate of motion. 'It is the opinion of an eminent foreign artist,' says Reid, the author of a standard article on clock and watch-making in the Encyclopædia Britannica, 'that a few clocks placed in this way would communicate the motion of their pendulums to each other, till they came all at last to beat at the same instant;' an opinion in which Reid himself expresses his entire concurrence.

The striking part of a clock is rather a peculiar and intricate piece of mechanism. In ordinary clocks, the impelling power is a weight similar to that which moves the time-measuring mechanism itself; but the pressure of this weight on the striking machinery is only permitted to come into play at stated periods in course of the workings of the time-keeping apparatus—namely, at the completion of every hour; when the minute-wheel, which revolves once in an hour, and carries the minute-hand of the clock along with it, brings it into action by the temporary release of a catch or detent, permitting the weight wound up on the cylinder of the striking apparatus to run down for a little, in doing which, the hammer is forced into action, so as to strike the bell. Whether the strokes shall be one or many, is determined principally by two pieces of mechanism, one called a *snail*, from its form or outline, with twelve steps, and the other a *rack*, with twelve teeth; but the intricate action of the whole it would be in vain here to attempt to explain. Suffice it to say, that the time during which the striking weight is *allowed* to descend, varies according to the turning of the twelve steps of the snail on its axis, and the position of the twelve teeth of the rack, at different hours of the day; being sometimes only long enough to permit one blow to be given by the hammer on the bell, and at another time long enough for twelve such blows.

The lifting piece of the rack-hook, in some clocks, may be raised by pulling a string attached to a small additional piece of mechanism, and thus the clock is made to repeat the hour last struck at any time required—an addition useful through the night, or to the blind. The modes, however, by which clocks as well as watches have been made repeaters, have been very various. Repeating-clocks were first invented by Barlow, an English clergyman, and executed by Tompion in 1676. Some have been made to repeat both hours and quarters at any time, and to indicate the time by blows which might be felt but not heard.

The bells connected with clocks, especially those of churches and other public buildings, are often worthy of notice, either on account of their gigantic size, or on account of the arrangements by which they are made to perform a variety of musical chimes. If cast to the proper size and shape, and of the right metal, the latter conditions are easily obtained, by applying the necessary striking apparatus; but to produce gigantic as well as perfect dimensions, and then to elevate the mass several hundred feet in some tower or spire, is a feat of no ordinary character. The size and weight of some of our British bells are enormous. Thus the celebrated Tom of Oxford, which is 22 feet in circumference, weighs 9894 pounds; the great bell of St Paul's, London, 11,470 pounds; Peter of Exeter Cathedral, 12,500; Old Tom of Christ-church, Oxford, 17,000; and the recently erected Peter of York Minster, 21,000. Enormous as these weights are, they are insignificant compared with some which have been produced in continental Europe and in China. Thus the brass bell of Strasburg is 22,400 pounds weight; that of Rouen Cathedral 36,000; the seven great bells of Pekin, according to Le Compte, weigh 12,000 pounds a-piece; while the monster bell of Moscow, which now lies unemployed, is about 67 feet in circumference, 21 feet high, and has been calculated to weigh not less than 443,000 pounds! The metal of which bells are made is generally an alloy of 80 parts copper and 20 tin. An English *bell-metal*, analysed by Dr Thomson, yielded 800 copper, 101 tin, 56 zinc, and 43 lead.

The illumination of clocks was a favourite idea in the seventeenth and eighteenth centuries, and is equally useful in a public way as the striking of hours or the ringing of bells. It was only during the current century, however, that any plan was adopted for public clocks; the first notion being to light them from without, by reflecting the light of a common lamp or gas jet on their dials. This simple method is still employed, but is vastly inferior to the employment of a translucent dial, with a strongly-reflected light from behind. Recently, the pure brilliancy of the Bude-light has greatly contributed to the improvement of this very useful practice.

Curious Clocks.

Various and ingenious, as well as often highly curious, have been the forms and purposes displayed in the construction of clocks, even from their earlier epochs down to the present day. We have already instanced some of an ancient date which pointed out the motions of the sun and moon, the ebb and flow of the tides, &c. Others of a more fanciful description followed. The famous astronomical clock of Strasburg, completed by Isaac Habrecht about the end of the sixteenth century, deserves a prominent place in our catalogue. It has been recently renovated by a M. Schwilgue, after four years' labour; but its original movements are thus described in Morrison's Itinerary:—'Before the clock stands a globe on the ground, showing the motions of the heavens, stars, and planets. The heavens are carried about by the first mover in twenty-four hours. Saturn, by his proper motion, is carried about in thirty years; Jupiter in twelve; Mars in two; the Sun, Mercury, and Venus in one year; and the Moon in one month. In the clock itself, there are two tables on the right and left hand, showing the eclipses of the sun and moon from the year 1573 to the year 1624. The third table, in the middle, is divided into three parts. In the first part, the statues of Apollo and Diana show the course of the year, and the day thereof, being carried about in one year; the second part shows the year of our Lord, and the equinoctial days, the hours of each day, the minutes of each hour, Easter day, and all other feasts, and the Dominical letter; and the third part hath the geographical description of all Germany, and particularly of Strasburg, and the names of the inventor and all the workmen. In the middle frame of the clock is an astrolabe, showing the sign in which each planet is every day; and there are the statues of the seven planets upon a circular plate of iron; so that every day the planet that rules the day comes forth, the rest being hid within the frames, till they come out of course at their day—as the sun upon Sunday; and so for all the week. There is also a terrestrial globe, which shows the quarter, the half hour, and the minutes. There is also the figure of a human skull, and the statues of two boys, whereof one turns the hour-glass, when the clock hath struck, and the other puts forth the rod in his hand at each stroke of the clock. Moreover, there are the statues of Spring, Summer, Autumn, and Winter, and many observations of the moon. In the upper part of the clock are four old men's statues, which strike the quarters of the hour. The statue of Death comes out at each quarter to strike, but is driven back by the statue of Christ, with a spear in his hand, for three quarters; but in the fourth quarter that of Christ goes back, and that of Death strikes the hour with a bone in his hand, and then the chimes sound. On the top of the clock is an image of a cock, which twice in the day crows aloud, and claps his wings. Besides, this clock is decked with many rare pictures; and being on the inside of the church, carries another frame to the outside of the walls, whereon the hours of the sun, the courses of the moon, the length of the day, and such other things, are set out with great art.'

Other ancient clocks displayed processions of saints, with obeisance to the Virgin and Child, &c.; and scarcely a town of any importance was without some curiosity of this sort peculiar to itself. Many curious specimens were invented in the seventeenth century, amongst which were a variety measuring time, or at least moved, by balls running down inclined planes, swallowed up by, and traversing the bodies of, brazen serpents, or descending in metallic grooves, to be again thrown up by Archimedean screws; some were made to go by their own weight, descending inclined planes, and thus avoiding the casualties to which mainsprings and weight lines are liable; others, by means of springs, were even made to ascend such planes. One was simply and ingeniously hung like a lamp from the ceiling, and was kept going by its own descent, the winding up consisting merely of pushing it again towards the ceiling. In another, the dial formed the brim of a plate, filled with water, in which swam a tortoise, turning marvellously with the hour, and ever pointing towards it—by magnetic attraction, as every one would now readily conceive; and this favourite idea was varied by many other simple contrivances. Within the last few years, not a little wonder of a similar kind, we recollect, was excited by a puzzle-clock, with an hour hand proceeding from the centre of a crystal dial-plate, perfectly transparent, and moving without any visible connection with mechanism. In this case a piece of glass itself, rotating in the interior of the dial, constituted the requisite mechanism.

More interesting, perhaps, than any of these, and yet of the simplest construction, and of the most common material, are the *electric*, or rather *electro-magnetic clocks*, lately invented by Mr Bain of Edinburgh. The prime mover of these machines is the electric currents of the earth, brought to bear upon the machinery, as thus described by a party for whom one of the earliest was constructed. 'On the 28th of August 1844, Mr Bain set up a small clock in my drawing-room, the pendulum of which is in the hall, and both instruments in a voltaic circle as follow:—On the north-east side of my house, two zinc plates, a foot square, are sunk in a hole, and suspended by a wire, which is passed through the house to the pendulum first, and then to the clock. On the south side of the house, at a distance of about forty yards, a hole was dug four feet deep, and two sacks of common coke buried in it; among the coke another wire was secured, and passed in at the drawing-room window, and joined to the former wire at the clock. The ball of the pendulum weighs nine pounds; but it was moved energetically, and has ever since continued to do so with the self-same energy. The time is to perfection; and the cost of the motive powers was only seven shillings and sixpence. There are but three little wheels in the clock, and neither weights nor spring; so there is nothing to be wound up.' The electric clock, as now patented and employed by the Electric Telegraph Company, is somewhat differently constructed. A plate of copper, and another of zinc, buried in the ground to the depth of nine feet, so as to be kept constantly moist, are the generators of the electric current, which is conveyed directly to the pendulum by wires. The pendulum is made of wood, suspended by a steel spring, and furnished, as usual, with a regulating bob; the current is conveyed down the wooden rod by wires, to a magnetic coil a little above the bob, and placed in juxtaposition to two permanent magnets, which maintain the oscillation; and about the middle of the pendulum rod an apparatus is placed on either side, for the purpose of alternately making and breaking the circuit. With the exception of the *break* apparatus, the whole machine is of extreme simplicity, and little liable to disarrangement. Many of these ingenious clocks have been since constructed, and an illuminated one, projected from the front of Mr Bain's workshop in Edinburgh, moves, as the inhabitants can testify, with the utmost regularity. One great advantage of this invention is, that supposing every house in a city provided with the simple apparatus before referred to, one electric current could keep the whole in motion, and thus preserve the most perfect uniformity of time. It is not too much to expect, therefore, that as we have now a common supply and diffusion of gas and water, so we may shortly have a common diffusion of time. In a highly-civilised and business country, the one is almost as necessary as the other.

Miscellaneous Clockwork.

The applications of clockwork to other purposes than that of measuring time, are numerous and important. In all of them, however, the principle is the same—namely, the indication of space, or, what is equivalent, the indication of time or number by mechanical motion. Thus, according to the unit we assume, any amount of space may be indicated either in a regular series, or in a decreasing or increasing series—the increment or decrement taking place progressively, or at intervals, as may be wanted. What can be done with space, can be equally accomplished with regard to time or number, and that with an accuracy and precision that no human powers can rival. It was by springs, and weights, and clockwork, that the *automata* which amused our forefathers were moved and directed. Whether they danced or made music, or in whatever way they simulated the conduct of living creatures, it was mechanism that governed their actions—mechanism which would have commanded our admiration the more, that it had been applied to useful purposes. All our *meters*, by which the discharge of gases and liquids are now measured, are but combinations of clockwork; as are also those numerous inventions for *registering* events connected with atmospheric temperature, rise and fall of barometric pressure, direction and force of wind, vigilance of sentinels, and the like.

Thus by a properly-constructed *anemometer* (literally, wind-measurer), not only may the force and direction of the wind be ascertained at any given moment, but the instrument may be made to trace or register the direction from which, and the force with which, the aërial current has swept during every minute of the day—all that is necessary being, to place under the tracing pencils a clean sheet of paper every twenty-four hours. In like manner, clocks are made for registering the daily fluctuations of the barometer, by means of a pencil floating on the surface of the mercury, and made to traverse a circular card, divided into 365 parts by radii lines, and turned on its centre by the clock once a-year. A curious time-keeping method of insuring the presence and attention of night-watchmen has been successfully tried of late years. It consists of a clock with pins projecting round the dial, which can only be pushed inwards at a certain interval, when the watchman's presence and attention are required to unlock the case, and do so, otherwise his neglect, and the exact quarter of an hour at which he was absent, is shown by the *tell-tale*. Amongst other recent inventions may be noticed a *lock-clock*, to prevent bankers' safes, &c. from being opened except at stated intervals. So also *odometers* (road-meters), or instruments for measuring the space travelled over, whether by pedestrians or wheel-carriages—motion being communicated by the moving body to the clockwork, which is fitted with indices and alarums to indicate any unit of distance required. The same principles have been applied to machines for graduating scales, for engraving tints, and other analogous processes, in which delicacy of line and accuracy of distance are the objects in view.

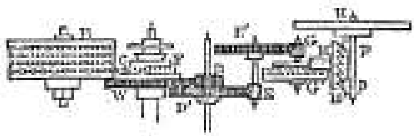
Closely allied to these varieties of clockwork, but evincing a greater degree of scientific skill, are the various machines which have from time to time been invented to lessen the drudgery of long and continuous calculation. The principles upon which the increase and decrease of numbers depend are as fixed as nature herself; and these once known, wheel machinery of determinate proportions may be constructed to perform every operation in arithmetic with the utmost facility and accuracy. It is well known that in calculations involving the powers and roots of numbers, progression, equations, logarithms, and the like, it not only requires great expertness, but accuracy—an accuracy which is scarcely attainable under the strictest human attention. Such calculations are of indispensable utility in astronomy, navigation, and geography, as well as in general mathematics; and for application, are usually printed in tabular forms, embracing many hundred pages of thick-set figures. To complete such tables with perfect accuracy would require the life-work of several calculators; and yet, by well-arranged machinery, it has been demonstrated that they can be calculated and printed, free from errors, in the course of a few weeks.

The most extensive and ingenious of *calculating machines* are undoubtedly those invented, and so far perfected, by Mr Babbage. That constructed at the expense of government for the calculation of astronomical and nautical tables, is, we believe, not yet completed, in consequence of some misunderstanding, which caused a suspension of its progress in 1833. This employed 120 figures in its calculation. At a later period, Mr Babbage began another on his own account, intended to compute with 4000 figures! Of the former invention, Sir David Brewster, in 1832, speaks in the following terms:—'Of all the machines which have been constructed in modern times, the calculating machine is doubtless the most extraordinary. Pieces of mechanism for performing particular arithmetical operations have been long ago constructed; but these bear no comparison, either in ingenuity or in magnitude, to the grand design conceived, and nearly executed, by Mr Babbage.' Somewhat later, we find a writer in Lardner's Cyclopædia stating that the principle on which this machine was founded was one of a perfectly general nature, and that it was therefore applicable to numerical tables of every kind, and that it was capable not only of computing and printing, with perfect accuracy, an unlimited number of copies of every numerical table which has ever hitherto been wanted, but also that it was capable of printing every table that can ever be required. It appears that the front elevation of the calculating machinery presents seven upright columns, each consisting of eighteen cages of wheelwork, the mechanism of each cage being identically the same, and consisting of two parts, one capable of transmitting addition from the left to the right, and the other capable of transmitting the process of carrying upwards; for it seems that all calculations are by this machinery reduced to the process of addition. There will therefore be one hundred and thirty-six repetitions of the same train of wheelwork, each acting upon the other; and the process of addition with which the pen would be going on successively from figure to figure, will here be performed simultaneously, and—as the mechanism cannot err—with unfailing accuracy. The results of the calculating section are transferred by mechanical means to the printing machinery, and the types are moved by wheelwork, and brought successively into the proper position to leave their impressions on a plate of copper; this copper serving as a mould from which stereotyped plates without limit may be taken.

WATCHES.

Clocks and watches are certainly amongst the most perfect, as, in the civilised world, they are the most indispensable, machines ever produced by human ingenuity. 'To become a good watchmaker,' says Berthoud, 'it is necessary to be an arithmetician, in order to find the revolutions of each wheel; a geometrician, to determine the curve of the teeth; a mechanician, to find the forces that must be applied; and an artist, to be able to put into execution the principles and rules which these sciences prescribe. He must know how fluids resist bodies in motion; the effects of heat and cold on different metals; and, in addition to these acquirements, he must be endowed by nature with a happy genius.' No one who has not closely attended to the matter, can conceive the difficulty which has been experienced even in dividing circles for the wheels of a watch into the requisite number of rigorously equal parts, and in 'pitching' them in, or adjusting them one with another. All the resources of art shown by Ramsden, Troughton, and other eminent mathematical instrument makers, have been here called into requisition. And as to the delicacy of touch and adjustment necessary in the mere regulation of the mechanism, after being thus accurately made and 'pitched in,' some slight idea may be formed from the fact, which we give in the words of Mr Thomson, that 'a second (a mere pulsation) is divided into four or five parts, marked by the vibrations of a watch-balance, and each of these divisions is frequently required to be lessened an exact 2880th part of its momentary duration!' England has great honour in having advanced the art of watch-making to its present high condition.

Before entering upon a description of the various parts, we here present the general arrangement of the wheelwork of a common vertical watch—the frame-plates being omitted, and the dial being supposed to be turned downwards:—B is the *barrel* or drum, containing the spring which produces the motion. F is the *fusee*, connected with the barrel by the chain *c*. W is the *fusee-wheel*, called also the first or great wheel, which turns with the fusee, and works into the pinion



D, called the *centre-wheel pinion:* this centre pinion, with the centre wheel or second wheel D′, turns *once* in an hour. The centre wheel D′ works into the *third-wheel pinion* E; and on the same arbor is E′, the *third wheel*, which gives motion to the fourth or *centrate-wheel pinion* G, and along with it the centrate wheel G′. The teeth of this wheel are placed at right angles to its plane, and act on the pinion H, called the *balance-wheel pinion;* H′ being the balance wheel, or scape wheel, or crown wheel, attached to the same arbor. The balance wheel acts on the two *pallets p, p*, attached to the *verge* or arbor of the *balance* K; and these being placed at a distance from each other, equal to the diameter of the balance wheel, and in different places, receive alternately from the scape wheel an impetus in opposite directions, which keeps up the vibratory motion of the balance. Such is the general arrangement of the powers and motions; we shall now proceed to the analysis:—

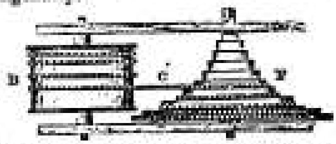
Mainspring and Fusee.

The invention of the mainspring in place of the weight, was the first pre-requisite to the formation of the watch. But although the mainspring was applied as the maintaining power to time-pieces of a very imperfect description, called watches, about the middle of the sixteenth century, and although the balance had, in such instruments as these, assumed its present form of a vibrating ring, with the greatest weight of course accumulated round a circumference, it was not until the spiral hair-spring was applied to the balance, some time after the invention of the pendulum, as a substitute in clocks for the balance itself, that a comparatively useless machine was converted into a time-measurer nearly as accurate, even in its ordinary form, as the pendulum clock. Though the invention of the balance-spring, however, was comparatively an early improvement, and the greatest the watch has ever received, we must pass it over in the meantime, till we briefly describe those parts of the mechanism which first rendered the existence of the watch possible at all.

The *mainspring* consists of a coil of thin elastic steel ribbon, enclosed in a miniature barrel or 'drum,' to the inner side of which the outer end of the coil is fixed, while the inner is fixed to an axis at the centre of the drum, and round which it may be wound or twisted, so as, by its elasticity and recoil, to cause the drum to make as many revolutions as it makes turns itself while it unwinds. Here, then, we have the main power which sets the whole mechanism of the watch in motion. But it is evident that this power, if thus at once applied to the wheels, would cause them to move with less and less rapidity as it became uncoiled, and as its springing power of course became exhausted; so that unless the wheels were so constructed that only the middle turns were required to be in action,

and not those in which it is at its greatest or its least power, a force sufficiently equal even for ordinary purposes could not be thus obtained. French spring-clocks, strange to say, are still, in general, made on this defective principle; but English watches and spring-clocks are supplied with a 'fusee,' which corrects the inequalities of the mainspring with a simplicity only equalled by its ingenuity.

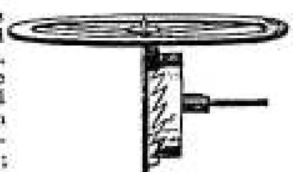
The *fusee* is a cone with a spiral groove, attached to the side of the first wheel of the watch, and connected with the barrel or drum containing the mainspring by a chain, hooked, at its ends, to both. The figure to the right, in the above cut, is the fusee; that to the left is the barrel.



In winding a watch, the key is placed on the axis of the fusee, and the chain is wound off the barrel on to the cone of the fusee. When fully so wound, the spring is at its greatest power of recoil; but the chain being then round the smallest part of the cone, the influence of the spring on the wheels is at its least amount; while, just as the power of the spring relaxes and diminishes, the cone enlarges, and its lever influence hence increases. The fusee, in short, is a variable lever, worked by the mainspring, with more purchase when it has less power, and with less purchase when it has more power. It is a very beautiful contrivance, completely answering the intended purpose, when properly made. By means of a spring contained in the interior of the fusee-wheel, the watch is maintained in motion, while the fusee itself is turned by the watch-key in winding up the mainspring. This is called the *going fusee.* When the watch or spring-clock has no fusee at all (and in very flat watches no fusee *can* be introduced), the barrel is immediately attached to the first wheel. In every case, however, the power of the spring is conveyed through the wheels, by nearly the same arrangement in all watches and clocks, to

The Escapement.

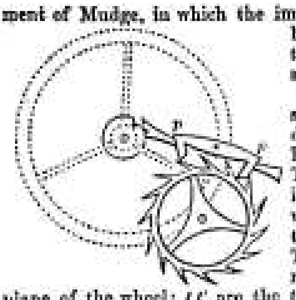
On the peculiar construction of this part of the mechanism, so as best to keep up the vibrations of the balance, the superiority of one watch over another principally depends; though much of course also depends on the skill of the workman, and the quality of his materials, in the construction of *every* part of so delicate a machine. The escapement, however, according to its peculiar form, is that by which the watch is chiefly distinguished:—



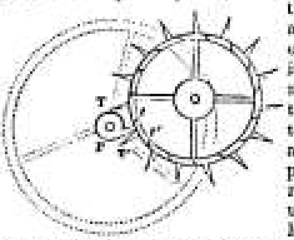
The *vertical watch* is so named from its old vertical escapement. This particular mode of escapement is still made in common watches, where it answers sufficiently well; but when applied to clocks regulated by pendulums, is found to be exceedingly defective. The mechanism of this—the *crown-wheel escapement*, as it is technically called—will be readily understood by reference to the preceding figure.

The *horizontal* or *cylinder watch* is so named from the horizontal escapement of Graham, introduced about the beginning of last century. In this mode of escapement, the impulse is given to a hollow cut in the cylindrical axis of the balance, by teeth of a peculiar form, projecting from a horizontal crown wheel.

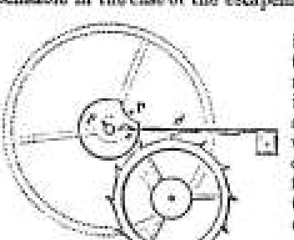
The *lever watch* is so named from the lever escapement of Mudge, in which the impulse is given to the balance by a lever attached to crutch or anchor pallets, *p*, *p*.



The *duplex watch* is so named from the duplex escapement of Hooke, perfected by Tyrer, in which the impulse is given by a wheel furnished with two sets of teeth. T T' are the teeth of repose, lying in the plane of the wheel; *t t'* are the teeth of impulse, and stand perpendicular to the plane of the wheel; P is the impulse pallet, fixed upon the arbor of the balance, immediately above the plane of the wheel, so that its extremity or claw may be caught by the teeth *t t'*, and receive the impulse from them as they successively pass. A small ruby roller is also placed upon the arbor, 'behind the pallet, having a notch in one side of it for receiving the teeth T T'. When the tooth *t* has passed the claw of the pallet, the tooth T falls upon the ruby roller, where it rests, until, by the returning vibration of the balance, the notch is brought to the point of the tooth. The tooth then falls into the notch, and thus passes the roller, and the next impulse tooth *t'* comes up to the pallet, where it acts with great advantage, in consequence of the long lever. As the successive impulses are given in the same direction, the balance necessarily makes two vibrations for each impulse given by the upright tooth. The main advantage of this construction consists in there being only one pallet, and in the action being independent of great accuracy in the execution of the teeth of the 'scape-wheel, which is indispensable in the case of the escapements above described.



The *detached watch* is so named from the detached escapement of Berthoud, improved by Arnold and Earnshaw, in which the vibrations of the balance are free, or detached from the influence of the crown-wheel, unless at the instant when it receives its impulse and unlocking; the wheels standing still till then. In the diagram, P is the main pallet, projecting from the arbor of the balance-wheel, concentric with which is another small pallet *p*, called the *lifting pallet*, which, when the balance is vibrating, lifts a slender spring *s*, so as to set at liberty the tooth held or locked by the detent *d*, which projects from the spring. As in the case of the duplex, the balance here makes two vibrations for each impulse. This mode of escapement, which requires no oil, forms a peculiar feature of the chronometer or marine time-keeper.



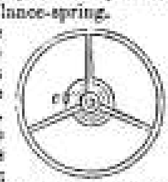
On the respective merits of these different kinds of watches, a few useful hints will be afterwards given. There are many other escapements, but those only now pointed out are in general use.

Balance and Balance-Spring.

These are the only other parts of the mechanism of the watch of which it is necessary here to treat.

The balance, as may be seen from the representations of it in connection with the different escapements just noticed, is a wheel finely poised on its axis; the pivot-holes in which it turns being frequently—in chronometers and clocks, as well as in watches—jewelled, or made of small rubies, diamonds, &c. as those of other of the wheels also are, for the sake of durability. The natural effect of an impulse given to such a wheel would be a complete rotation on its axis. This, however, as we have already seen, is convertible, by various escapements, into a vibratory motion. But as in clocks the pendulum was found to be a most invaluable adjunct, absorbing, as it were, in its own more or less extended oscillation every inequality in the rotation of the wheelwork, or the vibration of the balance, something of precisely the same nature for watch escapements was the great desideratum, when the balance-spring or hair-spring was invented; and, from this analogy, it even acquired the name of the pendulum-spring—improperly so, however, as Reid remarks, especially as there is a pendulum-spring of another description altogether.*

Simple and obvious as the suggestion of the regulative influence of a spring, applied to the vibrating mechanism of the watch-balance, in place of either weight or pendulum, may now appear, especially after the idea of the mainspring, as a substitute for the maintaining weight, had been suggested, this has been held to be a crowning invention in the mechanism of the watch; and the honour of its first suggestion has been claimed by no less than three very eminent men—by Dr Hooke, by Abbé Hautefeuille, a Frenchman, and by Hüygens, the Dutch astronomer. It was ultimately proved, that although Hüygens had applied for a patent at Paris in 1674, Hautefeuille had done so several years before; while Hooke had made a similar application in England in 1658. To Hooke, therefore, must be attributed the first idea of the balance-spring.

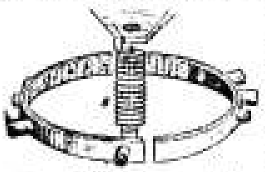


In its application to the balance of a watch, one of the extremities (*c*) of the spring is fastened to a point independent of the balance, while the other is attached near its axis. When the balance is at rest, the spring is inclined neither way, this position being called the point of rest; but when the impulse is given to the balance by the crown wheel of the escapement, it is clear that now a rotatory motion of the balance cannot take place, even though there should be nothing in the form of the escapement to prevent it; the balance will now only move round so far as the impulse given is able to overcome the elastic resistance of the spring; and when that resistance becomes equal to the impulse given, the balance will stop for a moment, and then be driven back by the elastic recoil of the spring, continuing thus to vibrate so long as the impulse is repeated or the watch is in motion.

The recoil of the spring is sufficient to drive back the balance to a distance nearly double the length of its first motion; this is therefore called the long arc of vibration. But when the motion of the balance is free, with a certain length of spring, the *long* arc of vibration is made in less time than the short one, to which the impulse is given: with a spring of greater length this principle is reversed; whence it was concluded by Le Roy and Berthoud, that equality of time, or *isochronism*, in unequal vibrations, could be more easily obtained by lengthening the spring than by tapering it. In principle, too, the stronger and shorter the spring,

* This little instrument, the hair-spring, is no less remarkable for the extreme delicacy of its construction, than for the great value which it shows the possibility of giving to a piece of steel, of exceedingly small and insignificant appearance, by manual labour. Four thousand hair-springs scarcely weigh more than a single ounce, but cost often more than £1000! 'The chisel of the sculptor,' as Mr Thomson justly remarks, 'may add immense value to a block of marble, and the cameo may become of great price from the labour bestowed, but art offers no example wherein the cost of the material is so greatly enhanced by human skill as in the balance-spring.'

the quicker will be its vibrations. Thus effects of an extremely varied description can be produced on the motions of a watch by the slightest difference of length and taper in a hair-spring. And it is thus that the correctness of the time-keeping is essentially dependent on the principle adopted in the formation of this apparently most insignificant little appendage. So much is this the case, that if the hair-spring be isochronal in a free or detached escapement, the time shown will be the same, notwithstanding changes in the motion of the wheels, or even in the power of the mainspring. In England, where time-keepers have been brought to their greatest perfection, it is considered that isochronism is most easily attainable by using the cylindrical helical spring (*s*), which is applied to all marine chronometers.



One of the most recent improvements in watches, or rather in chronometers, has been invented and patented by Mr Dent of London, and consists in coating the balance and balance-spring with *gold* by the electro-metallurgic process (see ELECTRICITY), by which means they are secured from rust. Another invention of the same gentleman is that of balance or hair-springs made of *glass*, which, singular to say, appear decidedly preferable to those of steel, their principal disadvantage being the difficulty of making them with certainty or accuracy.

Compensation.

But let a watch be ever so perfect—in the correction of the inequalities of its mainspring by a fusee mathematically adjusted to it, in the formation and the position or pitching in of all its wheels and pinions, in the principle and execution of its escapement, and even in the accuracy with which its hair-spring vibrates in equal times—still it will vary in the time it indicates *on every change of temperature*, however slight, unless it be *compensated*.

From what we have already stated in treating of the compensation-pendulum in clocks, the intelligent reader will readily appreciate the difficulties to be here overcome, and will probably conclude, that as in clocks the compensation has been effected by means of the pendulum, so in watches it must have been effected by means of the balance-spring or balance. Such is the fact: but as there was no room here, and indeed no analogous opportunity, for the introduction of mercury, the idea of compensation by virtue of the different degrees of expansion in different metals, as in the gridiron pendulum, was the only one that remained to be entertained; and here also the ingenuity of human invention has indeed triumphed; and the method of making compound balances for watches has been justly considered one of the most curious of our metalline manufactures. When completed, the compensation balance consists of a double or compound rim or ring, the outer part of which is of brass, and the inner of steel, to which the brass is added while in a molten state. The opposite sides of this ring are united by a steel bar, the whole of the steel part, indeed, being filed out of one piece of metal. One half of the ring is then cut or filed away at one side of the bar, and the other half at the other side, as represented in the figure last above given; and the balance is loaded either with small screws, as in that figure, or with sliding weights on each half of the ring, in order to regulate the rate of the chronometer or watch. The compensation, then, is thus effected: an increase of temperature *diminishes* the elastic force of the hair-spring, which would cause the machine to *lose* time; but the same degree of heat expands the outer or brazen part of the ring of the balance more than it does the inner or steel part—brass expanding more than steel by heat, and contracting more by cold—and so, not being able to separate, a curvature of the whole arm of the ring *inwards* ensues, which lessens the inertia or checking weight of the balance; so that the hair-spring now *requires* less force to influence it to the same degree as before; and thus its *loss* of power is *compensated*. On the other hand, cold *increases* the elastic force of the hair-spring, which would cause the machine to *gain* time; but the brass contracting more than the steel, curves the arm outwards, and increases the inertia, or resistance of the balance, allowing the spring no more influence over it now than it had before. The screws are turned in or out, or the place of the sliding weights adjusted, by experiments on the rate of the machine; so that if an increase of temperature causes it to gain time, or a decrease to lose, the screws must be turned outwards, or the weights moved farther from the ends of the arms; if the contrary be the case, then of course the contrary changes must be made.

The compensation-curb is another instrument for correcting variations in the rate of going from variations in temperature. It limits or extends the length of movement in the hair-spring itself, by a self-moving action, also caused by a difference in the effect of change of temperature on two different metals, and is called a *curb*, from the name of a small piece of mechanism which operates similarly on the balance-spring in regulating a watch by hand.

CHRONOMETERS.

The term *chronometer* is, properly speaking, applicable to all time-keepers, but it is now more usually applied to marine time-keepers only, which are machines of a size between watches and clocks. Some watches, however, made like chronometers in every respect but in size, are called pocket chronometers. But neither of these are anything else than merely such time-keepers as combine all those chief excellences in horological invention just described, including compensation balance, cylindrical spring, detached escapement, &c. so as to constitute the most accurate time-measurer possible; the purpose of marine chronometers being to discover the longitude at sea; for it is only necessary to ascertain the exact difference in time between two places on different meridians, in order to determine their difference of longitude, or distance eastward or westward of each other. Reverting to what has been already said on this subject under ASTRONOMY, the general reader will at once perceive that so soon as a time-keeper could be made that would keep time with perfect accuracy, such an instrument, set to the time of any seaport, for instance, in Britain—whose precise meridian or longitude was known—and carried abroad in a vessel sailing thence, would afford the means of ascertaining the longitude at sea, by simply observing the instant that the sun reached his meridian there, when of course it would be mid-day, or twelve o'clock noon; and at the same time observing the difference between this time and that shown by the time-keeper, which would necessarily be different if the longitude was different—the amount of the difference giving him his longitude, on the calculation that 15 degrees east or west make *one hour* of time, or 15 geographical miles *one minute*. If, for example, the time-keeper had been set to time at the meridian of Greenwich observatory [where, in fact, chronometers are now usually adjusted, and where a signal hoisted every day on the instant that twelve o'clock strikes, or rather on the instant that the sun arrives at the meridian there, proclaims the true time of day, on that meridian, to all the mariners in sight of it, that they may be able, without trouble or mistake, to adjust their chronometers accordingly], and if it was but eleven o'clock on the time-keeper thus set, while it was of course twelve o'clock or mid-day at the time and place where the meridian was taken at sea, then that place must have been in longitude 15 degrees *west* of the meridian of Greenwich; if, on the other hand, it was one o'clock instead of eleven at that moment, the longitude must have been 15 degrees *east*, not west, of the meridian of Greenwich. By knowing also the time when any particular star passed the meridian at Greenwich, the navigator, in a similar manner, could calculate his longitude by an observation of the same star at sea. Lunar observations, eclipses, or the like, might be made use of on similar principles.

It was a clear perception of the fact, that the longitude might thus be at any time determined, could time-keepers be made to measure time with accuracy, that led Sir Isaac Newton and others to recommend to government the offer of a public reward for the accomplishment of so desirable an object; and it was the hope of reaping the splendid reward of £20,000, which government accordingly did offer, that formed the very mainspring to all those high exertions of horological ingenuity which led to the final success of John Harrison, after an unwearied labour of forty years—a success which, in turn, resulted in the present highly advanced state of horology, the perfection of which, as a most scientific art, is perhaps only paralleled by the perfection of astronomy as a cognate science deeply indebted to it, and indeed to which it is as indispensable, in almost every respect, to the present condition of society.

USEFUL HINTS.

For the attainment of habits of punctuality, for the regulation of the usual routine of business and of everyday life, for the morning's timely arousement and the evening's sufficient repose, and for other and innumerable purposes of convenience, necessity, and pleasure, much, in reality, often depends on the judicious selection of a time-keeper. And even the character of a young man has been known to be much influenced by the quality of his watch, the possessor of an accurate time-keeper becoming ambitious to emulate its excellence, and thus gradually acquiring habits remarkable for punctuality. It is therefore to be regretted—even though in many cases a very indifferent time-keeper may be thought all that is required for general purposes—that no efficient instruction can be given to the inexperienced, especially towards the selection of a watch, as none but a workman possessing the highest knowledge of his art is capable of forming a correct opinion of its relative merits. The hints given by a skilful and practical artist himself, however, who has had years of the most attentive and constant experience, cannot but be deemed invaluable; and as such we would especially recommend to the inexperienced in horology, a popular little volume, published by Messrs Boone of New Bond Street—namely, 'Thomson's Time and Time-Keepers,' for the useful as well as pleasing and interesting instruction with which it is stored.

Amongst many valuable hints for the proper selection of time-keepers contained in Mr Thomson's little volume, we shall take the liberty of briefly instancing the following; and first of clocks:—These, in general, measure time more accurately than watches, especially eight-day weight or long-clocks, which are also cheapest. Long and heavy pendulums are to be preferred. The pendulum should occupy the whole available length of the case, except in regulators, or in pendulums beating seconds. A light pendulum shows a clock to be badly constructed, or deficient in power. Steel rods are better than brass, well-seasoned and varnished wood than steel, and compensation-rods than either. The clock should be steadily fixed to the wall, or firmly placed on *three feet* sufficiently far apart, so that the mechanism may be uninfluenced by the oscillations of the pendulum. Clocks are regulated by lengthening the pendulum, to make them lose, and by shortening it, to make them gain; this is very generally done by turning a nut or screw *below* the weight or *bob* of the pendulum, *to the right to gain, or to the left to lose*; or, if the screw is *above* the weight, the rule is *reversed*. Many French clocks, and a few old English ones, are liable to derangement in striking, unless the hands are moved rapidly *forward*. The hands of English clocks, in general, may be turned either way without injury, and the same with a watch, unless it has an alarum.

An intelligent, careful man, may be safely trusted with the cleaning, adjusting, or repairing of clocks, while a diversity of talent and experience is necessary to qualify him for the manipulation of watches. 'The possessor of a good picture would doubtless inquire into the ability of the artist before he intrusted him to retouch it; and this caution is equally necessary for a watch, as many of the best construction have sustained irreparable injury from the hands of unskilful workmen. Even bad watches (which are by far the greatest number) require the aid of better hands than those which constructed them.' A clever artist may enable even a bad watch to perform tolerably well. Watches should ordinarily be cleaned every second or third year; small, flat, or complicated ones oftener. All require care in handling. They should be regularly wound as nearly at the same hour as possible; and while being wound, should be held steadily in the hand, so as to have no circular motion themselves. When hung up, let the watch have support, and be perfectly at rest; or when laid horizontally, let it be placed on a soft substance for more general support, otherwise the motion of the balance will generate a pendulous motion of the watch, causing much variation in time. Should a watch vary by heat or cold, as when worn or not worn in the pocket, the hands may be set to time; but the regulator should not be altered, if set to the ordinary temperature of the season. Compensation-watches, if properly constructed, do not so vary. A trial even of a year or two is no proof of the substantial worth of a watch. Dealers themselves may be deceived. A duplex watch may be very bad, while a vertical one may be very good, so that workmanship is as important as principle. Many low-priced and bad watches have eight or even ten holes jewelled, while many good and costly ones have but four: a hole can be jewelled for three shillings. 'The high-sounding description, the handsome exterior, the offered trial, and enticing cheapness, are effective baits to the short-sighted.' External ornament forms but a small item of expense, and the prices therefore will, in general, point out the comparative qualities of the work in the shop of an artist of known integrity and ability.

The large thick old watch is less absurd than some recently made little thicker than half-a-crown, or even much smaller, as in the latest and rarest novelty amongst the beautiful and ingenious Genevese watches, some of which little exceed the size of a shilling. The lever watch is capable of great accuracy, and is preferable to the vertical, though the principle of the latter is more generally understood, and more easily repaired; lever watches, however, are neither expensive to repair nor liable to derangement. The horizontal or cylinder watch is liable to great tear and wear, but performs with considerable accuracy. The duplex watch, with a compensation balance, when well constructed, and treated with ordinary care, will keep time with the greatest accuracy; but being delicate, it does not stand violent exercise: a bad duplex watch is most expensive to repair. The detached watch, the escapement of which is the only one used in marine chronometers, is the most perfect, but requires care. Repeaters are expensive to repair as well as to purchase, but may be as accurate as others. Watches showing seconds are often useful, and, if well made, are neither expensive nor easily deranged. A watch may be handsome, yet bad; but a good watch is seldom unsightly. The spring for shutting the shells is not so good as the snap; it often allows dust to penetrate to the works. The covers of hunting-watches will not protect the glass when the hunters are very flat. The extreme accuracy of marine chronometers is partly produced by their being kept constantly in a horizontal position. They are only required to show *equal* time; whether they gain or lose is of little consequence, provided they are regular, and *keep* their known rate.

CHEMISTRY.

THE material world immediately under our observation, including such parts of the earth's crust as have been explored, the plants and animals upon its surface, and the atmosphere which envelops it, is found to consist of fifty-four simple substances, just as all the words which compose a language are resolvable into a few letters. These substances, having hitherto resisted all endeavours to divide or resolve them into any others, are termed the *elements of matter*, or *simple bodies*. By this it is not peremptorily affirmed that there are only fifty-four elementary substances in nature, for, as will hereafter be seen, several others have recently been added to the list; neither is it maintained that these substances are absolutely simple, and incapable of being reduced to fewer elements, or even, as some chemists have hinted, to a single primary element, of which all other bodies are but conditional phases. All that is here meant is, that at present there are upwards of fifty substances which cannot be reduced, by the known processes of chemistry, to any other condition. The investigation of the laws under which these various elementary bodies have formed the numerous compound substances which we see in nature, and the means by which compound substances can be resolved into their original elements, or simple elements thrown into new combinations, are the objects of the science of Chemistry.

The term *chemistry* is of doubtful derivation; but it seems to have been applied at an early period to various methods of melting or preparing metals, and was identified with the visionary efforts of alchemy, which professed to be the art of transmuting copper and other base metals into gold and silver. It is only within the last seventy or eighty years that chemistry has risen to the rank of a science; but during that period, it has advanced towards perfection with a rapidity unparalleled in the history of philosophy. The applications of chemistry are universal. There is no science so immediately conducive to human comfort. To whatever art or manufacture we turn our attention, we find that it has either been created by chemistry, or owes to it some of its greatest improvements. In the present sheet, it is our object to present a simple and intelligible view of the *principles* of this exceedingly important science, reserving its *applications* in the industrial arts for subsequent treatment.

CHEMICAL ATTRACTION.

When particles of different kinds of matter are brought into contact, they frequently unite, and form new substances, differing widely in many instances from those by whose union they have been formed. This is called *chemical attraction*, or *chemical affinity*; because it is said that the particles of certain bodies, having an affinity for each other, will unite, while others, having no affinity, do not readily enter into union. It might almost be supposed that there are such things as preferences and dislikes among the particles of matter. Thus if a piece of marble be thrown into vitriol or sulphuric acid, their particles will unite with great rapidity and commotion, and there will result a compound differing in all respects from the acid or the marble. This is at once an instance of affinity between two substances, and an exhibition of stronger and weaker affinity. The commotion or effervescence in the experiment arises from the disengagement of a gaseous (carbonic) acid in combination with the basis of the marble, in consequence of the sulphuric acid having a stronger affinity for it. When a piece of caustic magnesia is thrown into vitriol, we have a case of simple affinity, with a complete change also of properties. Both the vitriol and magnesia are eminently hurtful to life. All their elements combine, without any disengagement, and the result is the production of Epsom salts, a compound with properties entirely new. Neither ingredient has been destroyed; they can again be extracted pure from the compound; but they have changed their characters through the force of affinity. But if a piece of quartz or gold be thrown into the acid, no change is produced in either, because the particles of the respective substances have no affinity for each other.

This process of affinity is termed in chemical language *combination*, and is quite distinct from *aggregation*, which is the union of particles of a similar kind, forming a mass which has the general properties of the particles of which it is composed, whatever may be its structure or form. It is also to be distinguished from *mixture*, in which the particles, although they may be intimately blended, are not, as it were, amalgamated with each other, so as to lose their own individual properties. The difference between combination and mixture will be clearly seen from the following example:— If into a crystal bottle we pour a quantity of oil and a quantity of water, and shake them well, the two substances can never be made to unite permanently together. Although they appear to do so for a short while after the experiment is made, yet if the vessel be allowed to stand for a sufficient length of time, the particles of water, being heavier than those of oil, will descend to the bottom, whilst those of the oil will settle upon the top. Here it is evident that no chemical attraction has been exerted between the particles of the two bodies, because no chemical change has taken place. In a word, there has been a mechanical mixture, without any chemical combination. But if with the water in this experiment we mix a quantity of potash, so as to form a pretty strong solution, the results will be very different: the particles of the bodies will intimately combine with each other, and a compound will be formed having properties entirely different from either the oil or the potash. The compound substance thus obtained is the useful article soap; and if its water be evaporated by the application of heat, it assumes a solid consistency, as in the form in which it is commonly used for domestic purposes.

It sometimes happens that two bodies will readily combine with each other, but if a third body be added, the combination will be destroyed; the first of the two bodies having a stronger affinity for the third than it had for the second. Thus if magnesia be dissolved in nitric acid, a complete union takes place; but if lime be added to the compound, the nitric acid unites with the lime in preference, and the magnesia, which was formerly invisible, falls, or is *precipitated*, to the bottom of the vessel. Again, if a piece of aqueous sulphate of copper (common blue vitriol) be suspended by a thread in a glassful of water, the crystals shortly disappear, and the whole fluid becomes tinged with blue. Here the solid is said to be *dissolved*—that is, the cohesion of its particles is destroyed, and the compound is called a *solution* of the solid. Such a solution differs entirely from chemical union, and is merely a very perfect mechanical mixture—the same as if we had dissolved sugar in water, or salt in water. The restoration of cohesion to a body after it has been deprived of it, is exhibited in a great variety of instances. For example, if a quantity of sugar be dissolved in water, and the solution be allowed to stand till the water has evaporated, the attraction of cohesion will take effect between the particles of the sugar, which will again resume the solid form. Here, however, a remarkable circumstance has occurred: whatever the state of the sugar may have been originally, it invariably, in resuming its solidity, assumes a particular form, one of great regularity and beauty. It was formerly opaque, it is now transparent; originally a shapeless mass, it is now a prism of six sides, surpassing in lustre and symmetry the products of the lapidary's wheel. This solid spontaneous production is called a *Crystal;* the process by which it is produced, *Crystallisation;* and the science, the object of which is to study the forms of crystals, *Crystallography.*

Bodies, whether solid, liquid, or gaseous, are susceptible of assuming the *crystalline form*, and the substances which do so are numberless. The shapes which the crystals take, and the facility with which they assume them, are various. Instances of crystallisation, such as sea-salt, Epsom salts, saltpetre, are familiar to every one. Water, it is well known, when cooled to a certain degree, assumes the form of ice, which is crystalline. There are three methods of producing artificial crystals: first, by dissolving the substance in a hot liquid, and either allowing the solution to cool, or evaporating it by continued heat; second, by making the substance assume the aërial form; and third, by melting it by fire without the presence of a liquid, and allowing it to cool slowly. The two first are the most common methods of forming crystals, and by the third, sulphur, spermaceti, bismuth, &c. may be made to assume the crystalline state. If as much alum be put into boiling water as the water will readily dissolve, crystals will be deposited as soon as the liquid cools. The presence of the atmosphere has considerable influence upon the formation of crystals. If as great a quantity of Glauber salt (sulphate of soda) be dissolved in a flask half filled with boiling water as the water will hold in solution, and the flask be corked, no crystals will be formed as the liquid cools. Remove the cork, however, and crystallisation commences as the air enters, a solid crystalline mass being almost instantaneously formed. If the weather is warm, crystallisation will not perhaps take place even after the solution is cool. In this case the introduction of a small crystal into the flask will instantly induce the process of crystallisation.

The same body does not invariably exhibit the same form of crystals; there may be several forms of crystals belonging to one body, but in one or other of these it is sure to crystallise, and not according to any other form. It is also to be observed that very different kinds of matter may crystallise after the same model.

The general name for the substance formed by chemical attraction is a *compound*; the substances of which it is composed are called its component or *constituent parts* or principles. The separation of these is termed *decomposition*; and when decomposition is performed for the purpose of ascertaining the ultimate composition of a body, it is named *chemical analysis*. The reunion of the constituent parts is denominated *chemical synthesis*. Integrant particles of a body differ from the constituent particles thus:—The latter are the most minute parts into which a compound body can be resolved by decomposition, and are hence of a different nature, both with regard to each other, and the substance itself which their mutual union gives rise to. The integrant particles are the most minute parts into which any body can be resolved *without* decomposition.

LAWS OF COMBINATION AND DECOMPOSITION.

There are various laws connected with, and phenomena attendant upon, chemical attraction. While of course it can operate only between bodies of a different nature, the qualities which characterise these bodies when separate are changed or annihilated by their combination. Thus not only their active properties, but their density, temperature, form, colour, taste, smell, and sonorousness, are generally affected. Chemical attraction can take place between two, three, or even a greater number of bodies. The force of chemical affinity between the constituents of a body, is estimated by that which is requisite for their separation. It has been already remarked that the degree of attraction varies very considerably in different bodies; and it is evident that from this variation all chemical compositions and decompositions take place. The preference of uniting with another substance which any given body is found to exercise, is metaphorically termed *elective attraction*, or *affinity*. It is of two kinds, each of which derives its appellation from the number and the powers of the principles which may be brought into contact with each other. When a simple substance is presented to a compound one, and unites with one of the constituents of the latter, so as to separate it from that with which it is combined, and by this means producing a decomposition, it is said to be effected by *single elective affinity*. Some substances, however, will not be thus easily decomposed; and it is found necessary to introduce two or more principles, in order to effect the end in view. When two principles, therefore, are presented to a compound body, and when the principles unite each with one of those of the compound substance, two new substances are formed; and all instances of decomposition in this manner are said to be effected by *double elective affinity.* It is to be observed that all changes effected in this manner are permanent, and that the new compound thus formed cannot be decomposed, until a substance having a more powerful attraction for one of its constituents than they have for each other is brought into contact with them.

To Sir Isaac Newton we are indebted for the first attempt at a rational explanation of chemical combination. He was of opinion that the minute atoms of certain bodies attract each other with an unknown but enormous force, which begins to exert itself only when the particles are at very small distances from each other, and that, accordingly, this force exerts itself, and the bodies unite, when they are brought within the requisite distance. These views slowly made their way into the science; but towards the middle of the eighteenth century, they seem to have been almost universally adopted. The term chemical affinity was substituted for that of attraction, and the strength of the affinity existing in bodies came to be measured according to the order in which they were decomposed. It is unnecessary to mention the various tables of affinity which were published previously to that of Bergman, who, in 1775, gave to the world a copious table of affinities, and appears to have fixed the opinions of chemists in general to his own views of the subject. According to this philosopher, the affinity of each of the bodies, say *a*, *b*, *c*, *d*, for *x*, differs in intensity in such a manner, that the degree of affinity in each may be expressed by numbers. He supposed affinity to be elective, in consequence of which, if *a* have a greater affinity for *x* than *b*, if *a* be presented to the compound *b x*, a decomposition will ensue, *b* will be set at liberty, and a new compound *a x* will be formed.

ATOMIC THEORY.

This theory was not discovered all at once, and immediately acknowledged by chemists; it was gradually brought to light by the repeated experiments of successive philosophers, of whose labours, however, it will be impossible to exhibit a view in this place. To our countryman Dalton, we are indebted for the first development and demonstration of the fact, that bodies unite in definite proportions; and of which we shall now attempt to present the reader with as clear and simple a view as possible. Whilst engaged in determining the composition of the two gases called severally carburetted hydrogen and olefiant gas, he discovered that for complete combustion they require *different* but *determinate* quantities of oxygen gas. One volume—that is, any stated measure—of carburetted hydrogen requires two volumes of oxygen gas, whilst a volume of olefiant gas requires three.

The conclusions at which Dalton arrived are, that bodies consist of *atoms*, incapable of further diminution or division; that in chemical combinations it is these ultimate particles which unite; and that in the case above mentioned of the combustion of the two inflammable gases, carburetted hydrogen is a compound of one atom of hydrogen and one atom of carbon; whilst olefiant gas is a compound of one atom of hydrogen and *two* atoms of carbon. The atoms he considered as spheres, and represented them by such symbols as a circle with a dot in the centre, a circle with a vertical diameter, and the like. In this manner the composition of a number of the best known bodies was represented by him, and the ratios of the weights of the atoms of the simple bodies inferred. For instance, he concluded from his experiments that carburetted hydrogen is composed of—hydrogen one, and carbon six; while olefiant gas is composed of—hydrogen one, and carbon twelve. Now, as the former gas consists of one atom of hydrogen and one atom of carbon, then the weights of these atoms are to each other in the relation of one to six. If the weight of the atom of hydrogen, therefore, be represented by one, that of carbon will be six. In this manner the ratios of the weight of the atoms of all the simple bodies may be ascertained by a careful analysis of the compounds formed by their union.

The combinations of mercury or quicksilver with some other bodies, afford an illustration of the theory. Its first compound with oxygen, one of the gases of which the atmosphere is composed, consists of two hundred and two parts of mercury, and eight of oxygen. If, however, the metal be subjected to a considerable degree of heat, it will be converted into a red shining mass, which is also a compound of the metal with oxygen; but in the latter case, sixteen parts of oxygen have united with the two hundred and two parts of the metal. The explanation of this is, that eight is the chemical equivalent of oxygen, and two hundred and two of mercury. In every successive compound which they make, their proportions form a multiple of these equivalents. Every other simple body has, in like manner, its equivalent number, and to its compounds the same rule applies. Innumerable instances of this might be adduced, but these are sufficient to prove the remarkable truth, that when different substances combine by chemical attraction, the proportions of the ingredients are always uniform; that for every atom present of one substance, there is exactly one, or two, or three, &c. of the other. If, for instance, any quantity of sulphur, intermediate between the two combinations of that substance with mercury, be added, it will not combine with it, but remain as a foreign ingredient in the sulphuret of mercury, as the compound is termed. All bodies, however, do not unite in several proportions, thus giving rise to several distinct compounds from two elements; there are many elementary bodies which will only unite with each other in one proportion, so that any two of such substances can only form one compound. This law, however, is not universal, as it is well known that water and alcohol, and water and sulphuric acid, will unite in any proportions. Water will also unite in any proportion with soluble salt, until it becomes completely saturated. Bodies which unite in any proportions form an infinite variety of compounds, and are distinguished by their being united by a weak affinity, and also by the compounds formed differing little from their simple constituents or from each other.

These remarks must be held as applying to *inorganic chemistry* chiefly; *organic chemistry*, or that which treats of the properties of vegetable and animal substances, presents many exceptions to the principles of combination now laid down.

EQUIVALENT RATIOS—SYMBOLS—CLASSES.

The result of investigations of chemical unions has been the formation of scales exhibiting the equivalent ratios of the simple elements, expressed in numbers. For this purpose it is evident that some body must be fixed upon, and expressed by unity. Hydrogen gas, being the lightest known body in nature, and combining in the smallest proportion by weight with the other simple substances, has been taken as a standard of comparison for the combining proportions or *equivalent numbers* of all other bodies; and which, in all likelihood, are simple multiples of its number. Oxygen has also, by some chemists, been taken as the standard of comparison, and represented by ten. Water is a compound of eight parts by weight of oxygen, with one part by weight of hydrogen; which two gaseous bodies we shall afterwards describe. Whenever hydrogen and oxygen gases are burnt in any proportion whatsoever, they invariably form water; and they cannot be made to combine directly in any other proportion. From this, Dalton concluded that water is a compound of one atom of hydrogen and one atom of oxygen. But the weight of the latter gas being eight times that of the former, then it followed that the atom of oxygen was just eight times heavier than the atom of hydrogen. Hence if the latter be represented by one, then will the former be represented by eight, according to those who take hydrogen as the standard. Those who take oxygen as the standard, and represent it by 10, make the equivalent for hydrogen 1·25: the result is of course the same, the proportion of 1·25 to 10 being exactly the same as that of 1 to 8. These observations relative to water lead us to speak of the doctrine of volumes, so generally embraced by chemists upon the continent. The union of gases is always effected in simple proportions of their volumes; and a volume of one gas combines with an equal volume, or twice or three times the volume, of another gas; and in no intermediate proportion.

'The impracticability in many cases,' says Turner, 'of contriving convenient names expressive of the constitution of chemical compounds, especially of minerals, suggested the employment of *symbols* as an abbreviated mode of denoting the composition of bodies. It was thought that the names of elementary substances, instead of being written at full length, might often be more conveniently indicated by the first letter of their names; and that the combination of elements with each other might be expressed by placing together, in some way to be agreed on, the letters which represent them. The advantage of such a symbolic language was felt so strongly by Berzelius, that he some years ago contrived a set of symbols, which he has since used extensively in his writings; and other eminent chemists, as well as mineralogists, believing symbols to be useful, adopted those which Berzelius used. The consequence is, that symbolic expressions, called *chemical formulæ*, are now almost universally employed in the language of chemistry.' The following table exhibits at once the names, symbols, and equivalents of the commonly admitted elements:—

Elements.	*Symb.*	*Equiv.*	*Elements.*	*Symb.*	*Equiv.*
Aluminium, -	Al.	13·7	Molybdenum,	Mo.	47·96
Antimony, (Lat. *Stibium*), -	Sb.	64·6	Nickel, - -	Ni.	29·5
Arsenic, -	As.	37·7	Nitrogen, -	N.	14·5
Barium, - -	Ba.	68·7	Osmium, - -	Os.	99·7
Bismuth, -	Bi.	213·	Oxygen, - -	O.	8·
Boron, - -	Bo.	10·9	Palladium, - -	Pa.	53·3
Bromine, -	Br.	78·4	Phosphorus, -	P.	15·7
Cadmium, - -	Cd.	55·8	Platinum, -	Pt.	98·8
Calcium, -	Ca.	20·5	Potassium (Lat. *Kalium*), -	K.	39·13
Carbon, - -	C.	6·12	Rhodium, -	R.	52·2
Cerium, -	Ce.	46·	Selenium, - -	Se.	39·6
Chlorine, - -	Cl.	35·42	Silicon, -	Si.	7·5
Chromium, -	Cr.	28·	Silver (*Argentum*),	Ag.	108·
Cobalt, - -	Co.	29·5	Sodium or Natrium, - -	Na.	23·3
Columbium or Tantalum, -	Ta.		Strontium, -	Sr.	43·8
Copper (*Cuprum*),	Cu.	31·6	Sulphur, - -	S.	16·1
Fluorine, -	F.	18·68	Tellurium, -	Te.	64·2
Glucinium, -	G.	17·7	Thorium, - -	Th.	59·6
Gold (*Aurum*),	Au.	199·2	Tin (*Stannum*),	Sn.	58·9
Hydrogen, -	H.	1·	Titanium, -	Ti.	24·3
Iodine, - -	I.	126·3	Tungsten or Wolfram, -	W.	94·8
Iridium, - -	Ir.	98·8	Vanadium, -	V.	68·6
Iron (*Ferrum*),	Fe.	28·	Uranium, -	U.	217·
Lead (*Plumbum*),	Pb.	103·6	Yttrium, - -	Y.	32·2
Lithium, - -	Li.	6·	Zinc, - -	Zn.	32·3
Magnesium, -	Mg.	12·7	Zirconium, -	Zr.	33·7
Manganese, -	Mn.	27·7			
Mercury (*Hydrargyrum*), -	Hg.	202·			

, We exclude *Didymium*, *Erbium*, *Terbium*, *Lantanium*, *Niobium*, *Pelopium*, and *Ruthenium*—substances of very recent discovery, but by many now admitted as established elements. Their symbols are respectively D. E. T. La. Nb. Pe. and Ru.

Applying these symbols, HO or H + O represents water—that is, one equivalent of hydrogen and one of oxygen; S + 3O, sulphuric acid—that is, one equivalent of sulphur and three of oxygen; and in the same manner N + 5O, nitric acid; H + Cl, hydrochloric acid; and so on. The brevity and lucidity of the system is admirable; and to a practised chemical eye, a few lines of properly-constructed formulæ may convey more information than pages of description, and with less risk of misconception and error.

For the convenience of study, the fifty-four elementary substances have been arranged into classes. One system of classification, and that which we adopt, is dependent upon the elements being metallic or non-metallic. 1st, The NON-METALLIC elements are thirteen in number—namely, oxygen, hydrogen, nitrogen, chlorine, bromine, iodine, fluorine, carbon, boron, silicon, sulphur, selenium, and phosphorus. The first three are termed *gazolytes*, or bodies which are permanently gaseous; the next four *halogens*, or bodies which produce salts when in union with the metals; and the remaining six *metalloids*, or bodies which resemble the metals in the chemical relations. Oxygen, chlorine, bromine, iodine, and fluorine, having a tendency to combine with almost all other substances, and their union being generally accompanied by light and heat, have hence been termed *supporters of combustion*. Some of the other non-metallic elements, instead of supporting the combustion of others, are themselves combustible; and from their property of generally forming acids, when combined with the supporters of combustion, have been termed *acidifiable bases*. Those bodies which, when united with the supporters, become alkalies, have been called *alkalifiable bases*. 2d, The METALLIC elements are forty-one in number—namely, potassium, sodium, lithium, calcium, barium, strontium, magnesium, aluminium, thorium, glucinium, zirconium, yttrium, manganese, zinc, iron, tin, cadmium, cobalt, nickel, arsenic, chromium, vanadium, molybdenum, tungsten, columbium, antimony, uranium, cerium, bismuth, titanium, tellurium, copper, lead, mercury, silver, gold, platinum, paladium, rhodium, osmium, iridium. Of these the first twelve, combined with oxygen, form the alkalies and earth, and are therefore distinguished as the *metallic bases of the alkalies and earths*; the remaining twenty-nine are subdivided according to the effects which they produce upon water at a red heat, and to the effects produced by heat upon their oxides. Thus seven decompose water at a red heat; fourteen of them do not decompose water at any temperature, nor can their oxides be reduced by the sole action of heat; and the remaining eight are metals whose oxides can be reduced by a red heat.

ACIDS, SALTS, METALLIC OXIDES, EARTHS, ALKALIES.

Acids are a most important class of chemical compounds, and have the following characteristic properties:—The greater number of them have a sour taste, and are very corrosive. With few exceptions, they change vegetable blues to red, they are mostly soluble in water, and they unite with the alkalies, earths, and metallic oxides, forming what are called *salts*—an order of bodies of the highest importance in the arts, manufactures, &c. Some acids are destitute of a sour taste, but their affinity for the three classes of bodies above named is a universal characteristic. Acids are all compound bodies, and some of them have more than one *basis* or radical. There are a number of acidifying principles, but oxygen (which shall be immediately described) is the most extensive one. The acid is distinguished by the name of its base, and its degree of oxidation—that is, the quantity of oxygen it contains, by the termination of that name in *ous* or *ic*, or the prefix *hypo* (under). The highest degree of oxygenation is marked by the termination *ic*, as nitric acid, and the salt which is formed from it is made to terminate in *ate*, as nitrate of potash; the next by that of *ous*, as nitrous acid, and the salt which is formed from it is made to terminate in *ite*; and the lowest by *hypo*, as the hyponitrous acid. Sometimes oxygen combines in a greater quantity with the acidifiable radicals, in which case the product is said to be superoxygenated. All acids are not susceptible of these various degrees of oxygenation, some being limited to only one. There are a considerable number of acids, and the number is continually increasing by the discovery of new ones; but of the most important there are few, and these we shall notice as we come to treat of their bases.

A *salt* is the term usually employed to denote a compound, in definite proportions, of acid matter with an alkali, earth, or metallic oxide. When the proportions of the constituents are so adjusted that the resulting substance does not affect the colour of infusion of litmus or red cabbage, it is then called a *neutral* salt, because the peculiar powers of both bodies are suspended and concealed; they are rendered neutral or inactive. When bodies combine in such a way as to satisfy their mutual affinities, they are said to *saturate* each other. When the predominance of acid is evinced by the red of these infusions, the salt is said to be acidulous, and the prefix *super* or *bi* is used to indicate this excess of acid. If, on the contrary, the acid matter is deficient, or short of the quantity necessary for neutralising the alkalinity of the base, the salt is then said to be with excess of base, and the prefix *sub* is attached to its name. These must be understood, however, only as general rules. There are exceptions to be found in the case of some salts, as the compounds formed by an acid and an alkali, an earth, or a metallic oxide, are denominated. For example, a certain salt formed by nitric acid and lead, though the acid be perfectly neutralised, reddens vegetable blues; and a salt formed by boracic acid with soda retains the powers of an alkali, in the respect in question, though with a double proportion of acid in it. A *double salt* is a compound of two salts—as, for example, tartrate of potassa combined with tartrate of soda; and a *triple salt* is a compound of three salts.

Metals, such as iron, copper, lead, &c. are familiarly known to every one, but there are a great many others which are very rarely to be met with. The following are some of the characters which distinguish metals from other bodies:—They are for the most part hard and heavy, and are all opaque; insoluble in water; they possess a peculiar lustre; admit of being so highly polished as to reflect light; are capable of being melted by heat, and of recovering their solidity by cooling; most of them may be extended by hammering, and all are rapid conductors of electricity. They are of various colours, and require different degrees of heat to fuse or melt them. They generally occur in the earth in what are called *veins*, and are seldom found in the pure metallic state, but generally in combination with some other substance, in which state they are called *ores*. The metals, which are all simple bodies, will be individually noticed afterwards. (See also METALS AND METALLURGY.) Most of them, when subjected to heat until they become melted, combine with the oxygen of the atmosphere, and form what are called *oxides*. Oxides are destitute of those properties which distinguish the metal from which they are formed. Instead of being bright, shining, elastic, and ductile substances, they are generally a dry, earthy-looking powder. Other substances, besides metals, however, are capable of being converted into oxides; and it must be kept distinctly in view, that in every case there is not so much oxygen imparted as will produce *acidification*. Oxygen frequently combines in various proportions with a substance, rendering it an oxide, but without advancing it to the state of an acid. In order to distinguish each compound thus formed, the language of chemistry is very systematic. The first is called a *protoxide*; the second, a *deutoxide* or *binoxide*; the third a *tritoxide* or *teroxide*; and the highest degree of oxidation a *peroxide*. The Latin term *sesqui* (one and a half) denotes that the elements exist in a compound, in the ratio of one and a half—as the sesqui-carbonate of ammonia, When a simple non-metallic substance combines with another, with a metal, or with a metallic oxide, the name of the compound terminates in *uret*—as carburet of iron, sulphuret of mercury, &c.

The term *Earths* was formerly, and is still, but in a modified sense, applied to several substances which compose all the various rocky substances, clays, and soils, which constitute the crust of the globe. They are tasteless, inodorous, dry, uninflammable, sparingly soluble, difficult of fusion, and of moderate specific gravity. These bodies will be more particularly described when we come to treat of their metallic bases.

Alkalies may be defined as bodies which combine with acids so as to impair or neutralise their activity, and produce what are called salts. They are distinguished by properties the reverse of acids, and the two classes are generally looked upon as antagonist substances. Besides the power of neutralising acids, there are four alkalies—namely, potash, soda, ammonia, and lithia—which possess the following properties in a high degree: They change vegetable blue to green, red to purple, and yellow to a reddish brown; they have an acrid and urinous taste; they are powerful corrosives of animal matter, with which they combine so as to produce neutrality; they also unite with oils and fats, forming the well-known substance soap; they combine with water and alcohol in any proportion. Four of the earths—namely, lime, baryta, strontia, and magnesia—possess alkaline properties to a considerable extent, and are hence called *alkaline earths*. These bodies differ from the pure alkalies, inasmuch as they become insoluble in water when neutralised by carbonic acid. Moreover, alkalies possess the power of changing vegetable colours *after* being saturated with carbonic acid, and by this criterion they are distinguished from alkaline earths.

It was long observed that the properties of earths very nearly resemble those of the compounds of oxygen and metals called metallic oxides; but it remained for the brilliant genius of Sir Humphry Davy to show that both the earths and alkalies are metallic oxides. It thus appears, then, that the globe is one vast mass of various kinds of metals, disguised by various substances, but chiefly by oxygen. Earths and alkalies are simply metallic oxides; whilst a further impregnation of these substances with oxygen produces an acid; and, lastly, the union of acids with alkalies, &c. gives rise to that very numerous and important class of substances called salts.

ACTION OF THE IMPONDERABLES.

Before proceeding to the consideration of the individual elements, it will be necessary to advert to the influence which the *imponderables*—heat, light, and electricity—exercise over chemical phenomena. Referring to MATTER, OPTICS, and ELECTRICITY, where these agents are treated at length, we shall here merely recapitulate:—In our investigations of the phenomena of the material universe, we perceive two kinds of motion, which result from the two principles *attraction* and *repulsion*. Of the former we have already spoken; repulsion, like attraction, takes place both at sensible and insensible distances. The former is exemplified by the flying off of the same light bodies which have been first attracted, after they have been some time in contact with a piece of excited resin or glass, and also by the recession from each other of the two similar ends of two magnetised needles. Repulsion at insensible distances, which is chiefly excited by heat, or, as it is chemically termed, *caloric*, is exhibited in a variety of phenomena.

The principal effects of heat are expansion, liquefaction, vaporisation, evaporation, and ignition. With few exceptions, bodies are capable of *expansion* by means of heat; the gases being the most expansive, fluids less so, and solids least of all. The general law, therefore, is, that the expansion and contraction of matter are, with a few exceptions, dependent upon the increase and diminution of heat. The quantity or condition of heat that is discoverable by the thermometer, or by the organs of sensation, is called *temperature*. We are unacquainted with the extremes of temperature relative either to heat or cold. It has been compared to a chain, the extremities of which are concealed from view, whilst only a few of the middle links are exposed to observation. Although the universal result of an increase of temperature is an increase of bulk to the body thus subjected to heat, yet all bodies are not alike expanded by the application of the same quantity of heat. It of course follows as a general law, that different bodies at equal temperatures do not contain the same quantities of caloric. This quality of matter is called the *capacity* of bodies for heat, and the quantity of heat which is necessary to raise any particular body to a certain temperature, is called its *specific* caloric. Heat, however, in some cases, causes contraction instead of expansion. Thus water is of greater bulk at a temperature of 32° (the freezing-point) than it is at 39½°; and in like manner with the earth, alumina, to be afterwards described. Some solids also—as iron, antimony, bismuth, and many salts—contract when melted, and expand as they become solid.

The rapid production of a thin vapour, as when water is converted into steam, is termed *vaporisation*. The boiling-point of water, in a vessel exposed to the ordinary atmospheric pressure, is 212°, and although more heat be applied to the vessel in which it is contained, the temperature of the water is not increased. If this degree of heat be continued, the watery particles separate from each other, and become steam or vapour. Steam is colourless, transparent, and invisible, resembling the atmosphere, and is 1696 times greater in bulk than water. Water can be made to boil at a lower temperature than 212° by removing the pressure of the air. If a flask be half filled with water, the water made to boil, and as the steam escapes, a cork be put into the mouth of the flask, upon the heat being removed, the water will continue to boil, the heat in it being sufficient for that purpose when there is no pressure from the air. If the flask be put into cold water, the boiling will increase, from the steam being more effectually condensed; whereas, if the flask be put into boiling water, so as to prevent the condensation of the steam, the ebullition will immediately cease. Liquid substances give off vapour from their surface at temperatures below the boiling-point, which is termed *evaporation*. It is called spontaneous evaporation when this takes place at the ordinary temperature of the atmosphere. A large quantity of vapour is given off from the surface of the earth and sea, which eventually forms clouds, or is condensed into rain and dew. Evaporation always produces cold when heat is not applied; the heat necessary for it being derived from surrounding objects.

All substances become luminous when heated to 800° in the dark, and 1000° in daylight, unless they are converted into vapour at a less elevated temperature. The light is red at first, and in this state a body is said to be in a state of *ignition*. If more heat is applied, the body becomes white, when it is said to be *incandescent*.

When a body changes from the solid to the fluid state, there is a quantity of heat absorbed, which has no effect in raising the temperature. This has been called *latent* heat, a discovery effected by Dr Black, and which we shall shortly explain. For a demonstration of this doctrine, we may have recourse to water. If ice, at a temperature below 32°, be exposed to a warmer atmosphere, it receives caloric, and gradually rises to that point of the thermometrical scale. But as soon as it reaches it, the rise of temperature ceases, the ice begins to melt, and during the whole period of its liquefaction, its temperature, as also that of the water flowing from it, remains stationary at 32°. It is evident that, as caloric has continued to be communicated, a quantity of it has disappeared, and become absorbed during the fusion. The same phenomenon takes place when a liquid is converted into vapour; and the inference drawn from it is, that when a body passes from one state into another, a quantity of heat, or caloric, is lost, becomes latent, or passes into the body without raising its temperature. Dr Black was of opinion that this latent heat became chemically combined with the solid, and was the cause of fluidity. Dr Irvine, his pupil, took a different view of the subject. He supposed that the absorption of heat into the latent state is not the cause of liquefaction and vaporisation, but the effect. The absorption he attributed to what is called change of capacity for heat, or that quality of matter which causes one kind to be more or less heated than another, by the addition of the same quantity of heat. He concluded, as a general law, that the capacity of all solids for heat is increased by fusion, and that of all fluids by evaporisation.

Combustion is a process not yet perfectly understood. It is usually described as the union of a *combustible body* with a *supporter of combustion*, attended with the evolution of *light* and *heat*. The combustible body is that which *burns*, but in general will neither support combustion nor burn, except in presence of a supporter of combustion. The supporter, again, does not itself burn, though necessary to the burning of a combustible. Oxygen gas, the ingredient which enables the air to support combustion, possesses, when pure, a high degree of the supporting quality. If a lighted taper, a combustible body, be plunged into this gas, the taper burns vividly, but the *gas* itself is not ignited. If, on the other hand, the taper be plunged into a combustible gas, such as pure coal gas, the gas is instantly ignited, but the taper is extinguished. These are general rules, relating to supporters of combustion and combustible bodies. By examining the effects of combustion, in the case of a candle burning in the air of the atmosphere, it has been proved pretty clearly that a chemical action of the following kind takes place:—The combustible matter of the candle consists chiefly of two simple bodies—hydrogen gas and carbon—while oxygen is the supporter of combustion in the air. On burning a candle under a bell-shaped glass, filled with common air, a fluid gathers on the glass, which proves, on examination, to be pure water. The hydrogen of the burning body has here entered into combination with part of the oxygen of the air, forming water, a compound of the two. The carbon of the burning body also enters into union with a portion of the atmospheric oxygen, forming carbonic acid gas, which is left floating in place of the original quantity of oxygen. The presence of these can be proved, and the same process takes place in the case of coal, wood, &c. Thus it is seen that combustion only changes the forms of the burned bodies, and does not annihilate them. The phenomena of combustion are thus so far explicable, but unfortunately the source of the *light* and *heat* yet remains a mystery. It is unknown whether the chemical action is the cause of the light and heat being evolved, or the evolution of these the cause of the chemical action. Where all is doubt, it would be vain to dwell on this point. The laws stated respecting combustible bodies, and supporters of combustion, only apply generally, it is also to be observed, and under ordinary circumstances. Under the oxy-hydrogen blowpipe, the most incombustible bodies can be made combustible; and combustion can be shown to take place under an exhausted receiver, without the presence of any supporter, at least of a gaseous kind.

The nature of *light*, and the laws which determine its radiation, reflection, refraction, and so forth, have been fully explained under the science of Optics: here we can only take notice of its more prominent chemical relations. The connection between light and heat is so obvious, that it is scarcely possible to examine the one independently of the other. If a mass of iron be put into a fire for some time, no change is produced, except the expansion of the metal, and the elevation of its temperature. Gradually, however, as the heat is communicated, a remarkable occurrence will be observed: the iron becomes ignited, or red-hot; in other words, it emits light, and renders objects visible. The prime source of light is the sun, yielding what is termed *solar light*; all kinds of artificial light—as that from fires, candles, &c.—is called *terrestrial* light. Light passes freely through the atmosphere, and striking upon objects, is reflected, or thrown back by them; and thus they become visible. By means of a wedge of glass called a prism, light can be separated into seven colours, which are violet, indigo, blue, green, yellow, orange, and red. Light, taking the common acceptation of the term, is resolvable also into *luminous*, *calorific*, and *chemical* rays. Thus the heat of the sun's rays may be absorbed, or intercepted, without affecting their luminous properties, and so certain rays can be separated from their light; and their heat and light can also be intercepted so as to leave a principle which excites neither heat nor light, but which produces very remarkable chemical changes.

The chemical influence of light is conspicuous in a variety of natural and artificial processes. In vegetation it is indispensable, as without it plants do not acquire their due elementary constitution. They are weakly, inodorous, and fail to exhibit their natural colours and products. Vegetables which grow in the dark have a blanched appearance. The power of light to dispel vegetable colours is manifest in bleaching, where a dingy web becomes pure and white by exposure to the sun's rays. Its energy is still more decisively seen in the influence which it exerts in promoting chemical combination and decomposition; the latter effect having been made use of as a *photometer*, or measure of its power. Light enters into a kind of transitory union with certain substances, rendering them visible in the dark. Bodies which possess this property are called phosphorescent; such are the shells of fish, the bones of land animals, marble, limestone, and the like. The glow-worm is a remarkable instance of phosphorescence in living animals. The *Daguerreotype*, as well as Mr Talbot's method of *photography*, is founded on the action of the chemical rays on certain substances. The iodide of silver, formed by exposing a plate of silver to the vapour of iodine, is the substance used in the Daguerreotype; the chloride, iodide, and bromide of silver, formed on the surface of paper in a thin and uniform layer, are the bases of Talbot's method—both of which will be fully treated at length in a subsequent number.

The chemical agency of *galvanism* and *electricity* has been already described in No. 17. The latter is frequently employed to produce the combination of gases, and sometimes to effect their separation. It appears to act by the heat which it occasions, and therefore upon the same principle as flame.

I.—NON-METALLIC ELEMENTS.

Oxygen.

Oxygen gas is a permanently elastic fluid—that is, one which no compressing force, or degree of cold, hitherto applied, has ever been able to reduce to a liquid or solid state. It forms, as we have already observed, one of the constituents of the atmosphere, is colourless, and destitute of taste and smell. Its specific gravity is 1·1026, that of common air being reckoned unity. Combustible bodies burn in it with more brilliancy, and more light and heat is evolved, than when combustion takes place in the atmosphere. If a candle, the wick of which is red-hot, be introduced into a vessel containing oxygen, the candle will instantly be lighted. Oxygen has the power of combining with every other simple body; the multifarious compounds which it thus forms, such as oxides, acids, and bases, or alkalies, we have already adverted to. It was discovered by Priestley in 1774: its name, from *oxys* and *gennaein*, denotes that it is a *generator of acidity*.

In the act of respiration, oxygen, in the nice economy of the human body, is made to unite with it, and becomes a portion of the human frame. Vegetables also inhale and exhale it at certain seasons, so as admirably to supply what is absorbed by animals. It is the intensely rapid chemical union of oxygen with the combustible body, which gives rise to the light and heat in our common fires, candles, &c. Though necessary to respiration, it is singular that oxygen in a state of purity is deleterious. When an animal—as a rabbit, for example—is introduced into a medium of pure oxygen, it breathes at first without any apparent inconvenience; but after an hour or so, the circulation and respiration become rapid, and the system is highly excited. Symptoms of debility subsequently ensue, followed by insensibility; and in eight or ten hours life becomes extinct.

Oxygen may be readily procured from a variety of substances, as, for instance, from saltpetre, or the black oxide of manganese. These may be introduced into a gun barrel, with the touch-hole plugged up. From the orifice of the barrel let a tube be conducted into an inverted glass jar, filled with water. When the other extremity of the apparatus is subjected to heat, the oxygen gas is expelled from the manganese, and entering the glass jar, displaces the water, and fills the vessel. This is a cheap and easy method of obtaining this remarkable aëriform body. It can also be prepared by putting 1000 grains of binoxide of manganese into a retort with an equal weight of aqueous sulphuric acid. This is done by means of a retort fixed over a spirit-lamp. The bent tube of the retort enters a pneumatic trough, in which jars are placed for receiving the gas as it passes from the neck of the retort. When oxygen of great purity is required, it is better to obtain it from chlorate of potassa, heated nearly to redness in a green glass retort. Thus treated, the salt first liquefies; and as the heat increases, the gas is given off with effervescence, leaving a white compound behind, which is chloride of potassium. Symbolically represented, the change which takes place is this:—Original compound $KO + Cl\ O_5$; result, $KCl + O_6$; so that the six equivalents of oxygen are wholly liberated.

Hydrogen.

Hydrogen gas is a permanently elastic fluid, transparent and colourless, and when *pure*, destitute of taste or smell. It can scarcely be said to exist in an isolated state, but it forms one of the constituents of water, from which it can be disengaged by various simple processes. It is the lightest body with which we are acquainted, being nearly 14½ times lighter than atmospheric air. A bladder filled with this gas will ascend in the atmosphere, in the same manner as a piece of cork or wood plunged by force to the bottom of a vessel of water. Hydrogen will not support combustion, but is itself remarkably combustible, whence its early name, *inflammable air*. When one volume of oxygen is mixed with two of hydrogen, it burns with a loud explosion, by an electric spark, or the contact of a red-hot wire. The product of this experiment is water; hence the term hydrogen, or *generator of water*. It is said that a few cautious draughts of this gas may be taken; but it cannot be inspired for any length of time without occasioning death. Hydrogen was first correctly described by Cavendish in 1766.

By far the most important compound of hydrogen with any other substance is that with oxygen, forming the indispensable fluid which covers nearly two-thirds of our globe — *water*. Water is thus an oxide of hydrogen—a compound never found absolutely pure in nature. In the ocean it is salt and brackish, from the presence chiefly of chloride of sodium; in springs it is either carbonated — that is, contains carbonic acid; sulphureous, from the presence of sulphuretted hydrogen; chalybeate, from the union of the sulphate or carbonate of iron; and so on, according to the nature of the mineral ingredients through which it percolates. When it contains a chemical compound of lime, it is said to be *hard*, and in this condition it decomposes the soap which is employed with it, and destroys its detergent properties. The impurity of water may thus arise either from chemical union or mechanical mixture with other bodies. The latter can generally be removed by filtration; but when the union is chemical, distillation (a process to be afterwards described) is necessary to produce a pure liquid.

Hydrogen also unites with the other supporters of combustion; but the compounds, except muriatic acid (to be afterwards mentioned), are not of any great importance. The flame of hydrogen, though feebly luminous, is intensely hot; and the most intense heat that can be produced is caused by the combustion of hydrogen in oxygen gas. Upon this principle is constructed the *oxy-hydrogen blowpipe*, one of the most important applications of hydrogen gas.

Hydrogen may be prepared by putting 500 grains of zinc into a common beer bottle, and pouring upon the zinc three ounces of water and five drachms of aqueous sulphuric acid. The hydrogen is disengaged as the acid, the oxygen in the water, and the metal combine. By means of a bent tube from the bottle, the gas can be conveyed into jars placed in a trough.

Azote, or Nitrogen.

This gas is permanently elastic, transparent, colourless, and inodorous; specific gravity, 0·9722. When breathed, it destroys animal life (hence the term *a-zote*); and a burning body, if immersed in a jar containing it, is instantly extinguished. It is not combustible; it enters extensively into combination; it is an abundant element in animal matter; and its existence in such large quantity is a chief distinction between the constitution of animal and vegetable life. It was first noticed by Rutherford of Edinburgh in 1772; and discovered to be a constituent of the atmosphere by Lavoisier in 1775. The air consists mainly of nitrogen and oxygen, in the proportion (if these ingredients be alone regarded) of 210 oxygen to 790 nitrogen, by measure; and of 231 to 769 by weight. Common atmospheric air alone contains, as constant ingredients in every situation, a little carbonic acid gas and vapour of water. In volume, the carbonic acid forms about 1-2000th part; or 0·5 parts in 1000 by measure; which is equal to 0·75 parts in 1000 by weight. In some situations the carbonic acid is so much as 0·62 volumes in 1000—at other places, only 0·37 volumes in 1000. Its proportion is greater in summer than in winter, during night than in the day-time, in elevated situations than on the plains. The watery vapour is more variable in proportion. The mean is supposed to be about 10 parts in 1000 by weight, 15 by volume. The quantity is determined by the temperature, heat being the sole cause which sustains the vapour in the aërial state. Whether the nitrogen and oxygen of the atmosphere be merely a mechanical mixture or a chemical compound, is not precisely determined; the majority of chemists, however, lean to the former opinion, and found their reasonings accordingly. Be this as it may, it is the oxygen which performs the chief part in the process of respiration, the nitrogen acting in a negative capacity as a simple diluent. Each individual is supposed, on an average, to breathe about twenty times every minute—to take in about sixteen cubic inches of air (12·8 nitrogen + 3·2 oxygen) at each inspiration—to return nearly the whole of the nitrogen (12·8 cubic inches), and 4-5ths of the oxygen (2·56 cubic inches), and to replace the remaining 5th of oxygen by an equal volume of carbonic acid gas (·64 cubic inch).

That nitrogen has the property of combining with all the supporters of combustion, there can be little doubt; but the subject has not yet been thoroughly investigated. With oxygen it unites in no fewer than five proportions—namely, one of nitrogen to one, two, three, four, and five of oxygen respectively *by weight*, or one of nitrogen to a half, one, one and a-half, two, and two and a-half *by volume*. Of these compounds, by far the most important is nitric acid, or the *aqua-fortis* of the alchemists. The term nitrogen is derived from its being an element or *generator of* nitric acid.

Nitric Acid.—This virulent substance is a compound of one volume nitrogen, and two and a-half volumes of oxygen, or by weight N + 5O. Common nitric acid is of an orange colour, on account of its containing a little muriatic acid, as also a little sulphuric acid and water. Light has likewise an effect upon it. The specific gravity of the strongest procurable nitric acid, or *double aquafortis*, as it is sometimes called, is 1·55, and then it contains one-seventh of its weight of water; that of commerce is about 1·423, and contains two-fifths of its weight of water. Nitric acid has very remarkable effects upon water with regard to the production of heat. If diluted with half its weight of water, heat is evolved; but if the water be in the state of snow, intense cold is the result. Hence this compound is employed to produce great degrees of cold. If nitric acid, highly concentrated, be thrown upon phosphorus, charcoal, or oil of turpentine, it inflames them. It is very extensively used in the arts, particularly for the purification of gold, for etching on copper plates, &c.; and recently it has assumed additional importance from its being one of the principal ingredients used in the preparation of Dr Schönbein's 'gun-cotton.'

Nitric acid also forms a numerous and important class of salts, having the generic name of *Nitrates*—such as nitrate of silver, nitrate of potash, &c. Some of these we shall notice afterwards. *Nitrous acid* is a compound of the same kind, but with a lesser quantity of oxygen. Amongst the other compounds of azote and oxygen, that entitled the *protoxide of azote*, or, as it was formerly called, *nitrous oxide*, is the most remarkable. Davy discovered that we may breathe it for a short while without any effect being produced, except an exhilaration of the mind; hence the term *laughing gas*, which is sometimes applied to it. Combustibles burn in it more brilliantly than in common air. Faraday has lately succeeded in solidifying this gas under a pressure of 50 atmospheres at 45°; and is of opinion that it might be employed in this state with greater advantage than solid carbonic acid, for producing intense cold by its evaporation *in vacuo* when mixed with ether. There is also a *deutoxide of azote*, and a *hyponitrous acid;* but these do not require minute detail. Azote combines likewise with chlorine and bromine. Nitric acid can be procured by filling a glass retort about one-third full of equal weights of aqueous sulphuric acid and common nitre. The retort is then subjected to heat, and a vapour is distilled over, which, condensed, is nitric acid.

Ammonia, or *Hartshorn*.—This important substance is formed by the combination of azote with hydrogen, and is obtained in the state of gas, by means of the salt called *sal ammoniac*, which is a compound of muriatic acid and ammonia. This substance is to be introduced into a retort, along with quicklime, and then subjected to heat. Ammonia is driven off in the form of gas, and is to be collected in glass jars standing over mercury. Ammoniacal gas is colourless, has a strong pungent smell, an acrid caustic taste, and cannot be drawn into the lungs. Its specific gravity is 0·59027. Water absorbs 780 times its volume of this gas, and in this state it is employed for chemical purposes. When the gas is mixed with chlorine, a sudden combustion and detonation take place. The chlorine unites with the hydrogen of the ammonia, and forms muriatic acid, whilst the azote is disengaged in the state of gas. The muriatic acid formed combines with a portion of ammonia, and forms sal ammoniac. Ammonia is an alkali, and possesses the properties distinguishing this class of substances in a very decided manner. It of course neutralises acids, and the salts which it forms are numerous, and of considerable importance.

Chlorine.

This is a gaseous body, of a yellowish-green colour (whence its name), of a strong suffocating smell, and of a pretty strong astringent taste. It was discovered by Scheele in 1774, and regarded as a compound substance, till Davy, in 1809, established its title to rank with the simple bodies. Reckoning air as unity, its specific gravity is 2·5. If breathed undiluted, it destroys animal life; however, it not only supports combustion, but possesses the remarkable quality of setting fire to many of the metals, even at the common temperature of the air, when beaten out into thin leaves, and introduced into it. In these cases the combustible substances unite with the chlorine, and form *chlorides*.

Chlorine gas is obtained by the action of muriatic acid on peroxide of manganese. The most convenient mode of preparing it is by mixing the acid with half its weight of finely-powdered peroxide in a glass flask; the gas is liberated with effervescence, and should be collected in dry bottles. For the purposes of manufacture on a large and cheap scale, the process is modified thus:—Three parts of sea-salt are intimately mixed with one of peroxide of manganese, and to this mixture two parts sulphuric acid, diluted with an equal weight of water, are added.

Chlorine possesses the property of destroying all vegetable colours, and of rendering vegetable bodies exposed to its action white. This property has occasioned the introduction of chlorine (combined with lime) into bleaching; for if unbleached linens be exposed to its action, the matter which gives them their gray colour is destroyed, and the substance assumes a brilliant whiteness. Chlorine, however, must be used cautiously; for if applied in its pure, and not sufficiently diluted state, it destroys the fibre of the cloth. It is also used in fumigation, being destructive of effluvia arising from putrefaction, disease, &c. Chlorine combines with oxygen in four different proportions: two of them contain so much oxygen as to form acids; these are chloric acid and perchloric acid; but as the other two do not manifest any acid properties, they are to be considered as oxides, and are called protoxide of chlorine and peroxide of chlorine. Besides uniting with oxygen, chlorine combines with hydrogen, and forms the well-known acid called

Muriatic or *Hydrochloric Acid*.—If chlorine and hydrogen be mixed together in equal volumes, and exposed to common daylight in a glass flask, they will in a little time combine, and even explode in combining, if exposed to sunlight, or the light of a candle: two volumes of muriatic gas result. Its specific gravity is 1·2844; in its pure state this gas is transparent, colourless, and elastic; under very strong pressure it condenses into a liquid. Water absorbs this gas with avidity. One cubic inch at 69° absorbs 417,822 cubic inches of the gas; heat is produced, and, when cold, the bulk of the water is increased to 1·3433 cubic inches. This is liquid muriatic acid. With these proportions of constituents, its specific gravity is 1·1958; one hundred grains of it consist of 40·39 of real acid, and 59·61 of water. It is a colourless liquid; and when exposed to the air, it smokes, because the gas exhaled condenses the moisture of the atmosphere. It extinguishes both flame and life, and is not inflammable. It is of a pungent, suffocating, and somewhat aromatic smell. It powerfully reddens vegetable blues. The best method of obtaining it is by pouring sulphuric acid upon an equal weight of sea-salt, and collecting the gas which is given off over mercury. An immense number of salts are formed from the combination of muriatic acid with oxides; such as common sea-salt, which is a muriate of soda, or chloride of sodium. These are very extensively used, both in the arts and medicine. Chlorine combines with azote, and forms what is called

Chloride of Nitrogen.—This is an oily liquid, and the most powerfully-explosive compound known. In this respect it is one of the most dangerous substances of nature; it consists of four volumes of chlorine combined with one of azote. Chlorine combines with carbon, but the compounds are unimportant.

Bromine.

The term *bromine* is from a Greek word signifying 'a strong disagreeable odour.' This substance was discovered so lately as the year 1826 by Balard of

Montpellier. It resembles chlorine in many of its habitudes; at common temperatures, it is a liquid of a brownish-red colour, very disagreeable smell, sharp strong taste, powerfully corrosive of organic bodies; and when taken internally, a violent poison. Its specific gravity is 2·96; it destroys vegetable colours almost as powerfully as chlorine. Like chlorine, it sets fire to certain metals when brought into contact with it; it is not combustible, and it extinguishes combustion; it becomes solid at a little below zero; but if combined with water, so as to form a hydrate, it affords fine red crystals at 32°.

An acid is formed by the combination of bromine with oxygen, and is called bromic acid; another with hydrogen is called hydrobromic acid. Chlorine also combines with it, and forms a chloride. There are numerous other combinations of bromine, but the compounds are economically unimportant.

Bromine is usually extracted from *bittern*—that is, the uncrystallisable residue left after chloride of sodium (common salt) has been extracted from sea-water. It appears to be an essential ingredient of the saline matter of the ocean, and is found in all its waters, as well as in most of the plants and animals which inhabit them. It occurs also in many saline springs.

Iodine.

This substance was first discovered in 1812 by a saltpetre manufacturer of Paris. It is derivable from sea plants, and in some of its properties much resembles chlorine, which is also a marine production. If common sea-weed be powdered dry, and treated with sulphuric acid whilst subjected to heat, a violet-coloured vapour is expelled, which, if collected in a vessel, condenses into scaly dark-gray crystals, with somewhat of a metallic lustre. These are iodine, so called from the violet colour of its vapour; iodine being a Greek word, and signifying 'violet-coloured.' Its specific gravity is 3·0844. Its smell is disagreeable, its taste acrid and hot, and it possesses poisonous properties. It is a powerful stimulant, and has of late been much employed as a medicine. It destroys vegetable colours, but not so completely as chlorine. It melts when heated to 225°, and volatilises at 352°. It forms a beautiful blue colour when mingled with water holding starch in solution; it is itself slightly soluble in water, but more so in alcohol and ether. Iodine combines with oxygen in three proportions, forming iodic acid, iodous acid, and oxide of iodine; with chlorine, forming chloriodic acid; with bromine in two proportions, forming bromides; and also with azote and hydrogen. A compound of iodine and azote is exceedingly explosive. But a particular account of these substances does not require to be given in this place.

Fluorine.

The existence of this substance, strange to say, is conjectural; yet its separate identity is supported by the strongest analogies. It exists, or rather is supposed to exist, in fluor, or Derbyshire spar, and is thus provisionally called fluorine. If some of this mineral in powder be distilled with strong sulphuric acid, from a leaden retort into a leaden receiver, kept cold with ice, an intensely active fluid is produced. 'It has,' says Davy, 'the appearance of sulphuric acid, but it is much more volatile. When applied to the skin, it instantly disorganises it, and produces very painful wounds. When it is dropped into water, a hissing noise is produced, with much heat, and an acid fluid is formed.' This substance has been called *hydrofluoric acid*, because it is conjectured to have fluorine as a base, combined with hydrogen, to form an acid, upon the principle which we have formerly described. Other views have been adopted with respect to this substance, but the above is the one now generally admitted. The diluted solution, or the vapour of hydrofluoric acid, acts energetically on glass, and is sometimes employed for the purpose of *etching* on this material. Fluorine also forms acids with boron and silicon.

Carbon.

Carbon, or charcoal, is found in many different forms, and can be prepared by burning wood, coal, &c. in close vessels. The diamond is pure carbon, and plumbago, or black-lead, is principally composed of this substance with a little iron. It burns in oxygen with considerable brilliancy, although in common air it emits but a feeble light. If carbon be burned in a close vessel, filled with oxygen, the carbon will be entirely consumed, and the oxygen so much changed, that if a lighted taper be put into it the light will be extinguished. Carbon combines with all the supporters of combustion, and with oxygen forms carbonic acid.

Carbonic Acid, discovered by Black in 1757, and described by him under the name of *fixed air*, may be prepared in the pneumatic trough, by putting into the retort an ounce of hydrochloric acid, previously mixed with two ounces of water, along with a tablespoonful of the carbonate of lime. An effervescence takes place between the acid and the lime, carbonic acid gas being given off, which can be collected in the jars, and condensed in water. Carbonic acid is fatal to animal life, and the gas will extinguish a candle introduced into it. A candle cannot burn in a mixture of four measures of atmospheric air and one of carbonic acid; and no animal can live in air which contains sufficient carbonic acid to extinguish a candle; hence the practice of letting down a burning taper into old wells, pits, brewers' tuns, and the like, before any one ventures to descend. If the light is extinguished, the air is certainly impure; and there is generally thought to be no danger if the taper continues to burn; but instances have been known of the atmosphere being sufficiently loaded with carbonic acid to produce insensibility, and yet not so foul as to extinguish a candle. Water, under the ordinary pressure of the atmosphere, absorbs a certain amount of carbonic acid, and under pressure, may be saturated with it, in which state it sparkles when poured from one vessel to another. All kinds of spring and well-water contain carbonic acid absorbed from the atmosphere, and to its presence they are partly indebted for their pleasant flavour. Boiling deprives water of its carbonic acid, whence its insipid taste. The agreeable pungency of beer, porter, ale, and many other beverages, is in a great measure owing to its presence; by the loss of which, on exposure to the air, they become flat and stale. Thus, though deleterious when breathed into the lungs, carbonic acid is exhilarating and wholesome when taken in moderate quantities into the stomach.

Oxalic Acid is another well-known combination of carbon with oxygen, and may be formed by digesting sugar along with nitric acid. The acid is deposited in small crystals, which have an intensely acid taste, and when taken internally, even in small quantities, destroys life. It combines with bases, and forms a genus of salts called *oxalates*. Carbon is capable of uniting with chlorine in three different proportions, with bromine in one or two, and with iodine in two. But we must pass from these compounds to those of far greater moment which it forms with hydrogen.

There are many combinations of carbon with hydrogen, and much uncertainty prevails both with regard to their number and nature; they are all designated *hydrocarbons*, or more properly *hydrocarburets*;—*Carburetted hydrogen*, a spontaneous production of nature in mines, is one of the most terrific instruments of destruction, and a great obstacle to human industry; for, by mixing with a certain quantity of common air, it acquires the property of exploding when accidentally kindled, and thousands of human lives have fallen sacrifices to its violence, until Sir Humphry Davy's invention of the safety-lamp greatly divested it of its terrors. (See MINING.) Davy's safety-lamp consists of a common lamp surrounded with wire-gauze. On analysing the carburetted hydrogen, or fire-damp, Sir Humphry Davy found that it would not explode when mixed with less than six times, or with more than fourteen times, its volume of atmospheric air; that air rendered impure by the combustion of a candle will not explode fire-damp, though the candle will still burn for a time; and that, if a candle be burnt in a close vessel, with small apertures only above and below the flame, no explosion will ensue. The flame within will be enlarged, but no explosion take place; and it was found that the gas usually generated in mines will not explode in a tube less than one-eighth of an inch in diameter.

Bicarburetted hydrogen is the chief, although not the most abundant ingredient in *coal gas*, now so generally used for illumination; the other ingredients are carburetted hydrogen, hydrogen, and carbonic oxide. Coal gas is made by introducing a quantity of bituminous coal into a large iron cylinder called a retort, close at one end, and furnished with a mouth-piece at the other, for closing or opening it; there is also a tube for carrying off the gas and other products as they form. A quick strong heat is applied round the cylinder, and a vast quantity of gas, composed of the four ingredients just mentioned, is thus extricated, with tar and an ammoniacal liquor, both of which are condensed by passing through pipes immersed in cold water. There is a great difference in the relative proportions of the gases in the mixture, as also in the quantity of tar, according to the quality of the coal, and the mode of applying the heat. The more tar the gas holds dissolved, the more dense will be the flame when the gas is made to burn, and the more disagreeable will be the smell when it is not burning. A slow heat gives much tar and little gas, and that little of a poor quality; a quick heat gives much gas, of good quality, and less tar. Owing to these and other causes, the illuminating power of coal gas varies much. Before it is let through the conducting tubes for public consumption, it is well agitated in contact with a mixture of lime and water, or passed through strata of loosely-strewed hydrate of lime: it is thus deprived of much of its smell, and also of some of its illuminating power. (See LIGHTING.) There are other less important compounds of carbon and hydrogen, and the whole correspond with the law of multiple combination already described. *Naphtha* and *naphthaline* are hydrocarburets; the former a transparent volatile fluid, the latter a transparent volatile solid, which assumes the form of crystalline plates: both are obtained from coal tar by distillation.

Cyanogen.—This substance is a gaseous compound of azote and carbon—technically, a *bicarburet of nitrogen*. It burns with a purple flame, and destroys life on being breathed. Cyanogen unites with a variety of bodies, and forms many important compounds.

Boron.

The *borax* of commerce is a compound of boracic acid and soda, and is brought chiefly from India, under the name of *tinkal*. Boracic acid is a compound of oxygen and boron, in the proportion, it is supposed, of one atom of the latter to three of the former. Pure boron, the existence of which was discovered by Davy in 1807, is an opaque brownish-olive powder, infusible, and not volatile at any temperature to which it has as yet been subjected. It neither dissolves in, nor acts upon, water. At about 600°, it takes fire, and combines with oxygen, forming

Boracic Acid.—This substance evinces the usual properties of an acid, but it is not a powerful one at ordinary temperatures. At high temperatures, however, it displaces the strongest of the other acids, and is exceedingly useful in fluxing out the baser metals from the nobler. When the acid is detached from borax, by vitriol being poured upon that compound, it exhibits itself in scaly crystals. It dissolves in rectified spirits, and if the solution be set on fire, it burns with a green flame. Borax itself, when heated, melts into a perfectly clear glass, which is the basis of some artificial gems of considerable beauty. Borax communicates its own fusible nature to other bodies; hence it is used as a flux. *Flux* is a general term made use of to denote any substance or mixture employed to assist the fusion of minerals. There are a considerable number of such bodies; the alkalies are those most generally used. Boracic acid is the only known compound of boron with oxygen. There has been no compound yet discovered of boron with either bromine or iodine, but it combines with chlorine, forming a gaseous acid, to which the name of *borochloric acid* has been given; and also with fluorine, forming

Fluoboric Acid, which exists in the gaseous state. It is colourless, has an exceedingly acid taste, and a smell similar to muriatic acid. It contains no water, but possesses a powerful affinity for that fluid, and is on that account sometimes used as a test of the presence of moisture in gases. Its specific gravity is 2·362; and it seems to consist of one atom of boron and three of fluorine (BF_3). The combinations of boron with hydrogen, azote, and carbon, are still unknown.

Silicon.

Quartz, or *rock-crystal*, which constitutes so considerable a portion of the crust of the earth, consists essentially of a peculiar acid substance, called *silica*, or *silicic acid*. This substance is a compound of oxygen, with a base which has been entitled *silicon*; as established by Berzelius in 1824. It is a powder of a deep brown colour, and very similar to boron in its appearance, and in its relations to other matter. It stains the fingers, and adheres to everything that comes in contact with it. It can be exposed to a very high temperature without being fused; after ignition, the specific gravity of silicon is about 1·837. It dissolves in a mixture of fluoric and nitric acids with great facility, although it is not acted upon by them singly. When mixed with dry carbonate of potash, or soda, and heated far below redness, it burns vividly, at the expense of the carbonic acid; carbonic oxide is disengaged, and the residue is tinged black by carbon being deposited. By this process silicon is converted into silica, which is a compound of one atom of silicon and one atom of oxygen. Silicic acid forms several important compounds, called *silicates*, with the fixed alkalies, and various metallic oxides. Every kind of ordinary glass is a silicate; the varieties (bottle, plate, flint, &c.) depending on the nature of the alkali or oxide, the proportions of the constituents, and the admixture of foreign matters.

Silicon combines with chlorine, forming a *chloride of silicon*. This is a colourless volatile liquid, having a suffocating smell, and probably acid properties. With fluorine, silicon unites, and forms *Fluosilicic Acid*, which is a gaseous substance, transparent, colourless, and having a smell like muriatic acid. It smokes when mixed with moist air, and it is rapidly absorbed by water. Its specific gravity is 3·6. It combines with carbon, but no other compounds are known.

Sulphur.

Sulphur, or brimstone, is a substance whose appearance is too familiarly known to require particular description. In many parts of the world it is found in a state of great purity. It occurs plentifully in volcanic countries, and is an abundant ingredient in various minerals, as in iron and copper pyrites. It is a non-conductor of electricity, and, when rubbed, becomes highly electric. It has a specific gravity of about 2. Its point of fusion is 232°; between 232° and 280° it possesses the highest degree of fluidity, is then of an amber colour, and if cast into cylindrical moulds, forms the common *roll sulphur* of commerce. It begins to thicken about 320°, and acquires a reddish tint; and at temperatures between 428° and 482° it becomes thick and highly tenacious. From 482° to its boiling-point it again becomes liquid, but never to the same extent as when at 248°. When heated to 430°, or thereby, and suddenly cooled, by being poured into water, it becomes a ductile mass, and may be used for taking impressions of seals, &c. It begins to rise slowly in vapour before it is completely fused, but at

550°, or thereby, it volatilizes rapidly; its condensed fumes forming the fine powder known as the *flowers of sulphur*. Sulphur is extensively used in the arts; for instance, in the manufacture of gunpowder. With oxygen it combines in four proportions, forming four compounds, all of which possess acid properties.

Sulphurous Acid.—When sulphur is heated to 300° in the open air it takes fire, and burns with a pale blue flame, at the same time emitting abundance of fumes of a suffocating nature, which are sulphurous acid. It is colourless, extinguishes flame, is not inflammable, converts vegetable blues to red, forms a class of salts called *Sulphites*, and has a specific gravity of 2·2222. This gas blenches various textures, as those of silk, wool, and straw; the liquid acid bleaches sponge. Sulphurous acid is supposed to consist of equal bulks of oxygen and sulphur. Its proportions are one part of sulphur to two of oxygen.

Sulphuric Acid, or *Oil of Vitriol.*—This acid is made in great quantities for the use of bleachers, and other manufacturers, by burning sulphur in leaden chambers. At the same time a quantity of nitric acid, from the decomposition of saltpetre, is admitted into the chamber. The sulphur is converted into sulphurous acid. Five atoms of this acid unite with one atom of nitric acid, and two atoms of water, and form a white solid salt, which falls to the bottom of the chamber into a quantity of water placed to receive it. As soon as it comes in contact with the water, a strong effervescence takes place: the nitric acid is decomposed, and converts the sulphurous into sulphuric acid, while at the same time a quantity of deutoxide of azote is disengaged. This gas, coming into contact with the oxygen of the air, is converted into nitric acid, which combines with an additional dose of sulphurous acid, and is decomposed as before. Thus the process goes on as long as sulphurous acid and oxygen gas exist in the leaden chamber. Sulphuric acid thus obtained is a colourless liquid, possessing some viscidity; and when as much concentrated as possible, its specific gravity is 1·837. Sulphuric acid is one of the most powerfully-corrosive bodies known to us. The following are some of its principal properties: When mixed with water, to which it has a very powerful attraction, a decrease of volume occurs, and a considerable degree of heat is generated. It freezes when sufficiently cooled, and the crystals are sometimes large, distinct, and hard. When exposed to the air, this acid discharges whitish gray vapours, which are sulphuric acid in a dry state. Acid of specific gravity 1·690, contains about one-tenth of water, and is so volatile, that it boils at 120°. The constitution of sulphuric acid is—sulphur one part and oxygen three parts. It forms a very numerous and important class of salts called *Sulphates*. The other two compounds of sulphur and oxygen—namely, the hyposulphurous and hyposulphuric acids—it is unnecessary to notice. Sulphur unites with chlorine in two proportions. It also combines with bromine, iodine, and fluorine, but its next most important combinations are those with hydrogen.

Sulphuretted Hydrogen, or Hydrosulphuric Acid.—This is a colourless gas, having a strong fœtid smell, something like rotten eggs, and a sweetish taste. It is a non-supporter of combustion, and, when breathed, destroys animal life. Its specific gravity is 1·1805. It is combustible, and burns with a bluish red flame. Water absorbs 3·66 times its bulk of this gas; and if it be passed through water tinged with a vegetable blue, it will change the colour to red. A few drops of nitric acid let fall into a vessel filled with sulphuretted hydrogen, will set fire to it. This gas blackens silver, and darkens the woodwork of rooms painted with white lead, from human exhalations containing a portion of it. Its atomic constituents are said to be one atom of sulphur and one atom of hydrogen. Double the quantity of sulphur to the same proportion of hydrogen forms what is called the *bisulphuret of hydrogen*. No compound of sulphur and nitrogen is known, but with carbon there is more than one. With boron and silicon, sulphur forms sulphurets.

Selenium.

This is a substance nearly allied to sulphur in its nature, although it in some respects partakes also of the character of a metal. It was discovered by Berzelius in 1818, and derives its name from *selené*, 'the moon,' from its strong analogy to another element, tellurium, so called from *tellus*, 'the earth.' It melts at about 212°, and on cooling becomes solid, in which state it has a metallic lustre, and a deep brown colour. It is soft, and easily reduced to powder, which is of a deep red. Its specific gravity is 4·3. It is a bad conductor of heat, a non-conductor of electricity, and is also non-electric. Like sulphur, it sublimes into flowers. It combines with oxygen in three proportions, forming *oxide of selenium*, a gaseous body; *selenous acid*, which has an acid and acrimonious taste; and, lastly, *selenic acid*, which resembles sulphuric acid in its consistence and in many of its properties. It is to be remarked that the compounds of selenium and oxygen bear a strong analogy to some of those of oxygen with sulphur. Selenium combines also with sulphur, chlorine, and carbon.

Phosphorus.

This well-known substance is commonly prepared from bones, which consist chiefly of the phosphate of lime. This salt is decomposed by sulphuric acid, and after going through a difficult process, the phosphorus is distilled into a receiver in the shape of melted drops. It is an amber-coloured and semi-transparent solid. Its specific gravity is 1·748. It is so very combustible that it takes fire in the air, emitting a white smoke, having the smell of garlic, and appears luminous in the dark; whence its name from the Greek, *phōs*, 'light,' and *pherein*, 'to carry.' At the temperature of 148° it burns with a large resplendent flame, giving out a white smoke, which is—

Phosphoric Acid.—This substance can be obtained by other processes, in which case it exhibits itself as a transparent solid body like glass. It has no smell, but an exceedingly sour taste; it is not corrosive. Its atomic constituents are supposed to be two atoms of phosphorus to five atoms of oxygen. Phosphorus also produces another acid called *phosphorous acid*, containing a smaller proportional quantity of oxygen; and a third, called *hypophosphorous*, containing still less of the gas.

Phosphuretted Hydrogen is a colourless gas, has a smell like garlic, and a very bitter taste; its specific gravity is 1·7708. It burns spontaneously. When mixed with oxygen, *rarefaction* causes them to explode, as *condensation* produces explosion in other gases—a very remarkable property of this substance. This gas may be detonated also with protoxide and deutoxide of azote. When mixed with chlorine gas, it burns with a greenish-yellow flame. It is composed of equal volumes of hydrogen and phosphorus vapour. There are other compounds formed of these two substances: phosphorus combines also with chlorine, bromine, and iodine, in two proportions each; and unites with fluorine, carbon, sulphur, and selenium.

II.—METALLIC ELEMENTS.

Alkaline Bases.

Potassium is the base of that well-known and very useful article potash. The properties of potassium were first determined by Davy in 1807, to whom we are indebted for the discovery of the composition of the alkaline bodies. It is a white metal, like silver. At 32° it is hard and brittle, at 50° is soft and malleable, at 192½° melts, and at a low red heat evaporates. Its specific gravity at 60° is 0·865, being lighter than water. When exposed to the air, it rapidly absorbs oxygen, and forms potash. This latter body, as found in commerce, is always combined with water, which cannot be expelled by heat. When potassium is thrown on the surface of water, upon which it swims, it decomposes that fluid with such rapidity that the metal takes fire, and burns with a red flame. Potassium combines with two proportions of oxygen; it also unites with chlorine, bromine, iodine, hydrogen, sulphur, and several other bodies. The protohydrate of potassa, which is solid at common temperatures, is employed in surgery as a caustic, under the name of *potassa fusa*: it destroys all animal textures.

Sodium is a metal so similar in most respects to the foregoing, as to stand in no need of particular description. It is the base of the alkali called soda, which is formed when the metal is brought into contact with water, or when it is heated in oxygen. It decomposes water, and in its relations to other bodies, bears a strong resemblance to potassium. The uses of soda are well known, as are those of common salt, which is chloride of sodium. Sulphuret of sodium was lately discovered to be the colouring principle of the *lapis lazuli*, and since then has been used in the preparation of artificial ultramarine, the finer specimens of which are quite equal to the natural product, and much less expensive. Sodium, which was discovered after potassium in 1807, is called *Natrium* by the German chemists; hence its symbol Na.

Lithium is the metallic base of the alkali called lithia, which is of a white colour, and has a taste fully as caustic as that of potash itself. It is of course an oxide of lithium—LO. Lithium likewise unites with chlorine (LCl) and fluorine (LF), but its other combinations are unknown.

Bases of the Alkaline Earths.

Barium is the metallic basis of barytes, an alkaline earth, which is so named from its great density; *barys*, heavy. It is of a gray silvery appearance, absorbing oxygen rapidly by exposure to the air, thus forming barytes; and it also rapidly decomposes water. Barium combines with sulphur and phosphorus, and also forms compounds with chlorine, bromine, iodine, and fluorine.

Strontium.—This metal is the base of strontia, an earth very similar to the foregoing. Strontium and barium, both discovered by Davy, resemble each other very much in most of their properties, and their combinations with oxygen have also a very strong resemblance. Strontium also unites with chlorine, iodine, fluorine, phosphorus, and sulphur. It was originally extracted from strontianite, native carbonate of strontia, a mineral found at Strontian in Scotland; hence the name *strontites*, or *strontia*.

Calcium is the metallic base of the well-known and indispensable commodity lime. *Lime* (*calx*) has been known from the remotest ages, and appears always in combination with an acid, most commonly with the carbonic, constituting *limestone*, *marble*, *calcareous spar*, *chalk*, and frequently with sulphuric acid, constituting *gypsum*, *selenite*, and *sulphate of lime*. It combines also with various other acids. Calcium is white, like silver, solid, and much heavier than water. When heated in the open air, it burns brilliantly, and quicklime is produced. Calcium unites with oxygen in two proportions, forming lime and peroxide of calcium. Pure lime has an acrid taste, and is sparingly soluble in water. It, however, readily absorbs water poured upon it, and swells, producing at the same time a great heat. The fact is, that the water becomes solidified, and of course gives out a great quantity of heat, which accounts for the rise of the temperature. This process is called slaking lime. Lime combines with chlorine, and forms *chloride of lime*—a substance which has become an important article of commerce, under the name of *bleaching-powder*. It is a white powder, with a hot taste, having the power of destroying vegetable colours. Calcium combines with sulphur, phosphorus, iodine, fluorine, and bromine.

Magnesium.—This metal is the basis of magnesia, a substance universally known from its frequent employment in medicine. Magnesium is obtained in brown scales, which, when rubbed against agate, leave a metallic stain, of a leaden colour. It was indicated by Davy, but determined by Bussy in 1830. It burns with a red light, and by thus combining with oxygen, becomes *magnesia*. This is a soft, elastic, tasteless powder, not sensibly soluble in water, and slowly changing vegetable blues to green. Magnesium forms salts with chlorine, bromine, and iodine.

Bases of the Earths.

This family comprehends five substances, the oxides of which are white tasteless powders, distinguished by the name of *earths*:—

Aluminium.—Alumina, which, when pure, is a fine light powder of brilliant whiteness, is an essential constituent in every kind of clay, and constitutes the base of *alum*, from which substance it may easily be obtained. It is a compound of oxygen and aluminium, consisting of two parts of the former to three of the latter. This metal, when burnished, assumes a metallic lustre resembling that of tin. It is not easily fused; but at a red heat it burns with great splendour, and is converted into alumina. This substance, so useful in the manufacture of every species of pottery, is the only compound known of oxygen with aluminium. Alumina possesses the remarkable property of shrinking into less bulk, according to the intensity of the heat which is applied to it; hence it was employed by Wedgewood as a kind of thermometer, or rather *pyrometer*, for measuring very high degrees of temperature, in furnaces for instance. A gauge is used for measuring the amount of the contraction. Aluminium combines with chlorine, phosphorus, sulphur, and selenium.

Glucinium.—Glucina, which is the oxide of glucinium, exists to about fourteen per cent. in the beryl or emerald, from which it can be extracted. Glucinium is a dark-gray powder, which, when burnished, acquires the metallic lustre. It is very difficult of fusion. When heated in air or oxygen, it burns brilliantly, and affords the oxide glucina—the only compound which it forms with oxygen. Glucina, which consists of 100 metal and 44·44 oxygen, is a soft, tasteless, white powder, which, when wet, is somewhat plastic, like alumina. It neither dissolves in water nor melts in the fire. Its salts have a sweetish taste (whence its name), like those of alumina; and both of these earths are in this respect opposed to magnesia, which, with acids, affords salts of a bitterish taste. Glucinium combines with chlorine, phosphorus, sulphur, selenium, iodine, and bromine.

Yttrium.—Yttria, which constitutes the oxide of this metal, is obtained from a scarce mineral called *gadolinite*, found at Ytterby in Sweden. Yttrium is procured from it in iron-gray scales. If heated in common air or oxygen, it burns brilliantly, forming the earth yttria; and as far as is known, this is the only compound formed by the union of oxygen and yttrium. The latter substance combines with chlorine and the combustibles. Yttrium was discovered by Gadolin in 1794; and very recently Mosander asserts the existence of two closely-allied metals, which he calls *Erbium* and *Terbium*, also from Ytterby.

Zirconium.—The earth called zirconia is a harsh whitish powder, destitute of taste or smell. The base zirconium is composed of brilliant scales, which are probably metallic, although the substance has not as yet evinced the metallic lustre. When heated in common air, it takes fire, and is converted into zirconia, which is perfectly white. This is the only compound which it forms with oxygen. It unites with chlorine, carbon, and sulphur.

Thorium, discovered by Berzelius in 1828, is a metal of a leaden-gray colour, heavy, and under the burnisher shows metallic lustre. If it be heated in open air, it burns with much splendour, and the resulting snow-white oxide is the earth thorina. This is the only compound of thorium with oxygen, and the resulting substance is distinguished from the other earths by various properties. Thorium, when heated in vapour of sulphur, burns, and it also unites with chlorine and phosphorus.

Metals which decompose Water at a red heat.

Iron.—This well-known substance is one of the seven metals with which the ancients were acquainted; these were gold, silver, copper, iron, tin, lead, and mercury. Iron is a metal of great utility, and it is fortunately found abundantly. Almost every mineral contains it. The ore from which the iron of Great Britain is chiefly obtained is a *carbonate of iron.* Iron, after passing through a fiery ordeal, has a grayish colour, a metallic lustre, and when burnished, a good deal of brilliancy. Its hardness exceeds that of most metals; and when in the state of steel, it may be rendered harder than most bodies. Its specific gravity is 7·843 after hammering. It is attracted by the magnet, and may itself be converted into a permanent magnet. It is malleable at every temperature, very ductile, and very combustible, for we see a thin wire burn in the flame of a common candle. It burns brilliantly in oxygen, with which it combines in two proportions, forming oxides, or *rusts.* It combines also with chlorine, bromine, iodine, boron, sulphur, selenium, phosphorus, arsenic, chromium, and antimony; but the most important of its combinations with simple substances are those with carbon, which form the important compounds *cast-iron, steel,* and *plumbago.* Iron forms with the acids a numerous and valuable class of salts. (See METALLURGY.)

Manganese.—When this substance is pure, which is rarely the case, it is rather whiter than cast-iron, of a granular texture, and may be reduced to powder by pounding. Its specific gravity is 8·013. It is attracted by the magnet only at a very low temperature. It gradually absorbs oxygen from the atmosphere, and decomposes water, a property which it loses when alloyed with iron. It is much in use. Glass-makers use it for two purposes; first, for communicating a purple or violet colour, or for destroying all colour, and rendering the glass colourless. Manganese has a strong affinity for oxygen, with which it combines in seven proportions, forming acids and oxides. It unites also with chlorine, fluorine, carbon, and sulphur.

Nickel.—This metal, when pure, has a white colour, like silver; is rather softer than iron; is malleable both hot and cold; is attracted by the magnet; and, like iron, can be converted into one. Its specific gravity is 8·380 after fusion. The preparations of this metal contain poisonous qualities. Nickel combines readily with oxygen, forming two oxides. It also unites with chlorine, carbon, sulphur, phosphorus, and arsenic. Nickel is chiefly derived from a copper-coloured mineral found in Westphalia, called *kupfernickel; nickel* being an epithet of detraction, because the ore looked like copper, and yet none could be extracted from it. Nickel is a principal ingredient in the alloy called German silver.

Cobalt.—This metal has a gray colour, with a shade of red, and is not brilliant. Its texture is granular; it is rather soft and brittle; its specific gravity is 8·7. It is used for giving a blue colour to glass and porcelain; the tint is beautiful, and hence the metal bears a high price. It unites with oxygen, and forms two oxides; these are the preparations of cobalt used in the arts. It also combines with chlorine, sulphur, selenium, and phosphorus. Its name is derived from *kobold,* an evil spirit, because the German miners, at a time when they were ignorant of its value, considered it unfavourable to the presence of more valuable metals.

Zinc.—This metal is of a bluish-white colour, and is composed of plates adhering together. It is a hard metal, being acted on by the file with difficulty; and after fusion, its specific gravity is 6·896. It becomes malleable at 212°, and melts at 773°, or before it is quite red. When heated red-hot with access of air, it takes fire, burns with an exceedingly beautiful greenish or bluish-white flame, and is at the same time converted into the only oxide of zinc with which we are acquainted. It is of a snow-white colour, is tasteless, and insoluble in water. With copper, zinc forms that well-known and useful alloy called *brass.* Zinc combines with, and is set on fire by, chlorine; it enters into union with phosphorus, sulphur, selenium, iodine, and various metals.

Cadmium.—This metal, which is commonly associated with the ores of zinc, has a white colour, with a shade of bluish-gray, and resembles tin in its appearance. It is very malleable, and has a specific gravity after fusion of 8·6040. It unites with oxygen, chlorine, and some other supporters, but the compounds are unimportant.

Tin possesses a fine white colour, with a slight shade of blue, and has a good deal of brilliancy. Its specific gravity after fusion is 7·285. It is very malleable. Tin leaf, or *tinfoil,* as it is called, is about the one-thousandth part of an inch thick, and it might be made much thinner if requisite. It is ductile, but of inferior tenacity. It is very flexible, and produces a remarkable crackling noise when bended. It melts at 442°; but a very violent heat is required before it will evaporate. It slowly tarnishes with the air, and when intensely heated, oxygen being supplied, it burns with great brilliancy. Tin combines with oxygen in three proportions, forming the protoxide, which is *black,* the sesquioxide, which is *grayish,* and the peroxide, which is *yellow.* It also unites with chlorine, bromine, iodine, sulphur, selenium, phosphorus, and fluorine. It alloys with various metals. It is used in coating vessels, either in a pure state or alloyed. Pewter is composed of lead and tin; the latter rendering the former, a poisonous metal, quite innocuous.

Metals which decompose Water at any Temperature, and the Oxides of which are not reduced to the Metallic State by the sole Action of Heat.

Arsenic.—The *White Arsenic* of commerce is a combination of this metal and oxygen. When mixed with *black flux* (cream of tartar, with about half its weight of nitre, heated to redness in a covered crucible), and subjected to heat, it is reduced to the metallic state. It has a bluish-white colour, is soft, brittle, and easily reduced to fine powder. Its specific gravity is 5·672. When moderately heated, it evaporates, combining with oxygen, and forming the arsenic of commerce, so well known for its destructiveness to animal life. With oxygen, arsenic forms two acids—the *arsenious* and *arsenic. Arsenious acid* is a white, brittle, compact substance, having a weak, acrid taste, which at last leaves an impression of sweetness. It is one of the most virulent poisons known. *Arsenic acid* is quite similar in its constitution to phosphoric acid. Arsenic combines with chlorine, bromine, iodine, fluorine, hydrogen, sulphur, phosphorus, and selenium.

Antimony, which was discovered by Basil Valentine in 1490, possesses, when pure, a silver-white colour. Its texture is fibrous, and it is easily reduced to powder by being pounded in a mortar. Its specific gravity is 6·8. It melts when heated nearly to redness, and at a higher heat it is sublimated in white fumes. It combines with oxygen in three proportions, and forms three compounds, two of which possess acid properties. The other is an oxide, which constitutes the base of all the active medicinal preparations of this metal. With chlorine it combines in two proportions, forming two chlorides, which are analogous to two of the compounds formed with oxygen. It also combines with bromine, iodine, fluorine, sulphur, selenium, phosphorus, and arsenic. Antimony is extensively used in the arts, particularly in typefounding, stereotyping, and the manufacture of the white-metal utensils now so generally used as substitutes for silver.

Tellurium is a metal, having a silver-white colour, and considerable brilliancy. It has a laminated texture, is brittle, may easily be reduced to powder, and has a specific gravity of 6·1379. It fuses at a temperature rather higher than that which is necessary to melt lead. It combines with oxygen, and forms *oxide of tellurium.* This compound possesses at once acid and alkaline properties. When tellurium is heated before the blowpipe, it burns with a blue flame, emitting a white smoke, which is the oxide. Tellurium burns spontaneously in chlorine gas, and forms a *chloride of tellurium*. It also unites with iodine, hydrogen, and carbon. The other combinations of this metal are still unknown.

Chromium is a metal of a whitish colour and brittle consistency. Its specific gravity is 5·9. It requires a very high degree of heat to melt it, and is only obtained pure in small grains. No acid readily dissolves it, except the fluoric. Chromium combines with two proportions of oxygen, forming two compounds, which have received the names of *green oxide* and *chromic acid*. Chromium unites with chlorine, sulphur, phosphorus, and probably fluorine. It is used in coloured glass making, and glass and porcelain painting. It is also used in enamelling, and as a rich, strong, and durable pigment. To glass and enamel it communicates a green colour, but to the painter it affords one of his prettiest yellows. Chrome red is the bichromate of potassa.

Vanadium, which was discovered by Sefström in 1830, is a whitish metal resembling silver, brittle, a good conductor of electricity, and is easily dissolved in nitric acid and aqua regia. When heated rather under redness, it takes fire, burns with a dull flame, and is converted into a black-coloured oxide. It combines with oxygen in three proportions, forming, first, *black oxide*, or protoxide, the *binoxide*, and *vanadic acid*. It combines also with chlorine, sulphur, and phosphorus, but its other compounds are unknown.

Uranium is a metal of an iron-gray colour, of considerable lustre, and when heated to redness, takes fire. It produces a deep green protoxide, which gives a black colour to porcelain, and a fawn-coloured peroxide, which communicates to porcelain an orange colour. Its specific gravity is 9. *Molybdenum* has a silvery-white colour, is brittle, and has a specific gravity of 8·636. *Tungsten* is of a grayish-white colour, is very hard and heavy, having a specific gravity of 17·4. *Columbium*, when burnished, assumes a yellowish-white colour and a metallic lustre. *Titanium* has a copper-red colour, and considerable brilliancy. It crystallises in cubes, is hard enough to scratch rock-crystal, and has a specific gravity of 5·3. All these metals combine with oxygen, and some of the other supporters; but the oxides and acids so formed are not deserving of particular mention. *Cerium* exists in a reddish-coloured mineral found in Sweden, called *cerite*. Cerium is a dark-gray powder, having a metallic lustre; but its properties have not yet been properly determined. It, however, combines with oxygen, chlorine, carbon, sulphur, and phosphorus. *Lantanium* and *Didymium*, very recently discovered by Mosander, may also be ranked under this family, though likewise closely allied to Yttrium and Zirconium.

Lead.—This is one of the most abundant of all the metals, and one of the softest and most fusible. Lead has a bluish-white colour, and a good deal of lustre; but it soon tarnishes. Its specific gravity after fusion, which takes place at 606°, is 11·351. Lead is very malleable; it is also ductile, but its wire possesses little tenacity. By exposure to a very strong heat, it is volatilized, and at the heat of burning hydrogen, urged by oxygen, it burns with a bluish flame. While exposed to the atmosphere during fusion, it imbibes oxygen, and is converted into an oxide. There are three oxides of lead—the protoxide, which is known in commerce and the arts as a yellow paint, under the name *massicot*, or, if it be semi-vitrified, *litharge*; the deutoxide is also a paint of a brilliant red colour, inclining to orange; it obtains the name of *minium*, or *red lead*; and the peroxide, which is of a deep puce *brown* colour. When heated with sulphur, spontaneous combustion takes place. Lead also combines with chlorine, bromine, iodine, sulphur, selenium, arsenic, &c. It is rendered hard by antimony; and the alloy, mixed with a little tin, constitutes the material from which printers' types are elaborated. The salts of lead are numerous, and very important. *White lead*, or *ceruse*, the only white used in all oil paintings, is made by subjecting thin plates of lead, rolled up spirally, to the fumes of vinegar. The lead soon becomes corroded, and assumes a white appearance and a brittle consistency. If this substance be dissolved in acetic acid, or vinegar, it becomes *sugar of lead*. Lead is never found native; by far the most common state in which it occurs in nature is sulphuret of lead, or *galena*.

Copper, in point of general utility, ranks next to iron. It possesses a rose-red colour, and a great degree of brilliancy. Its specific gravity, after being rolled out into plates, is 8·953. It has great malleability, and very considerable ductility. A bar of cast copper, one quarter of an inch thick, requires 1192 lbs. to break it, whilst hammered copper requires nearly 1000 lbs. more to break it. It melts at 196°; and if the heat be increased, it evaporates in fumes, which are visible. When rubbed, it emits a smell. When heated in a hydrogen flame urged by oxygen, it burns brilliantly, emitting a dazzling green light; a piece of copper in a coal fire tinges the blaze green. When exposed to air, it oxidates into a green carbonate of copper, slowly, and when in contact with moisture. With oxygen it combines in three proportions, forming three oxides, two of which occur native; the other is not a permanent compound. Copper combines also with chlorine, iodine, sulphur, phosphorus, arsenic, and tin. Its alloys with the latter metal are very important, forming *bronze*, *bell-metal*, and other alloys.

Bismuth, discovered in 1530, has a reddish-white colour, and is composed of broad plates adhering to each other. It is one of the most fusible of the metals, melting at 476°; it communicates its fusibility to other metals; hence its use as a *flux* and *solder*. Its specific gravity is 9·833. Although not very brittle, it is not malleable, unless when heated, nor can it be drawn into wire. A mixture of tin, lead, and bismuth, is so fusible that it melts when thrown into boiling water. A toy of this kind is well known; it is a spoon, which, when immersed in a very hot liquid, immediately melts. Bismuth combines with oxygen, chlorine, bromine, iodine, sulphur, and selenium. What is called Newton's fusible metal, is a compound of eight parts by weight of bismuth, five of lead, and three of tin; it melts at 212°. The nitrate of bismuth has been used as a mordant; it also furnishes the medicinal powder called *pearl white*.

Metals whose Oxides are decomposed by a red heat.

Mercury or Quicksilver.—This metal has a silver-white colour, possesses great brilliancy, and remains fluid at the common temperature of the atmosphere. Its specific gravity at 60° is 13·56846; at 39° below zero, when it assumes the solid form, it is 15·612°. When solid, it may be beaten out with a hammer, or cut with a knife. When heated to 656°, it boils; and when heated in the open air, it oxidises. The oxides and chlorides of mercury afford an admirable proof of the truth of the atomic theory. It combines also with bromine, iodine, sulphur, selenium, and phosphorus. The compounds which mercury forms with the other metals are usually termed amalgams. This metal occurs in South America and in Spain, in great abundance; but the mine of Idria, in Carniola, an Austrian province, is perhaps the greatest in the world, and has been wrought for more than three centuries.

Silver.—This metal is of a fine white colour, with a slight shade of yellow. When polished, it displays a great deal of brilliancy and beauty. It is very malleable, and may be beaten out into leaves so thin as 1-100,000th of an inch. It is softer than copper, and harder than gold; but its tenacity is inferior to the former metal. When melted and cooled slowly, its specific gravity is 10·3946; when hammered and rolled, it is a little higher. Its melting-point is 1830°; and if it be kept melted for a long time, it absorbs oxygen; but possesses the very singular property of parting with the oxygen on solidifying. The presence of a little copper deprives it of this property. Silver forms with oxygen only one well-known oxide. It also unites with chlorine, bromine, iodine, sulphur, selenium, phosphorus, and arsenic. There are numerous alloys of silver, but few of much consequence. Silver is found in all parts of the world, sometimes associated with a variety of other metals and substances as an ore, and sometimes in the native state.

Gold, the most valuable of all the metals, always occurs in nature in the metallic state, although seldom pure. It has a beautiful yellow colour, and considerable lustre, which it retains, not being liable to be tarnished by exposure to the air. It is rather softer than silver, and after fusion, it has a specific gravity of 19·3. It is the most malleable of metals, and may be beaten out into leaves no thicker than 1-282,000th of an inch; and the gold leaf with which silver wire is covered is only 1-12th of that thickness. Its tenacity is considerable, but inferior to that of silver. It melts at 2016°. It is insoluble in sulphuric, nitric, and muriatic acid; but is readily dissolves in aqua regia, which is a compound of the two latter. It is difficult to oxidise gold, and still more to burn it; but both can be accomplished. Oxygen combines with gold in two proportions, possibly in three, forming oxides. Gold also unites with chlorine, bromine, iodine, sulphur, phosphorus, and arsenic. There are a number of alloys of gold; the standard gold coin of the realm is an alloy of eleven parts of gold to one of copper or silver, or sometimes both.

Platinum.—This metal is white, like silver; whence its name from the Spanish word *plata*, silver. Its specific gravity is 21·47, so that it is heavier than gold; its hardness is intermediate between copper and iron. It is very ductile and malleable, though much less so than gold. Its tenacity is considerable. It will not melt in the heat of our most powerful furnaces, but it may be fused by the oxihydrogen blowpipe. Its property of resisting high temperatures without fusion is a most important one; and on this account, as well as its property of resisting the action of most chemical agents, it has been employed in the formation of vessels which it is necessary to subject to an extraordinary degree of heat. Like gold, it resists the action of all the single acids, but dissolves in aqua regia. It combines with oxygen in probably four proportions, forming oxides. It unites also with chlorine, bromine, iodine, silicon, sulphur, selenium, and phosphorus. There are numerous alloys of platinum, but they are not of much importance. There is a form of this metal which possesses extraordinary properties; it is called *spongy platinum*. It is prepared by dissolving platinum in a mixture of nitric and muriatic acids by heat; muriate of ammonia is added, when a precipitate falls, which must be filtered and dried. If a small quantity of this powder be heated by a candle, it will become incandescent, as if it took fire. It is, when cold, fit for use. If a jet of hydrogen, from a tube of a very slender bore, be directed on it from a little distance, the metal immediately becomes red-hot, and it sets fire to the hydrogen. This may be repeated a great number of times; but the sponge at last loses its power; the smaller the quantity, the sooner its power is lost.

Palladium, Rhodium, Iridium, and Osmium.—These four metals occur in the platinum of commerce, and were discovered by Tennant in 1803. They are procurable in very small quantities; they have not been applied to any use of moment; they possess no very remarkable qualities, and therefore do not require to be minutely described. They all unite with oxygen and chlorine, and some of them with the other supporters. *Ruthenium*, recently discovered by Claus in the insoluble residue of the ore of platinum, may be added to this group.

Such is a brief sketch of the fifty-four simple substances (sixty-one, if we admit the metallic bases lately discovered by Mosander, Claus, and Rose), whose numerous combinations give rise to the infinite variety of objects which are found ready-formed in the laboratory of nature, or have been discovered in that of the philosopher. The minerals and metals of commerce will be further treated under the heads MINING and METALLURGY.

ORGANIC CHEMISTRY.

Vitality enables plants and animals to absorb and assimilate food, consisting of the elements necessary for their increase, and also to reproduce beings of their own kind, by means of certain organs; hence they are said to be *organized*, and the substances of which they are composed are known by the general name of *organic matter*. Earths, minerals, metals, and the like, not possessing vitality, have no organs, and consist only of *inorganic matter*. Organic chemistry—in contradistinction to Inorganic chemistry—is therefore that department of the science which treats of the composition, properties, and uses, as well as of the origin, of all substances produced in the animal and vegetable kingdoms, and of the artificial compounds arising from their decomposition. By virtue of his knowledge, the chemist can decompose, transform, reconstruct, and imitate in a wonderful manner the products of the inorganic world; but while he can in like manner decompose and transform the products of the organic, he is utterly impotent to reconstruct a single organ, or imitate its functions. The chemistry of Vitality is far beyond his art; he is only as yet beginning to acquire a faint conception of its principles and functions. He finds, however, so far as the ultimate analysis of organic substances can show, that plants and animals are composed of the same elements as inorganic matter; and that the two branches of the science are not essentially different, so far as the nature of these elements is concerned. There is this peculiarity, however, that a certain class of organic compounds possess the property of uniting with the elements, and of forming with them new combinations, which are analogous in their properties to the combinations of two simple bodies. Such compounds are called 'compound radicals;' hence the term *chemistry of compound radicals*.

VEGETABLE COMPOUNDS.

Notwithstanding the infinite diversity of form which vegetable substances assume, it has been proved that they are all mainly composed of the same elements, and these are only *four* in number—namely, oxygen, hydrogen, carbon, and nitrogen. These, again, by uniting amongst themselves, form the compounds which constitute the vegetable structure; and being the more immediate objects of sense in the investigation of any organisation, these are called their *proximate principles*. Existing ready-formed in roots, woods, barks, leaves, flowers, fruits, and seeds, we find a considerable number of proximate principles, in the form of acids, alkalies, sweet principles, bitter principles, oils, exudations; some poisonous, others wholesome; some spontaneously separating, others remaining obstinately combined. We shall give a brief outline of these, referring for further details to VEGETABLE PHYSIOLOGY, AGRICULTURE, ALIMENTARY SUBSTANCES, AND MEDICINE.

Common *Citric Acid* exists in the juice of lemons, and, when crystallised, one hundred grains consist of—water 23⅔, and pure acid 76⅓, which is a compound of 42·1 oxygen, 31·58 carbon, and 2·63 hydrogen. *Sorbic acid* is the sour principle of apples, sorbus berries, and other fruits. It consists of the same ingredients as the former. *Tartaric acid* is the sour principle of grapes; when a large quantity of them are left to ferment, the result, it is well known, is wine. On the side of the vessel containing this liquor, crystals of the acid, combined with potash, are formed, and these, when purified, are *cream of tartar*. Twelve parts in the 100 are water; and the remaining 88 consist of oxygen 52·97, carbon 32·39, and hydrogen 2·64 parts. *Oxalic acid.*—The plant called sorrel is valued for its acidulous taste, which is conferred upon it by this acid. It has no hydrogen in its composition, consisting merely of oxygen and carbon. It is an active poison, and from resembling Epsom salts in appearance, many persons have fallen victims to its virulence. The antidote is powdered chalk. *Gallic acid* is obtained from nut-galls. Its most remarkable property is that of changing the colour of solutions containing iron to an intense blue-black colour, as in the case of common writing-ink. One hundred grains consist of 56·25 carbon, 37·5 oxygen, and 6·25 hydrogen. *Prussic* or *Hydrocyanic* acid, found in various fruits and flowers, is a most powerful poison. It is formed of hydrogen and cyanogen, a noxious inflammable gas. Such acids as those just described exist ready formed in fruits, &c.; they are simple *educts*. But there are others formed by chemical changes produced on certain elements contained in vegetables, which afford the base of the acid; these are acid *products*: some are produced by the agency of heat, others by the action of nitric acid. *Acetic acid* or vinegar is one of these, being a product of any liquid capable of undergoing the vinous fermentation. Fermentation produces alcohol, and alcohol, by oxidation, is converted into acetic acid. Several acids, when distilled at a high temperature, undergo decomposition, and new acids are formed. Their names remain the same, or have the word *pyro* prefixed, as *pyrocitric acid*, *pyroligneous acid*, &c.

It has also been ascertained that *alkalies*, as well as acids, exist ready formed in plants as one of their constituent principles. Those which evince alkaline properties of a weak character are entitled *alkaloids*. The alkalies are *quinine* and *cinchona*, which resemble each other, have a bitter taste, and neutralise acids. *Morphia*, which is obtained from opium, is a white crystalline powder; *strychnia*, one of the most powerful bitters and poisons, which has of late been much used in medicine; *brucia*, also a violent poison; *digitalia*, which is procured from the leaves of foxglove; *hyoscyamia*, *atropia*, *veratria*, *emetina*, &c. which are derived from henbane, deadly nightshade, &c.

Of the other proximate principles, the first deserving of notice is the woody fibre which constitutes the solid basis of all vegetable structures. It is called *lignin*, from *lignum*, wood; and consists of 52 carbon, and 48 of oxygen and hydrogen, in the ratio which forms water. With lignin are associated various other bodies, such as *resins*, which are various and abundant. In the different species of the pine-tree, we discover that peculiar liquid resin called *turpentine*. From resins are obtained what are called *essential oils*; because, after the resin has been heated in a distilling apparatus, an odoriferous oil distils over, and leaves the resin hard, dark, and odourless. The *essence* of the substance is supposed to have passed away in the aeriform state; hence the name. From its speedily evaporating on being exposed to the air, it is also called *volatile oil*. The seeds of plants yield another oil, which, not evaporating, is called *fixed oil*. To these two oils there are two substances bearing some analogy—*wax* and *camphor*. The former, when melted, possesses some of the properties of a fixed oil; and the latter seems to possess the properties of a concrete volatile oil, although it possesses qualities distinct from those of all other bodies. *Gum*, for instance gum-arabic, has the following properties: namely, transparency, tastelessness, perfect solubility in water, viscidity of the solution, capability of cementing fragments, and of affording a varnish, and total insolubility in spirit of wine. There is a class of bodies called *gum resins* whose properties are intermediate between those of gum and resin; and somewhat allied to resins, although essentially different in most of their properties, are the substances *caoutchouc* and *gutta percha*. They are the exuded juices of peculiar trees, and are composed of carbon and hydrogen.

From wheaten flour a substance is obtained called *gluten*, from its glutinous nature. There are two principles in this substance—the one is called *gliadin*, and the other *zimomin*. A substance called *vegetable albumen* seems to be the basis of all emulsive grains in place of starch, and greatly resembles it. *Starch* is a fine white sediment, precipitated from the white and brittle parts of vegetables, particularly the tuberose roots, and the seeds of the gramineous plants. One of the most remarkable properties of starch, or, as it is called, *fecula*, is that of being convertible into sugar by the action of diluted sulphuric acid. Every one, we suppose, should know what *sugar* is; being in particular a sweetener of the kindly beverages tea and coffee. It is derived from many sources—from the sugar-cane, maple-tree, beetroot, and grapes. Nothing is easier than its formation from grapes: grape juice is to be saturated with chalk, clarified with white of eggs, or blood, and evaporated; after a few days, it assumes the form of a crystalline mass. *Tannin*.—From oak bark, or nut-galls, a peculiar substance is obtained, called tannin—so named from being the material employed in tanning leather. It is inodorous, colourless, and possesses a rough astringent bitter taste.

ANIMAL COMPOUNDS.

The chief substances which enter into the composition of animal matter are oxygen, hydrogen, azote, carbon, phosphorus, and lime. We also find certain acids and metals, but in quantity so minute, as not to affect the truth of the general statement.

Bone consists of phosphate and carbonate of lime, and two other ingredients—*cartilage* and *gelatine*. The latter is the coagulating, or rather elastic, principle in all *animal jellies*. When bones are burned in a close vessel, they form *ivory black*. *Fibrin* is obtained from the vessels; when recently obtained, it is elastic; but when perfectly dry, it is somewhat horny and transparent. There is an important substance called *osmazome*, which communicates to soups and broths their peculiar taste and smell, and the greater the quantity present, the better is the soup. The *tendons*, *ligaments*, and *membranes*, are nearly allied to gelatine in their nature. *Fatty* substances, as lard and oils, are formed chiefly of carbon, with a little hydrogen and oxygen, one or both. *Albumen* is a substance very abundant in animal matter. It occurs nearly pure in the white of eggs. Of this substance in the coagulated state, along with gelatine, are *horns*, *nails*, and *hoofs* composed. The *brain*, the thinking organ of man, consists of water 80, white fat 4·53, red fat 0·7, osmazome 1·12, albumen 7, phosphorus 1·5, sulphur and various salts 5·15 parts in the hundred.

Of the fluids of the animal body, *blood*, one of the most important, is viscid, of a red colour, exhaling a vapour of a peculiar odour. When left at rest a few hours, its appearance is very much altered, having separated into two parts—one quite liquid, of a greenish whey-like colour, and called *serum*; the other an elastic firm jelly, of a crimson red colour and thick consistence, resembling a deposit, which is called the *crassamentum*, or *clot*. If this clot be repeatedly washed with cold water, it parts with its red colour to the water, becomes white, and a fibrous matter remains, which, when subjected to analysis, proves to be *fibrin*. Serum coagulates when heated to about 160°, nearly in the same manner as the white of an egg, but the colour is not pure white. If the serum thus coagulated be cut in slices, a fluid will exude which is called the *serosity* of blood; it consists chiefly of water, holding a little altered albumen and a little common salt in solution. Serum is composed of water, albumen, soda, and some salts of soda. Clot is composed of fibrin, albumen, red colouring matter, a little iron, and carbonic acid. During the conversion of arterial into venous blood (as explained under ANIMAL PHYSIOLOGY), nitrogen, hydrogen, and other elements, are spent in the formation of new products, while the proximate principles of the blood remain, with an increased proportion of carbon. In this state it is exposed to the atmospheric air in the lungs, the oxygen of which abstracts its excess of carbon, and forms the carbonic acid expired; and this process constitutes the conversion of venous into arterial blood.

CHEMISTRY APPLIED TO THE ARTS.

CHEMISTRY, or that department of physical science which recognises the nature and composition of bodies, and the new forms and properties they may be made to assume, is now indispensable to the proper conducting of almost every useful art. Agriculture, which may be considered the most important of all the arts, is radically dependent on chemistry; for without a knowledge of that science, the husbandman remains ignorant of the constitution of his soils and crops, the action of the atmosphere and sun's light, and the properties of those materials which are required to enrich his exhausted fields. Baking, brewing, distilling, and indeed all the operations by which food is prepared from the condition in which it is furnished by nature, are in general a series of chemical processes. So, likewise, is the manufacture of pottery-ware, porcelain, glass, paper; the operations of bleaching, dyeing, and calico-printing; the preparation of soap, gunpowder, ink, salt, drugs, paints, perfumery, and various other articles in daily demand. The applications of chemistry to the arts are in reality so numerous, that, to do the subject justice, we should require to take in nearly the whole circle of manufacturing industry. To do so, however, is beyond our limited means, even were it desirable; and our object in the present sheet is to give a short account of the manner in which chemistry is practically applied in those industrial operations to which we have not elsewhere alluded. The design in view is not to teach any one art, but to incite to a *general study of chemistry* among those classes who are engaged in such branches of manufacture as involve an elementary change in substance. Manufactures of this kind may be termed *chemical*, in contradistinction to those whose elaboration mainly depends upon principles that are *mechanical*. Thus the conversion of sand, potash, and lime into glass; of common salt into soda; hides into leather; or charcoal, sulphur, and saltpetre, into gunpowder, are chiefly chemical processes: while the conversion of flax into cloth, iron-ore into sheet-iron, or clay into pottery, are principally mechanical, though in both there is a necessary blending of chemical with mechanical appliances. 'Technology' being a systematic exposition of the principles upon which all processes employed in the arts are based, CHEMICAL TECHNOLOGY may be regarded as the scientific title of the present subject, which should properly commence with a description of the principal apparatus required in practice.

THE LABORATORY.

A *laboratory* is a chemist's workshop. It is the place in which he performs his experiments, and requires to be airy and spacious, to have a command of water, to be provided with suitable tables and shelves, mortars, filters, furnaces, jars, retorts, and other apparatus. Above all, it should be furnished with the means of rapid ventilation, so as to carry off any noxious fumes that may arise; should be kept in methodical order—every substance being properly labelled, as little waste as possible allowed, and the greatest caution exercised, with a view to prevent mistakes and injuries. For beginners and amateurs, who may not possess an independent laboratory, any unfurnished apartment may be used; and sets of portable apparatus, accompanied with specimens of the elementary substances, may be procured from the dealers in most of our large towns. With such portable apparatus many highly interesting experiments may be performed, and a very considerable amount of practical knowledge obtained. Nor need great expense be incurred, if the student is possessed of an ordinary degree of mechanical skill, as, with a little ingenuity, he may make the same apparatus answer a variety of purposes.

Balances of an exact and very delicate nature are essentially requisite, as correct weighing is indispensable to every chemical experiment. There should be at least two balances; one for weighing heavy matters, and another for very minute quantities. The last instrument should be sufficiently delicate to weigh from 600 to 1000 grains, and downwards, indicating, distinctly and certainly, differences of an exceedingly minute amount, even to the thousandth part of a grain. As it is by carefully weighing substances, both before and after being experimented upon, that the exact constituent parts of bodies are determined, and the most important chemical truths ascertained, the balance and weights should be carefully examined at intervals, and their accuracy tested. Such balances ought to be preserved in glass cases, be fitted with apparatus for regulating their centres of suspension and gravity, and for rendering them immovable at pleasure, and have indices attached, whereby the minutest fraction of a grain may be ascertained. In weighing, variations of temperature, absorption of moisture from the atmosphere, and other similar conditions, must be carefully attended to, otherwise the results will be vitiated, and without value.

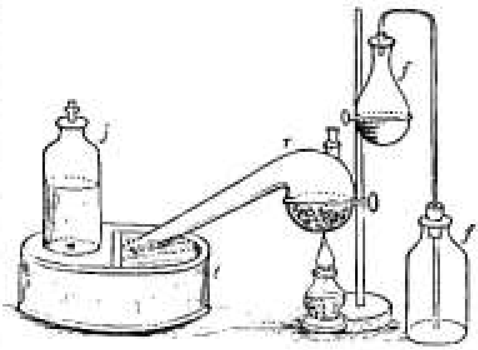
Measures are necessary for ascertaining the bulk of liquids or gases, and two integers are sufficient—the pint and the cubic inch. Measures should be made of glass, and have a graduated scale marked on both sides. They are commonly of a cylindrical shape, like a phial bottle, and possess a small spout at the orifice. The graduations on these instruments are sometimes very minute, and indicate exceedingly small quantities of the fluids and gases. The measures should be verified by weighing into them successively portions of mercury and water. A cubic inch of the former, at a temperature of 62°, weighs 3425·35 grains, and the same quantity of the latter, at the same temperature, weighs 252·458 grains. Water answers well enough for estimation down to the cubic inch, but for the tenths and the hundredths of an inch, mercury is both more exact and more expeditious.

Furnaces of one kind or other are indispensable, as heat is one of the most powerful and extensively useful agents employed by the chemist for ascertaining the properties of bodies. Dr Black's portable furnace, which is much used, consists of a stout iron case, like a round stove in shape. Above is an aperture for an iron pot, to contain sand; and other openings may also be observed, for introducing tubes and different kinds of apparatus. The pipe carrying away the smoke must be prolonged or connected with a chimney. Furnaces upon a large scale are constructed in various ways of fire-brick, as will be more fully described under METALLURGY. This degree of heat can be produced either by propelling air upon the combustible matter by means of bellows, in which case the furnace is called a *blast-furnace*, or by forming long flues, and raising a high chimney. The higher the chimney is raised, the more powerful is the draught. Upon the top of a furnace of this open kind, and also upon the flues, close by the fire, vessels containing sand, and hence called *sand-baths*, are placed. In these, bodies can be raised to a high degree of temperature. Where any degree of heat below 212° is required, *water-baths* are the media employed. Charcoal is the substance most commonly used in furnaces. It produces an intense heat, without smoke, but very soon consumes. Coke, or charred coal, produces a strong and lasting heat. One of the most convenient forms in which heat can be applied to any chemical operation, is that of placing a spirit-lamp under a glass retort, fixed to a simple kind of stand, as shown in next column. The lamp is trimmed with cotton wick, and fed by alcohol, which gives a pure flame, and generates a high degree of heat. Where a higher temperature is required, the *Argand*, or chemical burner, is applied. In general, common gas is now employed as the heating power.

The *blowpipe* is one of the most useful articles in the laboratory of the chemist or mineralogist. The principle on which it operates is that of a blast-furnace, on so minute a scale as to be capable of being held in the hand. The pipe, which is made of tin or brass, of a shape resembling that represented in the adjoining fig., is usually eight or ten inches in length; *m* being the mouth or upper end, through which the breath is impelled, and *o* the small orifice, at the point of the side tube, from which the blast comes. By placing the upper end of the instrument in the mouth, and urging a stream of air upon the flame of a lamp or candle, an intense degree of heat is produced, which may be brought to bear upon any substance. The orifice should be fitted with a platinum nozle or jet, as that metal resists any degree of heat which can be produced by the blowpipe, and can be readily cleared by burning when the opening happens to be stopped up by dirt or grease. In using the blowpipe, the air must not be forced directly from the lungs, as such would soon exhaust the operator, besides the injurious effect that it might have upon his health; but the mouth must be filled with air, and this suffered to pass very gradually through the instrument, aided by the compression of the muscles of the cheeks and lips, the operator breathing at the same time through his nostrils. This, which is confessedly rather troublesome at first, is rendered perfectly easy after a few trials; so that, with a little practice, a blast of several minutes' duration may be kept up without the least trouble or fatigue. Substances, when exposed to the flame, are supported on a piece of well-burnt charcoal, or at the end of a thin platinum wire bent into a loop. Otherwise, they are held by a pair of tongs or forceps with platinum points; and occasionally in a narrow glass tube, three or four inches long, and open at both ends; or in one of the same length, but of larger diameter, and closed at one end, so as to form a little flask or test tube. The rationale of the intense heat produced by the blowpipe, is that the gaseous matter of the flame undergoes complete and rapid combustion, and is moreover concentrated to a point or focus by the stream of oxygen made to play upon it. If the two gases oxygen and hydrogen be mixed together in the proportions which form water, and compressed to the amount of many atmospheres in a metallic box provided with a small tube, what is called an *oxy-hydrogen blowpipe* is formed. By this apparatus, which is quite safe when properly constructed, an almost incredible degree of heat can be produced. The self-acting *alcohol blowpipe*, in which the vapour of that spirit is made to act as the blasting force, is another variety of the instrument; more ingenious, however, than practically useful.

Crucibles are open vessels which resist very high temperatures. They are made of various shapes, triangular or circular, and of different kinds of materials, but by far the greater number are formed of earthenware—that is, of clay free from lime, mixed with sand or groundware of the same description. To promote chemical action, what are called *fluxes* (which will be afterwards described) are employed. Now it is important that the crucible be made of a substance which is not rendered more fusible by a flux. Wedgewood's crucibles are made of a close white ware; and although thin, they are not easily dissolved: they retain fluxes at moderate temperatures longer than other crucibles. Those made of a mixture of coarse plumbago and clay are also excellent in these respects. But the most valuable in the laboratory are the Hessian and Cornish crucibles. Charcoal and metallic ones are likewise used; those formed of platinum being the most generally useful, although at first somewhat expensive.

Retorts are vessels employed for many distillations, and most frequently for those which require a degree of heat higher than that of boiling water. This vessel (*r*) is a species of bottle with a long neck, so bent, that it makes with the globular belly of the retort an angle of about sixty degrees. The most capacious part of the retort is called its belly, its upper part the arch or roof (which may or may not be fitted with a ground stopper, according to the purpose for which it is employed), and the bent part the neck. Retorts are composed of different kinds of materials, those of glass being by far the most common. They answer for all operations conducted at temperatures less than that at which glass softens; and from their transparency, they admit of constant observation of the materials within: they are, besides, acted upon or injured by few substances, and



may be easily cleaned. To the bent neck of the retort various tubes can be fitted, and the evaporated substance conducted into a refrigerator. Common flasks (*f,f*) and bent tubes answer many purposes equally well, and are often more convenient. For distillations or sublimations requiring high degrees of temperature, metallic and earthenware retorts are had recourse to.

A *pneumatic trough* (*t*) is a vessel constructed so as to retain water, and large enough to admit of jars being filled in it. Shelves and supports are fixed in it beneath the surface of the water; on these, vessels may be firmly placed. If, now, a large open-mouthed glass jar (*j*) be filled with water, inverted beneath the surface of the water in the trough, and put upon one of these stands, a tube from a retort or other distilling vessel, introduced into the inverted mouth of the jar, will convey the gaseous matter, which, displacing the water occupying the jar, can thus easily be collected in it. In this manner gases are obtained. If the jar be provided with a stopcock, they can easily be withdrawn into vessels fitted to retain them. Instead of water, mercury, which is fluid at ordinary temperatures, is used in experiments where water would absorb the gases, or where exceeding nicety is required.

Tests.—Alkalies and acids in a free state possess the power, even in very small quantities, of effecting certain general and regular changes in the tints of some vegetable colours. Accordingly, colours of this description are used for ascertaining the presence of these bodies when in excess or uncombined, and are called *tests*, from their testing or distinguishing the chemical composition of bodies; or *re-agents*, from their reacting upon the elements of bodies. Litmus and turmeric are most generally used; the former a blue colouring matter prepared from the *Lichen rochella*, the latter a yellow colouring matter obtained from the *Curcuma longa*. They are prepared by dipping unsized and bibulous paper in concentrated infusions of these substances. The litmus imparts a fine blue tinge to the paper, the turmeric a yellow one. In using these test-papers with a fluid suspected to contain free acid or alkali, or knowing that one of these substances is predominant, in order to ascertain which is so, all that is necessary is, to moisten the papers with the liquid, and observe the change which is effected; if the fluid be acid, the blue colour of the litmus will immediately become red; if alkaline, the yellow colour of the turmeric will be changed to brown. *Test-tubes*, for holding minute quantities either of solids or liquids, are small tubes closed at one end, varying from four to eight inches in length, and of different widths. They are made of thin, well-annealed glass.

A *flux* is a substance made use of to assist the fusion and union of minerals or metals. It acts by protecting the substance from the air, by dissolving impurities which would otherwise be infusible, and by conveying active agents, such as charcoal and reducing matter, into contact with the substance operated upon. Upon a large scale, limestone and fusible spar are used as fluxes. What is called *crude flux*, is a mixture of nitre and cream of tartar, put into the vessel along with the substance to be fused. *White flux* consists of the same ingredients, in equal quantities, but they are first deflagrated in an earthen crucible heated red-hot at the bottom. *Black flux* has the same constituents as the preceding, but the weight of the tartar is double that of the nitre. Borax also forms an efficient and readily available flux.

Lutes are soft adhesive mixtures, principally earthy, used either for closing apertures existing at the junction of different pieces of apparatus, or for coating the exterior of vessels which have to be subjected to very high temperatures. The lutes employed for junctions pass into the nature of cements, which are substances used for uniting or joining together things of the same or different kinds, so as to form a whole. The best lute used for coating a vessel is made of Stourbridge clay. It is formed into a paste, which should be beaten until it becomes perfectly ductile and uniform, flattened into a cake, and then applied to the vessel which it is wished to coat. What is called *fat lute* is prepared by beating dried and finely-pulverised clay (pipeclay or Cornish clay) with drying linseed oil, until the mixture be soft and ductile. A paste of linseed meal forms an exceedingly strong lute; but becomes so hard, that it is difficult to remove it. Caustic lime, when mixed with various mineral and vegetable substances in solution, affords numerous cements and lutes, which become hard when dry, and are impervious to vapours. One of the best is that obtained by using white of egg diluted with its bulk of water. The fluids are to be beaten together until the mixture pours with perfect liquidity. There is then added a quantity of dry slaked lime in powder, until the mixture assumes the consistency of thin paste. A solution of glue, or the serum of blood, is sometimes substituted for the white of egg. White lead ground with oil also makes a very useful lute or cement. Soft cement consists of yellow wax (which alone is sometimes used as a cement) melted with its weight of turpentine, and a little Venetian red to give it a colour. When cold, it is hard like soap; but when pressed by the hand, the heat renders it pliant.

A great variety of other apparatus and materials besides those enumerated, are either necessary or useful in a laboratory. Electrifying machines, galvanic batteries, air-pumps, syringes, tubes bent into various forms, and of different sizes, for fitting into the necks of retorts, &c. mortars, dishes for holding both solids and fluids, as well as other materials which it is unnecessary to name, are frequently required; but, as already mentioned, a very convenient small laboratory, in which a vast number of interesting experiments can be performed, may be furnished at very little expense.

GENERAL PROCESSES.

Trituration.—As a general principle, the more minutely matter is divided, the more rapid will be the chemical action exerted between the particles. This division of matter is effected in various ways. First, by trituration, or the reduction of substances to a state of powder, which is a mechanical action not affecting the physical state of the body, and only relating to solids. In accomplishing this, the pestle and mortar are generally used. Externally, mortars are usually shaped like a flower-pot, the inside, at the bottom, being curved like the thick end of an egg. They are made of various materials, such as metal, porphyry, Wedgewood-ware, agate, and so on, according to the purposes to which they are applied. The pestle is generally of the same material as the mortar, and is a solid rod, having a rounded bulb at one end for pounding the substance in the mortar. Trituration answers very well the purpose of promoting chemical action in a number of experiments, but by fusion and solution it is rendered more complete. *Levigation* differs from ordinary trituration, inasmuch as a fluid is added to assist the operation.

Fusion.—Bodies are said to be in a state of fusion when, heat being applied to them, they assume the liquid form, a state in which all the particles of a substance move easily amongst themselves. Metals, as is well known, may be reduced to a liquid condition by melting or fusing them in a crucible over a sharp heat, or in a furnace. For the degree of heat at which most metals fuse, we refer to the previous sheet. Substances which admit of being fused are termed *fusible*, while those which resist the action of fire are termed *refractory*. Fusion differs from liquefaction, in being applied chiefly to metals and other substances which melt at a high temperature. *Igneous fusion* is the melting of anhydrous salts (salts without water of crystallisation) by heat, without their undergoing decomposition; *aqueous fusion* is the dissolving by heat of salts which contain water of crystallisation.

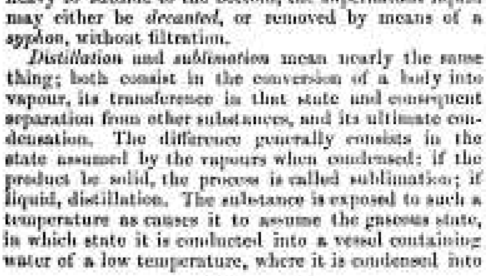
Vitrifaction is a peculiar kind of fusion, by which certain materials, when exposed to an intense heat, melt, and form that transparent substance called glass or crystal. The materials employed to form common glass are silica or sea sand, an alkali, such as carbonate of potass, and a metallic oxide. (See *Glass-making*, in article FICTILE MANUFACTURES.) It is less generally understood that a kind of glass, soluble in water, may be made from silica and carbonate of potassa. 'Mix intimately 200 grains of fine sand, and 600 of fine carbonate of potassa; fuse the mixture in a crucible capable of containing four times as much. Carbonic acid escapes, the silica and potassa combine, and produce glass. Pour out the glass, which is commonly termed *silicated potassa*, on an iron plate, and dissolve it in water, the large quantity of alkali rendering it soluble in this fluid. The compound formed in this manner constitutes pure *silica soap*, having all the detergent properties of common soap; it is, however, more active, and leaves a harsh feeling upon the hand. In commerce, silica soap is generally mixed with a considerable portion of common soap, and occasionally adulterated with sand.'

Solution.—When a solid body, such as a piece of sugar, is put into water, it is gradually dissolved; and when the lump of saccharine matter has disappeared, and become mixed with the water, and remains so, it is said to be held in solution by it. Liquids are called *solvents*, from their acting on, or holding in solution, either solid or aëriform fluids; and a fluid which holds in solution as much of any substance as it can dissolve, is said to be *saturated*. Supersaturated and subsaturated are relative terms, respectively signifying more and less than complete saturation. Heat greatly promotes the rapidity of solution; and for this purpose glass vessels having a rounded bottom, such as a Florence flask, and placed upon a spirit-lamp, are very commonly employed. In processes connected with the subdivision of matter, when hot water is merely poured upon the substance, the process is called *infusion*; and when the substance is boiled, the result is called a *decoction*. There is a process of solution called *lixiviation*, which consists in the separation of a soluble body from an insoluble one by means of washing; or it may be the soluble from the insoluble portion of the same body. *Maceration* is the steeping of any substance, with a view either simply to soften it, or to promote the separation of its parts.

Desiccation, or the drying of substances, may be carried on without exhaustion by means of what are called *desiccators* or dryers. This is better effected in close vessels than in the open air, unless a current be taken advantage of. In these processes, sulphuric acid, chloride of calcium, carbonate of potash, quicklime, and similar absorbents, may be used. A moist precipitate placed above a basin of common quicklime, the whole being covered with a jar or receiver, will speedily undergo complete desiccation.

Filtration consists in putting mixed substances into vessels which are porous enough to admit of the passage of one substance through them, but close enough to retain another. Unsized paper, cloth, flannel, tow, sponge, sand, pulverised glass, flints, porous stones, earthenware, and many other substances, are used on different occasions; but the first is almost exclusively used in a laboratory, a few of the others now and then being resorted to only on particular occasions. Of course it is only mechanically-suspended particles that can be separated by filtration; and the finer these particles, the closer must be the texture of the filtering medium. When the solid particles are sufficiently heavy to subside to the bottom, the supernatant liquid may either be *decanted*, or removed by means of a *syphon*, without filtration.

Distillation and *sublimation* mean nearly the same thing; both consist in the conversion of a body into vapour, its transference in that state and consequent separation from other substances, and its ultimate condensation. The difference generally consists in the state assumed by the vapours when condensed: if the product be solid, the process is called sublimation; if liquid, distillation. The substance is exposed to such a temperature as causes it to assume the gaseous state, in which state it is conducted into a vessel containing water of a low temperature, where it is condensed into



a fluid or solid state. A common still consists of a metal boiler for containing the substance to be distilled; a head terminating in a beak is adapted to it; the latter is made to fit into the commencement of a spiral tube, called a *worm*, fixed in a tub—the whole of this part of the apparatus being called the *refrigerator* (*r*). The substance is raised into vapour in the still, and being condensed in the worm, runs out at its lower extremity. Distillations are usually effected in the laboratory by means of glass retorts and flasks; for substances, however, which require a greater degree of temperature to effect their distillation, metallic or earthenware retorts are employed. Bodies which are very volatile are distilled or sublimed in an *alembic* (*a*), which consists of a globular bottom and conical-shaped head, whence a nose or beak passes off in a downward direction into a receiver. The recondensed products of sublimation are generally known by the name of *sublimates*. *Rectification* is the process of purifying by repeated distillation.

Evaporation is a process so simple, as scarcely to require description; it is merely the assumption of the gaseous form by bodies either at ordinary temperatures, or when heat is applied to them. In this general characteristic it resembles distillation and sublimation, but it differs from these processes in this respect—that the substance evaporated is generally allowed to pass off uncollected by a refrigerator, not being that part of the mixture which is required. The vessels used in evaporation are made of porcelain, glass, platinum, or silver, and have usually the shape of a shallow basin. A great improvement in evaporation has recently been introduced into the refining of sugar—namely, its being boiled in vacuum pans. It is well known that there are few articles of vegetable production which are not injured by being boiled at a temperature of 212°; but to boil them at a lower temperature, it is necessary to remove the pressure of the atmosphere. This is now accomplished by using close copper vessels of a flattened spherical form. On the top is a raised part, from which a pipe proceeds, attached to an air-pump. At the side of this pipe another enters the vacuum pan, from which fresh syrup can be made to enter at pleasure by means of a stopcock. At the bottom of the pan is another stopcock, through which the boiled syrup can be taken out when sufficiently concentrated. The pan is heated by means of steam pipes, which surround it; and the liquid boils at, or even below, 150°. The air-pump for removing the atmospheric pressure, in large sugar-refining establishments, is worked by a steam-engine. By this process the quality of any substance, particularly perfumes and medicinal extracts, from which liquid is to be evaporated, is greatly improved, and a saving of material effected.

Fermentation is the term which expresses the changes which animal and vegetable matter undergoes spontaneously when the principle of life is extinct; and is one of the means which nature adopts to destroy useless substances, and reduce them to their elementary properties. Chemists reckon five distinct species of fermentation—namely, the saccharine fermentation, in which gum and starch are changed into sugar; the vinous fermentation, in which sugar is converted into alcohol; the acetous fermentation, in which alcohol and other substances are converted into vinegar; the mucilaginous fermentation, in which slime is produced instead of alcohol from sugar; and the putrid fermentation, which is the decomposition of animal and vegetable bodies. The change of the substance of barley into sugar, or a material possessing the qualities of sugar, takes place on a large scale in *malting*. Malt is dried barley, which has previously been caused to sprout and partially grow by steeping in water; in the course of germination or malting, a chemical union is effected between a portion of the water and the starch of the barley, and the saccharine matter is the result. A saccharine material can, on similar principles, be produced by boiling one part of starch in twelve parts of water, and allowing the compound to stand for a month or so. At the end of this time, about one-half the quantity of starch is converted into sugar, a fifth into gum, and the remainder is found to be a starch paste somewhat altered.

Fermentation, whether of an infusion of malted grain or any other vegetable substance, is a necessary preliminary to change the material into an alcoholic beverage. The actual process of fermentation, for example, in reference to wine, is as follows:—Ripe grape juice is put into a vessel, and allowed to stand for some time, exposed to the ordinary temperature of summer. At the end of a certain period the liquor becomes muddy; an internal motion takes place, and sometimes the temperature is found to be elevated; air-bubbles rise to the surface, occasioning a bubbling noise when they break; and the bulk of the liquid being increased, it has a tendency to boil over. From this circumstance, the process is called fermentation, from the Latin word *fervere*, to boil. The bubbles created rise to the surface, involved in a viscid matter, the whole resembling froth, which, parting with the air, subsides to the bottom, and the liquor becomes tranquil and transparent. This viscid matter is well known under the name of *yeast* or *barm*, and it has the property of exciting fermentation in bodies not otherwise at the moment predisposed to it. The grape juice has now been entirely changed into an intoxicating liquor, the base of which is alcohol, and this process is termed *vinous fermentation*. A great quantity of carbonic acid is given out during this kind of fermentation, and the various chemical changes which take place have been thus briefly described:—Some of the carbon and some of the oxygen combine to form carbonic acid; while the remainder of the carbon, the remainder of the oxygen, and the whole of the hydrogen, combine to form alcohol; and we may totally neglect the decomposition of the yeast, it amounting to almost nothing. Thus is this inert, solid, fixed, sweet matter, resolved by a new arrangement of its principles into substances which possess none of these properties, and one of which exerts a control of so singular a nature over the animal economy.

Liquor vinously fermented is subject to a new series of phenomena. On being put aside for some time, a fresh commotion is observable, accompanied with the disengagement of a small quantity of gas; and floating filaments or shreds begin to thicken in the liquid, collecting into a gelatinous cake. This is indicative of another change. The vinous flavour and the alcholic or intoxicating quality have disappeared, whilst the liquid has become at once sour and transparent. In short, the wine has become vinegar, called in Latin *acetum*; and the process is called the *acetous fermentation*. Let this vinegar be kept for a length of time, and another, and, from the previous quality of the liquor, unexpected change takes place. It becomes mantled with a green mould; the acidity and pungent smell disappear, and a fetid odour becomes perceptible; in other words, *putrefaction* is produced, a process under which the material is resolved into invisible but odorous gases.

The most remarkable feature in the product of fermentation is the intoxicating quality. This quality arises from the chemical change into *alcohol*, a concentrated spirit or essence, which, in one of its purest forms, obtained from distillation, is called spirit of wine. Alcohol exists to a lesser or greater extent in all fermented liquors, such as ale, porter, or beer; but it is more concentrated, or free of watery fluids, in the form of brandy, whisky, gin, rum, and similar intoxicating liquids. The alcoholic part of such liquids stimulates, but gives no actual nutrition; the only nutritive part is the undecomposed starch and gum not changed into saccharine material. Alcohol dissolves the greater number of acids, the volatile oils, the resins, tar and extractive matter, and many of the soaps; while dissolving pure soda and potassa, it does not act on their carbonates. The composition of alcohol has been investigated by eminent chemists, and the result is, that of 100 parts there are 13·70 of hydrogen, 51·98 of carbon, and of oxygen 34·32. When alcohol is distilled along with certain acids, a peculiar compound is formed, called *ether*, an exceedingly volatile fluid, used in medicine and philosophical experiments.

While the various phenomena of fermentation, as above briefly noticed, are well understood by practical chemists, of the actual cause of the ferment little has yet been discovered. It is only known in a general sense that fermentation is the rapid growth of microscopic vegetation (see VEGETABLE PHYSIOLOGY), which continues to be developed so long as the elements necessary to its increase are present, and a certain temperature is maintained. For practical operations depending on the principles of fermentation, see ALIMENTARY SUBSTANCES.

Antiseptics.—Animal and vegetable bodies may be saved from putrefaction, or the last process of dissolution, by putting them in a substance which will coagulate the albumen, that being the first part which suffers decomposition. This may be effected by steeping the bodies in alcohol, oil of turpentine, or other volatile oils. Pyroligneous acid, from containing a small proportion of creosote, has a strong power of preserving animal matter from decay. The earthy salts are also antiseptics; but common salt, saltpetre, and sal ammoniac, are the articles most generally used for the purpose of preservation. For the purpose of extinguishing the odour, or offensive gases, arising from the decay of animal substances, none of the chemical products is so useful, or so readily available, as chloride of lime. By sprinkling a small quantity in an apartment containing an unwholesome putrefactive odour, the air is instantly deprived of its noxious properties, and is sweetened. Putrefaction goes on most rapidly at a temperature of from 70° to 80°, but is altogether stopped at the freezing-point. Thus fish and flesh may be kept fresh for any length of time when imbedded in ice. The abstraction of the oxygen gas will also preserve meat. The simplest manner in which this can be done is to enclose the meat in tin cases, leaving only a small hole in the closely-soldered lid. The air may then be expelled by dipping the cases for a minute into steam. On lifting them out, a drop of solder quickly placed on the hole prevents the rush of air back into the vessel. On this principle of excluding the air, cases of preserved meats are now manufactured to a great extent for exportation. (See PREPARATION AND PRESERVATION OF FOOD.) The proper drying of an animal substance is likewise an invariable preventive of putrescence. Animal matter should be dried at a temperature of from 120° to 140°; but even when dried, the addition of a little salt will be necessary. The salt is supposed to absorb the water from the albumen; and alcohol, sugar, &c. act in the same way. Animal substances may also be preserved for any length of time by being saturated with a vegetable extract known in chemistry by the name of *tannin*; and this has given rise to the common process of tanning the skins of animals, and so making them into leather. Tannin exists in all vegetables possessing an astringent taste and quality, but is found in greatest perfection in oak bark and nut-galls. The principle upon which it acts is the imbibing of an astringent and hardening quality by the mass of the substance, by which it is constitutionally altered. Corrosive sublimate, and other chemicals, are now extensively used for the prevention of decay in timber, canvas, and other vegetable preparations; but the applications of these we reserve for subsequent treatment.

Such is a brief outline of the leading processes by which the raw material of nature is made available to the purposes of civilised life. They will receive further exemplification when we come to treat of the arts to which they may be applied.

ANALYSIS.

The art of analysing the compounds of matter, or, in other words, of resolving them into the various elements of which they are framed, constitutes one of the most difficult yet important branches of chemical science. More particularly is it important in relation to numberless practical purposes of life. There are few trades which do not owe much of the success with which they are conducted, in an advanced state of society, to the light which chemistry has thrown on the nature of the substances employed in them, and the consequent improvements therein introduced. To the highest moral interests even of the social body, chemical analysis is of vital moment. It is the basis of medical jurisprudence. Without the knowledge of poisons possessed by the professors of that science, and their ability to separate by analysis the most minute portions of these from any compounds with which they may have been mixed, innocence might often perish under the erring severity of the laws, and guilt escape the penalty justly incurred.

When the investigation of any body is confined to the *nature* and *properties* of its constituent elements, the analysis is said to be *qualitative*; but if the *quantity* of every individual element is to be ascertained, the analysis is termed *quantitive*. A qualitative investigation may be made with a twofold view—either to prove that a certain body is or is not contained in a substance, as iron in water, or to ascertain all the constituents of that substance. The object of a quantitive analysis is to exhibit the elements revealed by the qualitative investigation, either in their absolute or proportional amount or weight.

The mode in which chemical analysis, so important in every respect, is conducted, may best be explained by individual examples; but a few general observations will not be out of place. Of the apparatus necessary for the chemical analyst in his laboratory, notice has already been taken; and it is only necessary to add that, in performing analyses, the principal tests and preparations are also required. The latter articles amount in number to about sixty or seventy. They consist chiefly of the sulphuric, nitric, and hydrochloric acids; sulphur, phosphorus, iodine; the principal alkalies and earths, with their most important compounds; mercury, iron, lead, tin, cobalt, antimony, gold, silver, and a few other metals, pure or in a compound state; with a few of the vegetable acids, such as the tartaric and oxalic. Tests and test-papers, most important matters in chemical experiments, are also to be procured. By the application of the common tests, most of the elementary substances can be readily detected; and a list of such tests, with their effects, should always be at hand. Thus acids redden litmus paper; alkalies convert turmeric to a deep reddish-brown; an infusion of galls blackens any solution containing iron; a piece of polished steel dipped in a solution containing copper is instantly coated with metallic copper; and so on with many other substances. Tests of this kind are chiefly valuable as indicators; for most practical purposes, the minutiæ of quality and quantity must be rigidly obtained.

In taking up any body of unknown composition for analysis, very minute quantities only, finely divided and weighed, are used. The body is then, if possible, dissolved, commonly in water, that the particles may be further separated as widely as possible, which is the most favourable condition for the action of other bodies upon it, and display of chemical affinities. It is possible that the body may be insoluble, or but partially soluble in water at a common temperature. In those cases, the processes of infusion, digestion, or decoction will be tried by the analyst, heat adding powerfully to the solvent powers of water. Lixiviation and maceration are also resources of the chemist. Sometimes alcohol or other solvents must be employed, and at times several solvents require to be used in succession, each having the power to take up something insoluble in the others. Once dissolved, the body, or portions of it separately, can be treated with tests; and happily there is not one substance in nature which has not such affinities for one or more substances, in preference to all others, as readily to betray its own nature. The common results of adding one body as a test to another in solution, are either alteration of colour, or precipitation, or gasefaction. In the first case, the two bodies may form a compound, soluble, but of new colour; in the second place, an insoluble substance may be thrown down to the bottom of the solution; and in the third, a gas may be set free. All of these results may be combined in some cases. The experimenter may, moreover, vaporise and crystallise: fusion and condensation are processes also at his command. When simple solution can be effected in no way, and at no temperature, the analyst may have recourse to other agents. Chemical action may be induced by pressure, by electricity, or even by light.

These are the general ways and means by which the chemical analyst prosecutes his investigations. By way of particular example, let us take a case in the department of *medical jurisprudence*. Let us suppose a medical man called upon to examine a case of poisoning, where the only cause of death that can be suspected is the use of copper vessels when corroded by articles of food. The object, then, is to analyse the vegetable or animal fluids remaining on the stomach, or preserved otherwise, in order to detect the copper, if it exists. Being boiled, the fluid in question is treated or mixed with diluted acetic acid or vinegar, which dissolves out the copper from among the other matters present. Well aware that sulphur has so strong an affinity for copper as to unite with it whenever they meet favourably in solution, forming a compound of both, called a sulphuret of copper, Professor Christison then directs the introduction of sulphur, in the shape of sulphuretted hydrogen gas, after the following preparations have first been made:—'The suspected mixture having been prepared by the addition of acetic acid, is to be subjected to filtration, and any matter left on the filter is to be washed, collected, and dried, the washings being of course added to the fluid which first passed through. The process here divides itself into two; for the oxide of copper may be left on the filter in the form of an insoluble salt, or it may have passed through in solution. But it may be observed in passing, that very few of the salts of copper are insoluble in diluted acetic acid, so that if copper is present at all in a suspected mixture, there are many chances in favour of its being found by the first branch of the analysis.

'*1st*, The solution is to be examined first, both because it is the more likely quarter in which to find the copper, and because the analysis is more easy than that of the solid matter. The solution, then, is to be treated in the usual way with a stream of sulphuretted hydrogen, and immediately boiled to expel the excess of gas. If a brownish-black, or even pale-brown precipitate is then thrown down, there is a presumption in favour of the existence of copper: if there is no precipitate or brown colouration, there is no copper in the fluid. To ascertain precisely the nature of the precipitate, which is some metallic sulphuret, the superincumbent fluid, after ebullition and subsidence of the precipitate, is to be cautiously withdrawn, and its place supplied with water; and when the washing has been several times repeated in the same manner, the precipitate is to be transferred into a watch-glass, or, still better, into a white porcelain cup, and dried. It is next to be collected, and incinerated in a glass tube, to destroy any adhering vegetable or animal matter. The last step in this branch of the process is to convert the sulphuret into the sulphate by the action of a few drops of nitric acid, aided by a gentle heat; and then to add an excess of ammonia, either without or with previous filtration, according to the degree of muddiness in the nitrous solution. If copper is present, the usual deep violet-blue tint will be struck.

'*2d*, If copper is not detected in the filtered part of the suspected matter, it will be necessary to examine also what remained on the filter. This proceeding, which constitutes the second branch of the analysis, will be seldom required in ordinary medico-legal researches, being rendered necessary only by the possibility of the oxide of copper having, either originally or after mixture with the suspected matter, assumed the form of an inorganic salt, insoluble in water or acetic acid. The matter on the filter is first to be well dried, and then heated to redness in a crucible till it be completely charred. The copper which is thus reduced to the metallic state is next to be treated with nitric acid, diluted with its weight of water, and aided in its action by gentle heat. A solution is then procured, which is to be removed by filtration, and tested with ammonia, and the other liquid tests.' Ammonia has a strong affinity for copper, and when added to a saline solution of the latter, throws down a deep blue powder, called the ammoniuret of copper.

The analysis of mineral waters, where the nature and amount of the whole ingredients, and not of one only, form the subject of inquiry, is a task of very great difficulty. Generally, however, non-professional experimenters upon liquids of this description are anxious merely to ascertain the existence or non-existence of certain ingredients, without entering into minute proportional quantities or the like details. The report of a case communicated by the Rev. W. Robertson, junior, of Inverkeithing, to the 'Edinburgh Philosophical Journal,' may give a fair idea of the mode of procedure under such circumstances. It is that of a mineral spring issuing from the coal-formation near Fordel in Fife.

A gas bubbled up through the spring which Mr Robertson first examined. The elementary as well as compound gases have properties and affinities as well-marked as those of fluids or solids, and can be as readily detected. For example, the gas called carbonic acid, present so largely in nature, has such an affinity for lime, that, on contact, it is at once absorbed by lime-water, and renders that liquid turbid. By trials with a graduated glass tube, where the gas or air containing carbonic acid is brought into contact with lime-water, the loss of the acid gas by absorption may be measured, and the proportion of it present in the examined air at once determined. So with other gases, when tested in relation to their respective affinities. Having satisfied himself about the gases present in the spring of Fordel, Mr Robertson then tried the following preliminary experiments to determine the substances contained :—

'Even when recent, it did not perceptibly redden tincture of litmus, though the tint was compared with the colour of the tincture diluted to a similar extent. It did not affect the colour of Brazil wood or turmeric test-paper. With tincture of galls it gave a slight tinge of purple, and ultimately a scanty purplish-brown flocculent precipitate, showing the presence of iron, and by the purplish tinge, also the presence of earthy or alkaline salts.

'The water next day gave no tinge with the tincture, showing the iron to be principally in the state of a carbonate. When the water was evaporated by a gentle heat, flocculi of oxide of iron were deposited; and upon being boiled, gave a considerable yellowish-white precipitate, indicating carbonates. This precipitate was soluble, with considerable effervescence, in nitric acid.

'The water decanted from this precipitate gave no tinge with tincture of galls, but on boiling it with a few drops of nitric acid, to peroxidise the iron which it might contain, the excess of acid being afterwards neutralised by ammonia, it gave unequivocal traces of iron, by a darkish tinge with the tincture. From this it was inferred that the iron in it was in the state of protoxide. A portion of this water, after being thus treated, also gave a red tinge, with sulpho-cyanite of potash. With ferro-cyanite of potash, and a drop of muriatic acid, the water, when recent, gave a whitish precipitate, becoming blue by exposure to the air, indicating iron in the state of protoxide.

'With lime-water, the recent water gave a copious flocculent precipitate, the lime uniting with the excess of the carbonic acid, and the whole of the carbonates falling down together. This precipitate was re-dissolved on adding more of the mineral water, which showed a considerable excess of carbonic acid; and it was also soluble with effervescence in dilute acetic acid. With the bicarbonate of potash there was no precipitate, the whole being kept dissolved by the excess of carbonic acid.

'With ammonia, and also with potash, a flocculent white precipitate took place, partly owing to the abstraction of free carbonic acid. With the carbonates of potash, soda, and ammonia, there were similar precipitates, but more scanty: they were all soluble in a dilute acetic acid.

'With a solution of soap in alcohol, a great milkiness. With acetate of lead, a considerable milkiness, and a precipitate insoluble in acetic acid. With oxalate of ammonia, a considerable precipitate, indicating the presence of lime.

'With carbonate of ammonia and phosphate of soda, an immediate milkiness, and a precipitate, after standing, indicating magnesia; the precipitate soluble in acetic acid. With carbonate of ammonia, or phosphate of soda, separately, no milkiness, after standing for the same length of time.

'With muriate of baryta, a slight precipitate, insoluble in muriatic acid, indicating sulphuric acid. With nitrate of silver, a copious precipitate, white while secluded from the light, becoming rapidly purple on exposure to light, indicating muriatic acid.

'Two ounces of the water, evaporated to dryness, gave, with nitro-muriate of platinum, slight traces of potash. The water, very much concentrated by evaporation, gave, with starch and sulphuric acid, no trace of iodine.

'From the above indications, it was concluded that the water contained sulphuric, muriatic, and carbonic acids, together with protoxide of iron, lime, magnesia, and a little potash. The presence of alumina was inferred to be incompatible with that of the earthy carbonates, neither could any be subsequently detected.' The determination of the quantities of each substance present was the next object with Mr Robertson; but it is not necessary here to carry our notice of the subject beyond generalities.

The agricultural chemist proceeds in a similar way, and with similar instruments. He has the advantage, generally, of knowing beforehand the probable character of the matters on which he operates, and the point is, to determine in what proportions they exist in the particular soil under examination. Where a less exact analysis will suit the purposes of the agriculturist, the following simple plan of ascertaining the qualities of soils may be adopted. We quote, with some slight alterations, from Mr Young's 'Letters of Agricola:'—

'In the field to be examined, take earth a little below the surface, from four separate places, about a quarter of a pound from each: mix them together, and again separate them into four quantities of a quarter of a pound each. Then take one quantity and expose it to the sun, or before the fire, till completely dry; and turn it over frequently, that it may be well mixed together. Being thus powdered, pass it through a fine sieve, which will allow all the particles of sand and gravel to escape, but which will hold back stones, small fibrous roots, and decayed wood. Weigh the two parts—the fine and the rough—separately, and take a note of each. The stones and other bulky materials are then to be examined apart from the roots and wood. If they are hard and rough to the touch, and scratch glass easily, they are siliceous and flinty; if they are without much difficulty broken to pieces by the fingers, and can be scraped by a knife to powder, they are aluminous or clayey; or if, when put in a wine-glass, and common vinegar poured upon them, small air-bubbles ascend to the top of the liquid, they are calcareous. The finely-divided matter which ran through the sieve must next undergo the test of experiment. After being weighed, agitate the whole in water, till the earth be taken up from the bottom and mechanically suspended, adding water till this effect be produced. Allow the mass then to settle for two or three minutes, and in that time the sandy particles will sink to the bottom. Pour off the water, which will then contain the clay in suspension, and the insoluble earth arising from animal and vegetable decomposition. The sand should be first attended to, and if, from inspection, it be thought either siliceous or calcareous in its nature, the requisite tests may be instantly applied. By this time the mixture in the poured-off water will leave deposited at the bottom of the vessel the clay and other earths, with the insoluble animal and vegetable matter. After pouring off the water, dry the sediment, and apply a strong heat, by placing it on the bottom of a pot ignited to redness, and the animal and vegetable matter will fly off in aëriform products. The remainder lying in the bottom will be found to consist of clay, lime, or magnesia.

'To obtain accuracy, another quarter of a pound may be taken, and the whole process gone over a second, a third, or even a fourth time, so that the operator may rectify any blunders he had previously committed, and be satisfied as to the results of the experiment. He should provide himself with a pair of fine scales, and a set of weights, divided at least into half and quarter ounces and drachms. Although vinegar will detect lime by effervescence, it does not dissolve it so effectually as the nitric or muriatic acids, small quantities of which may be obtained from the druggists at a small expense.'

Having ascertained by these, or any other inquiries, what is the composition of the soil, a pretty accurate notion, other things considered, may be obtained respecting its capacity for productive husbandry. If it be necessary to enter on a course of improvement, the defect in composition may be remedied by the application of materials of an opposite quality—an excess of calcareous matter being counteracted by sand and clay, an excess of clay by the admixture of sand, or an excess of sand by the application of clay, peat, &c. An excellent soil for bearing wheat has been found to contain in 100 parts—carbonate of lime, 28; silica, 32; alumina, 29; and of animal and vegetable matter, with moisture, 11. Oxide of iron, to the extent of 2 or 3 per cent. is not unusual in productive soils. (See article AGRICULTURE.)

SPECIAL APPLICATIONS.

In a regular exposition of the industrial applications of chemistry, those arts ought naturally to take precedence which have reference to the production, preparation, and preservation of food. Among these may be ranked Agriculture, as it relates to soils, crops, and manures; Baking of fermented and unfermented breads; Cooking, and the preparation of condiments, as salt, sugar, and the like; Brewing and Distilling of beverages; and we may add Medicine, with its numerous remedial appliances internal and external. As these, however, will form subjects of separate consideration, we here merely indicate their position and connection, and proceed to notice a few of those manufactures the elaboration of which depends more on chemical than on mechanical principles.

Soap.

This exceedingly useful article, of which the ancients were entirely ignorant, is a compound of certain principles in oils, fats, or resin, with a salifiable base. If this base be potash or soda, the compound is used as a detergent in washing clothes. When an alkaline earth or oxide of a common metal, such as lead, which forms litharge, &c. is the base, the compound is insoluble in water. The insoluble compounds, however, are very little used, except in some few cases of surgery. Animal fat, grease, or tallow, as it is variously termed, is a compound of a solid substance called, in chemistry, *stearine*, and of an oil called *oleine*, the basis of which is carbon, with a little hydrogen and oxygen. On subjecting tallow to a hot lye of potash or soda, a chemical change takes place in the constituents, and we have the material named *margaric acid*, and a fluid, *oleic acid*, and together they enter into a saline combination with the alkali. The result, a soapy substance, is thus said to be a union of an alkaline margarate with oleate. Saponification also takes place with vegetable fats and oils, which are now largely employed in commerce.

The commonest *hard soap* is that made chiefly from kelp and tallow. Kelp itself is a result of chemical action. It is made by reducing certain kinds of seaweed to ashes by burning; the result in soluble material is a crude alkali, consisting of sulphate of soda, soda in carbonate and sulphuret, and muriate of soda and potash. It was at one time manufactured in large quantities on the shores of the Western Isles of Scotland, but has latterly been disused, in consequence of the substitution of barilla, and soda-ash from the decomposition of sea-salt. Supposing kelp to be employed in making soap—to every ton of kelp, about one-sixth of new-slaked lime is added. The whole, after mixture, is put into a large tub called a cave, having a perforation at the bottom, shut with a wooden plug. Upon the materials water is very slowly poured. The liquid, after digestion, is suffered to run slowly off into a reservoir sunk in the ground. The first portion, or lye No. 1, is of course the strongest, and is reserved for the last operation in soap-boiling. Six days are required to make one boiling of soap, in which two tons or upwards of tallow may be employed. The lyes 2 and 3, mixed, are used at the beginning, diluted with water, on account of the excess of sea-salt in the kelp. A quantity of lye, not well defined, is poured on the melted tallow, and the mixture is boiled, a workman agitating the materials to facilitate the combination. The fire being withdrawn, and the aqueous liquid having subsided, it is pumped off, and a new portion is thrown in. A second boil is given; and so on, in succession. Two or three boils are performed every twelve hours, for six days, constituting twelve or eighteen operations in the whole. Towards the last, the stronger lye is brought into play. Whenever the workman perceives the saponification perfect, the process is stopped, and the soap is lifted out, poured into the moulds, and afterwards cut into bars.

The compounds of tallow or oils with potash, remain of a soft consistency, and form what are termed *soft soaps*, useful in scouring. We can only afford space for an account of the process of manufacturing one of the common kinds of soft soap, as lately practised by an eminent soap-boiler near Glasgow. Whale or cod oil, to the amount of 273 gallons, is put into a boiler, along with four hundredweight of tallow, and 252 gallons of potash lye. On heat being applied, the mixture froths up very much, but means are adopted to prevent its boiling over. There are then added at intervals fourteen measures of stronger lye, each measure holding twenty-one gallons. After suitable boiling without agitation, the soap is formed, amounting in all to one hundred firkins of sixty-four pounds each, from the above quantity of materials.

What are called *toilet soaps* are made from purified hogs' lard, with the addition of olive, almond, palm, cocoa-nut, and other oils. These, when prepared, are perfumed with various scents. The soap is cut into thin shavings with a plane, and melted in a pan placed within a hot-water or steam bath. When melted, the colouring matter and perfume are added, which generally consist of vermillion, ochre, bergamot, musk, essence of orange-blossom, cinnamon, &c.

Of late, numerous patents have been obtained for the use of dissolved bones, naphtha, hair, fish, dextine, and other substances, in the manufacture of soaps; but as yet few, if any of them, have been commercially successful. The better the raw materials, the finer and more economical the manufactured product; and all that can be expected from the employment of such substances as above-mentioned, is a cheap and inferior article. Another class of these inventions are the soaps which contain admixtures of certain detergent mineral substances, as silica, alumina, soap-stone, porcelain-earth, and fullers'-earth. The firmness of the soap is not diminished by the addition of such substances, which exert, however, a purely mechanical action, and are contained in no kind of chemical combination. The value of the article so manufactured is very much reduced, as a great portion of the real soap is replaced by a substance of similar, but inferior efficacy, and whose price bears no comparison with that of the fats. *Sand soap*, for example, is one of these recent manufactures, and contains from 60 to 70 per cent. of pure sand; *pumice soap* is another, containing from 20 to 30 per cent. of siliceous matter; and *silica soap*, perhaps the best of them, about 20 per cent. of insoluble residue. *Chlorine soaps*, which are now so largely advertised, are preparations intended to realise the idea of the union of the detergent properties of soap with the bleaching effects of the compounds of chlorine. It is almost unnecessary to remark that such a union is impracticable; and these chlorine soaps, in the words of a high authority, 'are nothing more than foolish novelties.'

The real value of soap is mainly dependent upon the amount of dry soap (the dry combination of alkali with the fatty acid) which it contains; and an abundant supply of such a commodity is economically, socially, and morally invaluable. 'Of two countries,' says Baron Liebig, 'with an equal amount of population, the wealthiest and most civilised will consume the greatest weight of soap. This consumption does not subserve sensual gratification, nor depend upon fashion, but upon the feeling of the beauty, comfort, and welfare attendant upon cleanliness; and a regard to this feeling is coincident with wealth and civilisation.'

Candles.

The process of making candles by simply melting tallow, and pouring it, in a liquid state, into moulds containing wicks, requires no particular notice. It is of the improved mode of making tallow-candles to resemble those of wax, and involving an intimate knowledge of chemistry, that we wish to speak.

Some years ago, M. Chevreul, a French chemist, undertook an investigation into the nature of fatty substances, which he found to be composed of what we now know them to be—two materials, *stearine* and *oleine*. He ascertained that the oil does not combine directly with the alkali, but that its two components are converted by it into two corresponding acids, the stearic and oleic, which then combine with the alkali, like the mineral acids. He found, indeed, the analogy perfect between them in every respect. They unite with all the bases, forming compounds, which differ in the degree of their solubility: with potash, for instance, a very soluble compound is formed (soft soap); with soda, hard soap, which is dissolved with more difficulty; while its combination with lime gives rise to a perfectly insoluble compound. These facts have been most important to the soap-maker, in enabling him to reduce his art to scientific principles; they explain why a solution of soap may be used as a test for the purity of water; why rain water is preferred to that from the spring for washing; and why we add soda to hard water before using it with soap, for soda separates the lime which the hard water contains, and thus enables us to dissolve the soap, without producing the curdy precipitate which destroys its cleansing properties.

M. Chevreul separated these acids from their compounds, and found them possessed of the following properties:—Oleic acid is a liquid, clear when pure, and closely resembling oil; stearic acid is solid, and resembles wax in so striking a manner, as to be with difficulty distinguished from it. On finding he could manufacture it at a price much inferior to that at which wax is sold, he, in conjunction with M. Gay-Lussac, another distinguished chemist, took out a 'brevet d'invention' for the preparation and sale of 'chandelles steariques,' from which they never derived any benefit, solely on account of the name, which, merely implying candles prepared from tallow, attracted no attention; whereas manufacturers who took up the trade after the expiration of the patent, and who announced, with less regard to truth, their productions as 'bougies,' or wax candles, speedily made large fortunes. If the reader wishes to prepare and examine the artificial wax himself, it may be easily accomplished. Let him dissolve a little hard white soap in hot rain or distilled water, and to the clear solution, while hot, add some vinegar or other acid. The stearic being a weak acid, is easily separated from its combination with soda, as it exists in soap. Acetate of soda is formed, and the stearic acid rises to the top of the liquid as an oily substance, which, on cooling, solidifies into a cake of artificial wax, mixed with a certain portion of oleic and impurities, which render it softer than if this fluid had been expelled by pressure. A similar process is pursued on a large scale, but regard must be had for economy. The tallow is saponified, not by soda or potash, as in the preparation of soap, but by quicklime. It is only necessary to boil the lime, tallow, and water in a large vessel for some hours, when these ingredients are converted into a kind of hard soap. From this substance stearate and oleate of lime, also the stearic and oleic acids, are separated by the addition of oil of vitriol. They are melted like tallow, run into cakes, and subjected to the powerful action of a hydraulic press, which separates all impurities, and leaves the stearic acid as pure and white as the finest bleached wax, which may be used immediately for the formation of candles. In France, the wicks, besides being plaited, are dipped in a solution of borax, and then dried. The borax fuses during the combustion, and forming a globule on the summit of the wick, assists by its weight to bring it out of the flame in contact with the atmosphere, and thus insures perfect combustion, and obviates the necessity of snuffing. Palmer, an English patentee, accomplishes the same end by making the wick consist of two halves, which are twisted in opposite directions, and at the same time wrapped round by a slender wire. The result is, that the halves separate on combustion, and fork outwards to the exterior portion of the flame, where they are completely consumed.

It was found that the artificial wax generally crystallised in the moulds—a circumstance which prevents the formation of a solid candle. In England, this difficulty was overcome in some cases by the addition of arsenic; but the use of this substance either for this purpose, or for causing the wicks to be more readily reduced to ash, ought never to be permitted, as it is highly prejudicial to health. The French, more scientific than we, had recourse to their knowledge of the laws of crystallisation for the remedy. It is known that regular crystallisation only takes place when the transition of the mass from a fluid to a solid state is so gradual, as to allow time for its molecules to arrange themselves in those determinate forms called crystals: this condition was fulfilled in the cooling of the moulds and their contents; but by plunging them in cold water as soon as the melted stearic acid had been poured in, crystallisation was prevented, and a perfectly solid candle procured. Stearic candles, which can with difficulty be distinguished from wax candles, are now manufactured on a large scale in England, and from their comparative cheapness, are coming universally into use in the houses of the middle and higher classes of society. So much for the value of a knowledge of practical chemistry in one of the commonest of our industrial operations.

Leather.

Leather-making is the art by which the skins of animals are rendered impervious to the action of those external agents which would otherwise decompose them. This effect is brought about by steeping the skins in the certain astringent principle called *tannin*, and may be performed either with the hair on, or, as is generally the case, when it is taken off. Tannin is obtained from the bark of a number of trees, particularly the East India catechu, the common oak, the Spanish chestnut, the Leicester willow, &c. It is found in the largest quantities in catechu—one pound of this, according to Mr Purkis, being equal to seven or eight pounds of oak bark. Tannin is also obtained, by a peculiar preparation, from the gall-nuts of the Levant oak. When the bark of trees is to be used for tanning, it should be stript from the trunk and branches in the spring, when the sap flows most freely. The trees should not be less than thirty years old, for it has been found that the bark possesses more tannin when old than when in a young state. The bark, when dried, is ground in a mill, to reduce it to a rough powder, after which it is ready to be used.

The first process which the skins undergo is steeping in lime-water, which is continued for a longer or shorter time, according as the skins are dry or fresh. Sometimes the skins are salted when they are imported from abroad; and in this case they require to be steeped, beaten, and rubbed, until they are brought to a fresh state. The horns are then cut off, and the skins put in heaps for a day or two, after which they are hung up in a shed. During this process, a slight putrefaction takes place, by which the hair on one side, and the fleshy matter on the other, are easily removed. This is done by a blunt knife, or scraper, the skins being stretched upon a wooden beam called a *horse*. The skins are then immersed for about forty-eight hours in water mixed with a little sulphuric acid, which has the effect of distending the fibres, causing the skins to swell. This process is called *raising*, and by it the tannin principle more easily reaches the inner fibres. When sufficiently raised, the skins are put into a pit with a layer of bark in the bottom. On this skins are laid, and then bark and skins alternately. The pit is filled up with a strong decoction of bark, and the whole is allowed to lie undisturbed for about six weeks. At the end of this time, it will be found that the tannin has become entirely exhausted, when the skins must be taken out, and put again into the pit, along with fresh bark. In this they are allowed to lie for three months; and this process is repeated two or three times, according to the quality of the leather required. From six to eight months in all are sufficient to complete the tanning of the commonest kind of sole leather, called *crop* by the trade; but for the better kinds of sole leather, from a year to a year and a half will be required. *Bend leather* is the strongest of all sole leather, and in manufacturing it, the tanning process is continued for a longer period than is necessary for crop. The best and thickest skins also are selected for this kind.

When properly tanned, crop leather is hung up in an airy house to dry, which is performed slowly, and the article is then fit for the market. Bend leather, after being dried, is beaten into a firm consistence, so that when cut, the edges present a glossy appearance. The instrument with which bend leather is beaten is a broad brass hammer; and this kind of leather may be easily distinguished from its being darker in the colour, in consequence of lying longer in the tannin.

A coarse kind of upper leather is also made from cow-hides, the weakest and thinnest being selected for this purpose. When taken out of the lime-water, and the hair scraped off, these hides are immersed in a solution of the ordure of pigeons, which has the effect of neutralising the lime. They are then stretched upon a board, and from the inner or fleshy side slices are taken with a sharp knife, until the operator thinks it is reduced to a proper thickness—an operation which is technically called 'shaving in the butt.' The skins are then put into the tan-pits, where they remain for about six months, after which they are sent to the currier. The skins of seals, calves, &c. are manufactured into upper leather in the same way, except that an equal extent of shaving is not required. Such was the old, and, till very recently, the only mode of procedure in this most important branch of our manufactures.

Several improvements, however, have recently been made in the manufacture of leather, by which the tannin principle is more readily admitted to the inner fibres of the skins. One of the improved methods is that of Messrs Herapath and Cox of Bristol, and consists in using a machine of two rollers, which is placed in the middle between two tan-pits. The hides having been previously divested of the hair, &c. are fastened together, and put into the tan-pit in regular folds. After lying in this for a certain time, the end of the belt of hides is laid upon the under roller, which, being set in motion, carries the belt over to the other tan-pit. This is done without pressure; but when the hides have become soft, the upper roller is pressed down against the under one. The hides are again passed through between the rollers, which press out the exhausted tannin, and prepare them for being submitted to a fresh infusion. By the old method, the hides were taken from one pit to another without receiving any pressure, and consequently a quantity of exhausted tannin must have remained in them when put into the fresh liquor. By using this machine, however, this is altogether obviated; and leather may now be tanned in four months, a process which formerly took from eight to twelve.

More recent improvements are those of Mr John Cox of Gorgie Mills, near Edinburgh, and for which he has obtained patents. He announces *six* improved processes of tanning, any of which may be adopted. His great object is to force the liquid tannin into the vesicles of the skin, and this he proposes to do as follows, in his *fourth* process, which he considers the most suitable in ordinary circumstances. The skin is to be sewed into the form of a bag, and immersed in tanning liquor, while the interior is also filled and compressed from a supply of liquor through a pipe from a cistern placed a few feet above the pit:—'The hide or skin bag being tied tightly at the neck-end to the feeding tube (which tube should be long enough to dip a little down amongst the liquor in the pit in which the bag is to be immersed), tanning liquor is to be supplied to the feeding cistern, when the bag will swell until it can contain no more liquor, when percolation will commence, and be continued with a vigour proportionally to the height of the liquor in the feeding cistern above the liquor in the pit of immersion. As the bag fills with liquor, the pit (having been previously full) will overflow, unless the liquor is supplied from the pit of immersion; and therefore a run-way must be made for the liquor to flow to a reservoir, from which it may be pumped or lifted again to the feeding cistern; and as the percolation goes on, the liquor will flow to the reservoir, again to be raised and circulated as before. In this process of tanning there is a double hydrostatic pressure exerted—a greater, which is exerted inside of the bag; and a lesser, which is exerted outside of the bag; and it is the surplus pressure (which is equal at all parts of the bag) of the one above the other that causes the percolation of liquor from within outwards.' By any of Mr Cox's processes we understand that a hide may be as effectually tanned in a week, as it was by the old tan-pit method in twelve months, while there is at the same time a saving of tanning material and gelatine.

More recently still, Dr Turnbull of London has patented a very ingenious process, depending upon the principles of *endosmose* and *exosmose*; and another, in which the forcing-pump is employed to expedite the impregnation of the hide with the tanning liquid. The theory of endosmose and exosmose was first broached by Dutrochet, who discovered that small bladders of either animal or vegetable membrane, if filled with milk, and securely tied, when thrown into water, absorbed a quantity of that fluid, and acquired weight; while, on the contrary, if the bladders were filled with water, and thrown into milk, they lost weight, from the water being attracted through the membrane into the milk. From these and other experiments, he concluded that if two fluids of unequal density be separated by a membrane, the heavier fluid will attract the lighter through that membrane. The attraction from the outside to the inside he called endosmose; from the inside to the outside, exosmose. Upon this principle Dr Turnbull fills his skins (sewed up in the form of bags) with a super-saturated solution of tannin, and places them in a reservoir filled with a sub-saturated solution (or *vice versâ*), upon which the permeation goes on with rapidity; and what formerly required months, can be effected more thoroughly in as many days.

Skins intended for the *manufacture of gloves* require in the first place to be washed with pure water. This is done in a cistern placed, if possible, near a running stream; and immediately after being washed, the skins must be worked, or they are liable to become marked with indelible spots. They are next rubbed upon a convex beam, and the rough parts removed with the fleshing-knife. The fleshy sides of the skins are then covered with a cream of lime, and piled together with the wool sides of each pair outermost. They are left in this state for from four to six days, or until the wool is found to come easily off. The skins are then washed in a running water, to free them from the lime, and the wool is taken off by means of small spring tweezers. After this they are fleeced smooth by a rolling-pin, or by rubbing with a whetstone.

The next operation to be performed is steeping the skins in a strong solution of lime, for the purpose of swelling and softening them. They are then put into weak lime-water, and drained upon inclined tables, which is repeated several times, the process occupying about three weeks. The outsides are then rubbed with a whetstone, to remove any wool which may still remain; and the skins are then fit for what is called *branning*. Into twenty gallons of water forty pounds of bran are put, and the skins are steeped in this mixture until they sink, which they will generally do in about two days in summer and eight in winter. During the branning process, the skins must be frequently stirred, that each may get a due share of the liquid. They are next steeped in a solution of alum and sea-salt, which is called the *white stuff*. From twelve to eighteen pounds of alum, and about three pounds of salt, are put into a copper with twelve gallons of water. This mixture is dissolved by heating the copper; and when about to boil, three gallons of the solution are poured into a basin, in which twenty-six skins are worked one after another. The twelve gallons are thought sufficient for one hundred skins; and when all have been worked, they are allowed to steep for about ten minutes. The skins are then taken out, and fifteen pounds of wheat flour are added to the solution. This is next run out of the copper vessel, and the yolks of fifty eggs put into it, in which the skins are worked, and afterwards allowed to steep for a day. They are then taken out, stretched upon poles, and allowed to dry. By this operation the leather is rendered very white and soft, which enables it to bear the working of the softening-iron. This consists of a plate of iron about a foot broad, mounted upon an upright beam thirty inches high, which is fixed to the end of a plank three and a half feet long. This plank is heavily loaded; and the skins having been previously wetted, they are rubbed with the iron upon a board. The skins are sometimes stretched upon the horse, and well rubbed with a blunt two-edged knife, and afterwards polished with pumice-stone. They are then worked upon the stretching-iron, and afterwards smoothed with a hot iron.

Sheepskins are frequently dressed for household purposes, and on this account are technically called *housings*. For this purpose, those skins are selected which have the longest and most beautiful fleece. They are first well washed and steeped in water, to render them soft, and then thinned with the fleshing-knife, after which they are put into the bran pit for four days. The same process as for glove leather, of steeping in alum water, and rubbing with paste, is then performed. The skins are next worked upon the horse, stretched upon the stretching-iron, and then dried in the sun with the fleecy side outermost.

Chamois leather is prepared by washing, steeping in lime-water, taking off the fleece, and then branning the skins as before described. The outer skin, or epidermis, is next cut off upon the horse, which removes all excrescences, and renders the skins equal in thickness. They are then branned for a short time, the liquid wrung out of them, and then well beat in a fulling-mill. The next process is to oil the skins, which is done by sprinkling and rubbing over them any cheap animal oil. The skins are afterwards oiled and beat several times, and are then subjected to a fermenting process; after which they are washed in potash lye, and then dried. The very thick and firm, but pliable sort of leather called *buff* (originally made of buffalo skins, but now also from cow-hides), is dressed in oil, and prepared much in the same way as chamois.

Morocco or *Turkey leather* is manufactured from goatskin, but a spurious article is frequently sold under this name which is made from sheepskin. The process is much the same as for glove leather, except that the washing is performed oftener, and the skins are salted previous to being dyed. Morocco leather is dyed with cochineal, about an ounce being required for each skin. The cochineal gives a scarlet colour to morocco leather; but other colours may be given to it, such as black, by using the red acetate of iron; blue, by indigo; yellow, from the roots of the barberry. The skin is next tanned in a decoction of sumach. The tanning is performed twice, the process requiring about twenty-four hours. The skins are then rubbed hard with a copper blade, and hung up to dry.

Russia leather, well known for its durable properties, is prepared by steeping in alkaline lye, and then in dogs' dung; after which it is fulled and tanned with birch bark. It is generally dyed of a pale orange colour, is roughened in the surface by an iron tool, and receives its peculiar odour from being rubbed with the empyreumatic oil of birch. *Maroquin*, commonly of a red or yellow colour, is another Russian leather similarly prepared. *Shagreen*, brought chiefly from Astracan, is prepared from the strong skin which covers the crupper of the horse or ass. Its peculiar granulated surface is produced by treading small round seeds into the skin when soft; these are afterwards removed, the leather dyed green, and the surface worked down by rasping, when it finally presents the appearance of white dots on a green ground.

Currying is the process by which the newly-tanned rough leather is converted into the soft, flexible, and jet-coloured article from which the upper leathers of shoes are made. The currier first steeps the leather, and then places upon it a piece of basket-work, upon which he treads, in order to soften it. He then shaves the leather by means of a double-edged knife, with a horizontal handle at each end. The edges of this knife are curved, and in cutting, it is held nearly at right angles to the leather, which is thrown over an upright beam. The currier stands behind this beam and scrapes downwards. By this means all inequalities are removed, the leather being rendered uniform in thickness and firm in the texture. What is called a stretching-iron is also used, which still further firms the grain; and cleaning-knives to make the surface smooth. The leather is then pommelled by an instrument grooved on the under side, and with a cross strap on the top, under which the hand of the workman goes. The leather is folded with its grain side in contact, and rubbed strongly with the pommel, which gives it a granular appearance and greater flexibility. It is then conveyed to the drying-house, where grease is applied to soften it. The grease employed is a mixture of tallow and cod oil, called *dubbing*, and is applied to the leather by means of hard brushes upon a large broad table. When well greased, the leather is hung up to dry, in order that it may thoroughly imbibe the oily matter. It is then well scraped, to free it from all superfluous oil, which would otherwise injure its appearance, and prevent it from receiving the colour readily. The leather is then rubbed on the flesh side with a brush dipped in a composition of oil and lamp-black, until it is thoroughly black. It is then black-sized with a brush or sponge, rubbed again with the oily matter, and afterwards scraped with glass. When coloured (that is, blacked) upon the grain side, a solution of sulphate of iron or copperas is employed. The leather is then wetted with stale urine, and afterwards rubbed with an iron, to render the grain as fine as possible. The bright shining varnish now common on dress shoes is called *enamelling*.

Cow-hides, when dressed for upper leather, are called *neat's* leather, and the shoes made from it are coarse. Common shoes are in general made from calf-skin, which is prepared in the same manner. The uppers of boots are all made from calf-skin, the best part for this purpose being the back and flank. This also applies to cow-skin leather. A considerable number of shoes are made from a description of leather called *kip*, which is prepared from the hides of young cattle, and is consequently intermediate in quality between calf-skin and cow-hide. Horses' hides were formerly much used for making leather, generally known as *cordovan;* but they are now almost entirely superseded by cow-hides, which are greatly preferred. *Parchment* and vellum, well-known preparations, we reserve for our article on BIBLIOGRAPHY.

Colours—Pigments.

There are, as is well known, two modes of imparting colours—dyeing and painting; the former applied to articles coloured by a liquid infusion, and the latter applied to the laying of a colouring substance on the surface. We *dye* cloth, and *paint* a house. The materials employed in dyeing are usually drugs, salts of some kind, or vegetable fluids; but in painting, the prepared colours are chiefly pigments. The preparation of dye-stuffs and pigments is one of the chief departments of practical chemistry.

According to the definitions of men of science, there is no such thing as material colour. The colour is not in the substance; it is only a result of the operation of rays of light on the peculiarly-formed particles in the mass. It is stated that when the rays strike upon the surface of a body, they are decomposed into their elementary tints, and some substances reflecting one colour, and some another, the impression is made on the eye accordingly. When the particles of the body do not reflect any of the rays, the body appears black; and when they reflect them all equally, it appears white. A piece of blue silk, for instance, absorbs six rays, and reflects one, the blue, by which a blue appearance affects our eye. What is the precise constitution or figure of the particles in a substance which produces the phenomena of colours, has never been ascertained. It is certain, however, as we have just mentioned, that colouring less or more depends on the well-known principle of the refrangibility of light. (See OPTICS.) Both dyers and painters require to be more conversant with chemical than optical science; yet there are cases in which a knowledge of the laws of light are of importance. It is a well-known truth that the common white ray of light can be refracted into three primitive colours—red, blue, and yellow—and that these can be recombined into the white ray. A dyer could not expect to dye white by employing an infusion of red, blue, and yellow drugs, but it is certain that the application of a little blue improves a white colour; and this is perfectly understood by paper-makers. Mixtures of Prussian blue and cochineal pink are likewise used to improve the whitening of silks. The colours resulting from a mixture of two primitive colours, as green from blue and yellow, are only a delusion of the eye. Both the component colours are present and distinct, but they are so blended, that we cannot separate them by the naked sight. For instance, a gray hair, when seen by a microscope, is not actually gray, but a composition of small black points on a whitish ground.

The substances used as *paints* are partly artificial, and partly natural productions. They are derived chiefly from the minerals by certain chemical processes; and even when animal or vegetable substances are used for colouring, they are always united with a mineral substance (an earth or an oxide), because by themselves they have no body, which they acquire only by a mixture with a mineral. In painting, the colours are ground to a great degree of fineness, and applied, by means of some liquid, with a brush or camel-hair pencil. Different fluids are employed for this purpose; and the difference of the material used, with the method of employing it, has given rise to the modes of painting in water-colours, oil-colours, in distemper, and in fresco (painting on damp plaster as an absorbent). Oil-paints are usually prepared with boiled linseed-oil, which is drying in its nature; the colours employed all consist of metallic oxides, or salts, or of combinations of sulphur. Among the metallic oxides used as pigments are minium and masticot, from lead; the ochres, burnt sienna, umber, from iron; smalt, from cobalt. Among the salts, or saline metallic combinations, are white-lead, cremnitz white, from lead; Prussian blue, from iron; verdigris, mineral green, Brunswick green, from copper. Metallic combinations containing sulphur are cinnabar, from quicksilver, and orpiment, from arsenic. The lake colours have tin or alum for their bases, and owe their tint to animal or vegetable colouring substances. Among these are the red or pinkish lakes prepared from cochineal, madder, and Brazil wood; the yellow, from fustic, &c.; the brown, from several other colouring barks; finally, indigo, which, however, is entirely vegetable. In staining porcelain and glass, the metallic colours which are not driven off by heat, and are not easily changeable, are used. Gold containing tin gives a purple, nickel green, cobalt blue, iron and manganese black, uranium yellow, chrome green. From the chromate of iron, or rather ferruginous oxide of chrome, one of the most beautiful yellow pigments is now prepared for the use of painters. Ultramarine, another of our most beautiful, and, till lately, one of the most expensive of our pigments, is now prepared cheaply and abundantly by a process strictly chemical. Originally obtained from the lapis-lazuli, a mineral of unrivalled azure-blue, it became the duty of the chemist to discover the constituents of that mineral, and thereafter to endeavour to imitate the natural product. 'The analysis of lapis-lazuli,' says Liebig, 'represented it to be composed of silica, alumina, and soda, three colourless bodies, with sulphur, and a trace of iron. Nothing could be discovered in it of the nature of a pigment, nothing to which its blue colour could be referred—the cause of which was searched for in vain. It might therefore have been supposed that the analyst was here altogether at fault, and that at anyrate its artificial production must be impossible. Nevertheless this has been accomplished, and simply by combining in the proper proportions—as determined by analysis—silica, alumina, soda, iron, and sulphur. Thousands of pounds weight are now manufactured from these ingredients; and this artificial ultramarine is as beautiful as the natural, while for the price of a single ounce of the latter we may obtain many pounds of the former!'

The material principally employed by respectable house-painters to give consistency to their paints, is white-lead or ceruse. This substance is an oxide of lead saturated with carbonic acid. It is prepared by exposing thin plates of lead in a closed vessel to the vapours arising from hot vinegar. The vapours of the acetic acid become saturated with the metal, and change the latter into a whitish substance, which is scraped from time to time off the plates. The whitish substance is afterwards pulverised, and mixed with properly prepared oil. Much of the white-lead in common use is adulterated with whiting—that is, purified and ground chalk—which is much less durable, and may be easily washed off by an alkaline solution.

Oil or spirit of turpentine is also largely used by house-painters, chiefly for the purpose of imparting a drying quality, or of deadening the glitter of the paint. Turpentine is a fluid extract from certain kinds of fir-trees, from which it exudes, and being distilled, the oil or spirit of turpentine is obtained; the residuum is resin. Turpentine is of a powerful acrid quality, and is now employed for certain purposes in medicine. All the *varnishes* used by painters are of the class of gums or resins, properly prepared—such as copal, mastic, sandarach, lac, gum-lac, dragon's blood, &c. All are extremely inflammable, and great caution is necessary both in their preparation and general use.

Inks, either for writing or printing, are as much the result of chemical operations as paints or dyes. Black ink is a decoction of partly vegetable and partly metallic substances, the basis of the latter being iron. The ingredients commonly used are Aleppo galls in powder, logwood, gum-arabic, and sulphate of iron, in certain proportions; but latterly the art of manufacturing the article has been greatly improved, chiefly with the view of giving great fluidity as well as colour. *Printing-ink* is quite a different substance, being a thick viscid body, resembling a black paint. Its ingredients are boiled linseed or nut oil and lamp-black, in the proportion of two and a half ounces of black to sixteen ounces of oil. The preparation of the oil is one of the most dangerous processes in the arts, and great care is required to prevent conflagration of the oleaginous material. There are various qualities of ink to suit different kinds of work. The prime object of attainment in making printing-ink is to give it a deep black colour, which will endure after exposure on the pages of a book. Unless very great trouble be taken in grinding and mingling the materials in exact proportions, the ink, on being used, will gradually become brown, by the spreading of the oil. The French printing-inks are much superior to those made in Britain. *Indian ink* is used in China for writing with a brush, and for painting upon the soft flexible paper of Chinese manufacture. It is ascertained, as well from experiment as from information, that the cakes of this ink are made of lamp-black and size, or animal glue, with the addition of perfumes, or other substances not essential to its quality as an ink. The fine soot from the flame of a lamp or candle, received by holding a plate over it, mixed with clean size from shreds of parchment or glove-leather not dyed, will make an ink equal to that imported. The science of chemistry having, as it were, at its command the production, change, and reproduction of colour, by the use of its numerous compounds, a variety of what are called *sympathetic* inks have been invented, and others attempted, which might withstand all chemical obliterants. Some of these are made to remain invisible till some re-agent be applied, others require chemically-prepared papers, and others again can be rendered visible or invisible at pleasure.

Dyeing.

A remarkable circumstance connected with dyeing, is the different degrees of facility with which animal and vegetable substances imbibe the colouring matters applied to them. Tissues composed of the former, as silk and wool, receive more brilliant colours than those composed of the latter, as cotton and linen. The cause of this difference has not hitherto been discovered.

Although in the most numerous class of cases it is easy to impart colour to various tissues, yet when these become exposed to moisture, the dye-stuff is removed. It has therefore been found necessary to employ certain chemical substances, which shall have the property of permanently fixing the colour upon the body which is dyed. These substances have obtained the name of *mordants* (from the Latin word *mordere*, to bite), because they were supposed at first, figuratively speaking, to bite the dye into the cloth. The same name has also been applied to those preparations which possess the property of altering the shade, or of heightening the colour, as it is called. The latter, at the suggestion of Berthollet, are sometimes termed *alterants*. The principal mordants are alumina, employed universally, we believe, in the form of a salt, as that of alum; the oxides of tin, employed like the former in the shape of salts, which are prepared by dissolving tin in muriatic acid. Silk and woollen dyers, however, employ nitric acid or aqua-fortis for forming the salts of tin which they use. The salts of lead and copper are likewise had recourse to as mordants; and the gall-nut, which contains two very peculiar vegetable substances—tannin and gallic acid—is not only employed as a mordant, but also as a simple and powerful dye-stuff.

By varying the mordant, a great variety of shades may be derived from the same colouring matter. Indeed, the mordant itself, in many instances, supplies a colour. For example, in dyeing with cochineal, when the aluminous mordant is employed, the colour produced is crimson; but when oxide of iron is substituted for the alumina, a black colour is the result. The whole phenomena are accounted for on the principle of chemical affinity or attraction. The mordant employed should have an attraction both for the stuff to be dyed and the colouring matter, and act, as it were, like a third party, in reconciling two inimicals. The way in which it is used must depend entirely upon the degree of affinity exerted between the stuff and the colouring matter. Where that is slight, the former should be saturated with the mordant before the latter is communicated. A knowledge of the nature and chemical affinities of the substances used is necessary, before mordants can be had recourse to as a medium of union in imparting colour to cloths, or other stuffs which we wish to dye; for, by an indiscriminate use of them, results the very opposite of those anticipated may take place.

Calico-Printing.—In impressing the representation of figures on calico goods, the object generally held in view is the fixing of mordants on the cloth, which is afterwards dyed in the usual way, those parts which have received the mordant only retaining the colour, the rest remaining white. In some cases the colour is removed from certain portions of cloth already dyed, so that they may either remain white, or receive some new colour afterwards. Sometimes it is applied to cloth before it is dyed blue, in order to prevent the indigo from being fixed on those parts to which it is applied, that they may remain white, or receive other colours afterwards. Substances possessed of this property are called resist-pastes. Lastly, it is frequently employed to communicate mordants and colouring matter at once to cloth. The thickening of the mordants is of considerable importance towards the successful practice of the art. The application, or the bringing out of the colours, is an ingenious chemical process. Madder is the substance commonly used for red by the calico-printers, and the addition of sumach, fustic, or quercitron bark, will produce a variety of tints with the various mordants at one operation. 'Suppose,' says Dr Ure, 'we wish to produce flowers or figures of any kind, containing red, purple, and black colours, we may apply the three mordants at once by the three-colour cylinder-machine, putting into the first trough acetate of alumina thickened; into the second acetate of iron; and into the third a mixture of the two; then drying in the air for a few days to fix the iron, dunging, and dyeing up in a bath of madder and sumach. If we wish to procure the finest madder reds and pinks, besides the purple and black, we must apply at first only the acetate of alumina of two densities, by two cylinders; dry, dung, and dye up in a madder bath. The mordants of iron liquor for the black, and of iron liquor, mixed with aluminous, for the purple, must be now grounded in by blocks, taking care to insert these mordants into their precise spots; the goods being then dried with airing for several days, and next dunged, are dyed up in a bath of madder and sumach. They must be afterwards cleared by branning.' (See No. 22.)

After the cloth is dyed, it is washed either with soda, potash, soap, or fresh water, according to the nature of the ingredients used in the dyeing process. Great care is necessary in this department; for if the washing liquor be too strong, the mordant may be injured. Cow-dung diffused through hot water, is applied to calico goods in a particular stage of the manufacture. This is done in order to dissolve and carry off from the cloth a portion of the thickening matter, and also to prevent any undissolved mordant or acetic acid from injuring the blank parts of the piece. The dunging, as it is called, is performed several times, generally between the washings. The piece should be immersed, if possible, without folds, and to secure this it is made to pass through rollers. As soon as it comes out of the dung-bath, it is washed in the dash-wheel as in bleaching. The cloth is then finished by being passed through a calender, which greatly improves its appearance. The action of the solution of cow-dung in cleansing from impurities is both mechanical and chemical; as respects the chemical part of the operation, it will be understood when we mention that cow-dung contains muriate of soda, sulphate of potash, sulphate of lime, carbonate of lime, and other detergent matters.

Bleaching.

Bleaching is the art by which various articles may be deprived of the colours which they naturally possess, and so rendered white. Formerly, it was the custom to submit textile fabrics in a moist condition to the free action of the atmosphere and sun's light; but this process of bleaching was not only imperfect, but tedious; and the substitution of a chemical effect, as suggested by the celebrated chemist Berthollet (1787), was a great improvement, such as the state of manufacturing industry required. Berthollet's plan consisted in employing chlorine, which possesses a wonderful power of removing vegetable colours. The bleaching-powder, or chloride of lime, as it is usually called, is manufactured by exposing slaked lime (hydrate of lime) to the action of chlorine gas, till as much of the latter is absorbed as the lime is capable of combining with under these circumstances. The chlorine in the bleaching-powder, which is not applied till after sundry preparatory washings of the cloth, acts upon vegetable substances, by dissolving their hydrogen, which is the colouring agent; the air would have the same effect, but would require a much longer time than can be allowed. The cloth is left in a cold solution of the bleaching-powder for about six hours, and is then taken out and washed with water. The next part of the process is called *souring*, which is immersing the cloth in a solution of sulphuric acid, so diluted that it does not injure the texture of the goods, whilst it improves their colour. The sulphuric acid dissolves and removes the oxide of iron with which the cloth is always contaminated; it also removes the lime which may have attached itself to the cloth during its previous treatment with that substance. It is again washed, boiled in an alkaline lye, and once more carefully washed in cold water. Another solution of bleaching-powder, two-thirds the strength of the former, is then prepared, in which the cloth is immersed, and left for five or six hours; it finally undergoes another process of souring, by which means it is rendered perfectly white. The acid is carefully removed by washing; and after each piece of cloth has been stretched to its full length, it undergoes a process of mangling, by being passed successively between cylinders forced towards each other by levers, to which a considerable weight is attached. The cloth being thus stretched, smoothed, and wound upon a roller, is rendered fit for *starching*. The starch is that of flour, deprived of its gluten by remaining for twenty-four hours in water, and then passed through a sieve, which retains the bran, and allows the starch to pass. A little indigo is mixed with it, and sometimes porcelain clay. The starch is applied in the state of a pretty thick paste whilst the cloth is passing between a pair of rollers. The goods are then dried, and passed through a calender, for the purpose of giving them a gloss and texture.

Such is the process of bleaching, as practised in the large bleaching establishments on the common class of goods. The number of processes which the cloth undergoes amounts to about twenty-five, but some of the earlier ones are occasionally omitted. The expense of bleaching and finishing a yard of cotton cloth is about one halfpenny, and the time required is trifling. A bleacher in Lancashire, we are told, received fourteen hundred pieces of gray muslin on a Tuesday, which, on the Thursday following, were returned bleached to the manufacturers, at the distance of sixteen miles; and on the same day they were packed up and sent to a foreign market. But for this new process of bleaching by chlorine, it would scarcely have been possible for the cotton manufacture of Britain to have attained its present enormous extent. Chlorine is easily and chiefly obtained from the muriatic acid generated in the process of extracting soda from sea-salt. In liberating the chlorine from the compound acid, the main expense is caused by the employment of manganese; but it is more than likely that the use of this substance will shortly be superseded by one or other of the processes which have lately been patented for the purpose. We may remark, in conclusion, that the common prejudice against stuffs bleached by chlorine is groundless; they suffer less in the hands of skilful workmen than those bleached in the sun. (See No. 22.)

Combustibles.

The class of combustibles in the manufacture of which a knowledge of chemistry is more particularly required, includes gunpowder, gun-cotton, fulminating powders, the material of Congreve and skyrockets, bombshells, percussion-caps, rapidly-igniting matches, and of fireworks generally. The term *Pyrotechny* (from *pyr* fire, and *techné*, art) has been applied to the art of making and compounding those substances.

The leading ingredients in most explosive combustibles are charcoal, saltpetre, or nitre, and sulphur. In making fireworks of a varied kind, however, numerous other substances are employed. The chief are chlorate of potass, fulminating silver, and mercury, preparations of steel, copper, and other metals, with various oils, spirits, and resins. Charcoal, as is mentioned in the preceding sheet, is simply wood reduced to a charred condition (pure carbon), by being burnt to a kind of blackened cinder in a vessel closed from the atmosphere. For making gunpowder, light woods, such as the willow and alder, are the best, and the pieces are stripped of their bark before being used. In preparing this kind of charcoal, it is important that the vapours be allowed freely to escape, otherwise its combustibility will be impaired. The preparation is usually effected by iron retorts over furnaces; and by a connecting tube the vapour escapes, and is condensed into a tarry acid, from which pyroligneous acid is afterwards distilled. After being thus prepared, the charcoal is reduced to a fine powder.

Saltpetre, nitre, or nitrate of potass, is abundant in nature, but may be also compounded by the artificial union of its two ingredients—nitric acid and potass. It is procured largely from India, and also from Egypt, Spain, and other countries, where it is found on the surface of limestones, marls, and chalky strata, being spontaneously generated and reproduced there by some atmospheric influence not well understood. The slight silky tufts of the nitre are swept up with a broom, and are lixiviated, allowed to settle, evaporated, and crystallised. In this state it is exported; but the impurities which it contains require its subjection to successive solutions and crystallisations, ere it can be employed in the manufacture of gunpowder. The last process is that of fusion, in iron pots at a regulated heat. It is tested by adding to its solution in distilled water nitrate of silver, with which it occasions no perceptible opalescence.

Sulphur is procured in many volcanic countries, but the great emporium for it is Sicily. It can also be obtained from the metallic sulphurets as from iron pyrites. At the gunpowder works it is purified for use either by distillation or by fusion. In the first instance, the pure part is distilled over, and in the second, skimmed off, the impurities being left behind.

Gunpowder.—The three ingredients, charcoal, nitre, and sulphur, being duly prepared by trituration, and passed through fine sieves, they are ready to be mixed. There appears to be a great difference of opinion and practice in determining the relative proportions of the ingredients. The following is a scale of proportions in 100 parts, adopted by different gunpowder makers:—

	Nitre.	Charcoal.	Sulphur.
Royal mills at Waltham Abbey, -	75	15	10
French, for war, - - - -	75	12·5	12·5
... for sportsmen, - - -	78	12	10
... for mining, - - -	65	15	20
Chaptal's proportions, - - -	77	14	9
Mr Napier's ditto, - - -	80	15	5

The mingled ingredients are now carried to a mill, to be properly blended, by the pressure of a revolving stone on edge; the stone is of a calcareous quality, and goes round on a bedstone of the same nature; no metal or sandstone is employed either about the machinery or the mill-house, in order to avoid the danger of sparks. 'On this bedstone,' says Dr Ure in his history of the manufacture, 'the composition is spread, and moistened with as small a quantity of water as will, in conjunction with the weight of the revolving stones, bring it into a proper body of *cake*, but not of *paste*. The line of contact of the edgestone is constantly preceded by a scraper, which goes round with the wheel, continually scraping up the cake, and turning it into the track of the stone. From fifty to sixty pounds are usually worked at once in each mill-wheel. When the cake has been thoroughly incorporated, it is sent to the corning-house, where a separate mill is employed to form the cake into grains or corns. Here it is first pressed into a hard firm mass, then broken into small lumps; after which the graining is executed by placing these lumps in sieves, on each of which is laid a disk of lignum-vitæ. The sieves are made of perforated parchment. Several such sieves are fixed in a frame, which, by proper machinery, has such a motion given to it as to make the lignum-vitæ runner in each sieve move round with considerable velocity, so as to break the lumps of the cake, and force the substance through the sieves, forming grains of several sizes. These granular particles are afterwards separated from the finer dust by proper sieves and reels. The corned powder is next hardened, and the rougher edges taken off, by being revolved in a close reel or cask turning rapidly on its axis. This vessel somewhat resembles a barrel-churn: it should be only half full at each operation, and has frequently square bars inside, parallel to its axis, to aid the polish by attrition. The gunpowder is now dried, which is done generally by a steam-heat, or by transmitting a body of air, slightly heated in another chamber, over canvas shelves covered with the damp gunpowder.'

Gun-cotton.—Much interest and excitement (we abridge from the English edition of Knapp's 'Chemical Technology') have been recently caused by the announcement of a substitute for gunpowder, which is said to be four times more powerful than that substance, weight for weight, to ignite at a much lower temperature, to be uninjured by water, and to burn without smell, smoke, or residue. This substance is the gun-cotton of Dr Schönbein, to whom the credit is due of discovering and making known the various useful purposes to which this remarkable body may be applied, although its actual discovery dates from a period prior to that when Schönbein published his experiments. Without entering upon either its history or its theoretical composition, as manifested in what are called xyloidine and pyroxyline, we shall merely advert to the plan adopted for the preparation of gun-cotton in the laboratory of the chemist—no minute description of its manufacture upon a commercial scale having yet been published:—Well-cleansed cotton is immersed in a mixture composed of equal parts* of concentrated nitric and sulphuric acids, for about ten or fifteen minutes; and to prevent accidents, no portion of the cotton should be above the level of the liquid. The acid should then be pressed out, and the cotton which remains impregnated with it is well washed with water, until no acid reaction is perceptible to the tongue; it is now dried at a temperature not exceeding 212° Fahrenheit. Care should be taken in drying this substance to allow a free current of air to pass over it, and to spread out the cotton as much as possible, to prevent its forming into dense masses, which are said to be much more liable to explode.

The properties of the substance so prepared are very extraordinary, and create a greater degree of astonishment, in consequence of its outward appearance bearing the strictest resemblance to ordinary cotton wool, which, however, is not so harsh to the feel. It is insoluble in water both hot and cold; and when removed and dried, is found to have lost none of its original properties. It explodes violently when heated to 356° Fahrenheit, or on ignition, leaving scarcely any residue, and creating very little smoke. The temperature at which it is thus decomposed is so much below that at which gunpowder explodes, that the cotton may be lightly placed upon the surface of gunpowder, and detonised by a red-hot wire without setting fire to the powder. Friction of the ordinary kind will not explode gun-cotton; but when placed on an anvil, and powerfully struck with a hammer, the heat generated by the stroke causes it to detonate. With reference to the projectile force of gun-cotton as compared with gunpowder, no authoritative statements have yet been made; but there appears reason to apprehend that its action in its present form is too rapid, and resembles too much that of fulminates, to render it applicable to the purposes of artillery. The gaseous products from its combustion are also such as cannot be altogether resisted by firearms, although, if air be absent, no great amount of corrosion can ensue; and as it has been found that gun-cotton impregnated with chlorate of potash or nitre has a still more powerful effect than that prepared in the usual way, the addition of these substances would at the same time tend to modify the corrosive action of the acid products of combustion. As a substitute for gunpowder in all mining and blasting operations, however, the superior local force of the cotton will be highly valuable; and it has indeed been found to effect as much as four times its weight of powder.

Rockets.—The common modern rockets, which are generally employed as signals or tokens of rejoicing, may be described as tubular cartridges of paper, pasteboard, wood, or metal, filled with combustible substances, which, on ignition, cause the cartridge to shoot rapidly through the air. The movement may be irregular, parabolic, or perpendicularly upwards, according as a small stick or guide is attached, or otherwise, to the cartridge, to direct its movements. The principle on which rockets rise in the air is simple, and may be explained here, once for all, as it applies to all varieties of flying fireworks. A vessel containing a fluid which tends to expand, will be motionless so long as the vessel is closed on all sides, because the pressure is then equal everywhere; but if an opening exist, the pressure will not be equal, and the vessel will then tend to move in the direction in which the pressure exists. If the opening be below, the tendency will be to rise; and if the expansive force be great enough, and the vessel sufficiently light, the vessel will obey the pressure, and ascend. When the expansive force is exhausted, it will again descend, by the ordinary influence of gravitation. In the case of the rocket, the combustion, commencing below, creates the expansive gas, and the pressure forces the rocket upwards. The cartridge or tube, commonly of pasteboard or pasted paper, must be very strongly formed, if large, and intended to ascend high. Inside of it is a second tube, called the *soul* or *fusee* of the rocket, the purpose of which is to leave a vacant space round the axis, that the volume of elastic gas which the ignition produces may act on a vacant space. On account of its somewhat conical form, hollow rods, adjustable to different broaches or skewers, are used in packing the charge, the cartridge being sustained by a copper mould or cylinder at the time. The charge of sky-rockets varies according to the bore of the cartridge. Nitre 16, sulphur 4, and charcoal 7, are the contents and proportions of the charge when the bore is three-fourths of an inch; and the charcoal is merely increased a very little when the bore is enlarged. This is the common rocket, with the usual light of gunpowder. When a rocket with a *brilliant* light is wanted, 3 parts of fine steel-filings are added; and when the light called the *Chinese-fire* is desired, 3 parts of fine borings of cast-iron form the addition to the three ingredients first mentioned. These are the common rockets: the sources of other kinds and colours of light will be noticed immediately.

* Schönbein recommends the use of 3 parts sulphuric acid, and 1 nitric acid of the specific gravity 1·5.

The *garniture* of a rocket, as the crackers, showers of fire, stars, serpents, &c. are called which are commonly attached to it, with what is termed the *pot*, are of course added before igniting the charge in the central tube or fusee. 'The pot is a pasteboard tube, wider than the body of the rocket, and one-third of its length. After being strangled at the bottom like the mouth of a phial, it is attached to the end of the fusee by means of twine and paste: these are afterwards covered with paper. The garniture is introduced by the neck, and a paper plug is laid over it. The whole (for still greater strengthening) is enclosed within a tube of pasteboard terminating in a cone, which is firmly pasted to the pot. The quick-match is now finally inserted into the *soul* of the rocket, and a light rod or stick attached to the end of the whole, to keep it in a perpendicular ascent.' The beauty of the rocket depends much on the style of the garniture. These, whether stars or serpents, are charged fusees, stronger or weaker, formed into the shape wanted, and giving kinds of light modified by the ingredients. Stars which give golden showers are formed of nitre, 16; sulphur, 16; charcoal, 4; gunpowder, 16; lamp-black, 2. *Petards* are sealed cartridges, which burst in the air; and *crackers* are square boxes of pasteboard, hooped, and charged with gunpowder. But the finest accompaniment of the rocket is the Roman candle, which is a fusee so formed as to throw out in succession, as the combustion reaches them, very fine stars. These stars are small cylindrical masses of nitre, sulphur, and gunpowder, steeped in spirits and gum. The variety of rockets of course depends on the difference of size and garniture.

Congreve rockets, first used in the attack of Boulogne, 1806, are of various dimensions, and are differently armed as they are intended for the field or for bombardment. Those of the first sort carry shells or case-shot; the others are armed with a very combustible material, and are called *carcass rockets*. Their form is cylindrical, and they are composed of strong metallic cases. The sticks employed for regulating their flight are of different lengths, according to the size of the rocket. The carcass rockets are armed with strong iron conical heads, pierced with holes, and containing a substance as hard and solid as iron itself, which, when once inflamed, is inextinguishable, and scatters its burning particles in every direction. When this substance is consumed, the ball explodes like a grenade. The rocket is projected horizontally, and whizzes loudly as it flies through the air. The ammunition is divided into three classes—heavy, medium, and light: the heavy including all above forty-two pounds; the medium, those from forty-two to twenty-four pounds; and the light, from eighteen to six pounds inclusive. The Congreve rockets were used at Leipsic and Copenhagen; but experience has proved them to be much less efficacious than common artillery, and, besides, the secret of their manufacture is now known everywhere.

Bomb-shells are spherical cases of metal, fitted to be discharged by cannon, and containing a central charge of gunpowder, with an external charge of substances fitted to spread and inflict injury on the explosion of the powder, which is ignited by a fusee. The bombs also spread combustion where they alight. The experience of the late sieges of Antwerp by the French, and Acre by the British, has shown that this species of warlike machine is calculated to rise into greater importance than it has hitherto done, rendering forts and cities untenable when it is well used.

Of *fixed fireworks*, or those whose motion is confined to a spot, as jets, wheels, suns, trees, lances, spirals, revolving suns, double or Catherine wheels (two suns in one axis, revolving opposite ways), and many other beautiful contrivances, are now common exhibitions. In all preparations of a pyrotechnic nature, nitre, sulphur, charcoal, and gunpowder, are the chief ingredients. By means of spirits, gums, resins, and oils, the quality and duration of the light are modified, and the principal articles of that description in use are alcohol, bitumen, camphor, wax, turpentine, lard, and the like. Again, the colour of the fire, on which so much of the splendour rests, is modified by employing other articles. Copper-filings and sal-ammoniac give a greenish tint to flame; zinc, a fine blue; amber, and very dry common salt, a yellow; lamp-black produces a deep red with gunpowder, and a pink with nitre in excess; camphor gives a fine white; lycopodium gives a rose colour; and sulphate of strontia, a beautiful purple light. Many other substances are at the command of the pyrotechnist, which produce variations of colour.

Instantaneous Matches, commonly known as *Lucifers*, are nearly all made of one substance—the chlorate or oxy-muriate of potass. Dr Ure's formula for making the matches is as follows:—Thirty parts of the chlorate, in fine powder, are to be mixed gently with a knife upon paper with ten parts of very fine sulphur, eight of sugar, five of powdered gum-arabic, and enough of powdered vermillion to give a rose tint to the whole. The chlorate, gum, sugar, and vermillion are then gently but well mixed, after which as much water as will make a thin paste is added, and then the sulphur is thoroughly mixed with the whole. A great improvement, however, has lately taken place in the use. The matches were dipped formerly in sulphuric acid; but by adding a little more of the chlorate and sulphur than is in Dr Ure's recipe, they are lighted by friction on sand-paper, or any other rough substance.

Of the numerous *fulminating powders* known to chemists, none, comparatively speaking, has any economical importance, except the fulminate of mercury, which is used for *percussion-locks*. We believe that a report to the government of Great Britain in 1831, made by Dr Ure, had the effect of introducing the improvement of percussion-locks into the public service. The formula which that report gives for the manufacture of the fulminate is as follows:—Dissolve 100 parts of mercury in 1000 parts of nitric acid, and add the solution to 830 parts of alcohol, a large vessel being used. A gas rises, which must be allowed to escape, and at a distance from flame. When the effervescence ceases, the contents of the vessel are to be poured out on a large double paper filter in a glass funnel, and cold water thrown over it till the drainings no longer redden litmus paper. The powder adhering to the vessel is also to be placed on the filter, with a little water. The superfluous acid thus washed away, the powder of fulminate of mercury, adhering to the filter, is lifted away, and opened out on plated copper or stoneware heated by steam. The powder, when dried, is in the form of small gray crystals, and is then to be packed in small parcels, and kept close from the air in bottles or boxes. Dr Ure examines several other modes of making the fulminate, but points out defects in all; and his own, though not free from them, was the one adopted most generally we believe. Two and a half pounds of the fulminate, when prepared for the purpose, will charge 40,000 percussion-caps, according to the calculation of French manufacturers. The preparation consists in grinding the fulminate upon marble with 30 per cent. of water, adding six parts of gunpowder for every ten of the fulminate. A dough is obtained, which, when dried in the air, is introduced in small fixed portions into the bottom of the percussion-caps. The fulminate was formerly placed dry in the bottom of the cup; but of late a most important improvement has taken place, in so far as an alloy of copper is made for the purpose, which contains the fulminate within itself, so that there is now no chance of injury by wet, or danger from the mixture.

When combustibles are ignited, they *explode* with a loud noise, and with an extraordinary degree of force. The explosive sound is caused by the rapid resolution of the combustibles into gaseous products, and the shock of these striking upon the volume of the external atmosphere. The explosion is indeed a chemical process, in which a tangible material suddenly vanishes into gases, and is no more seen; its force depending on the strength of the charge—that is, the quantity of elastic vapour to be expanded.

FICTILE MANUFACTURES.

We employ the term *fictile*—from *fingo*, I fashion—to comprehend all those arts which, like that of the potter, involve the moulding or fashioning of crude materials into determinate forms. Thus, with some degree of latitude, earthenware, porcelain, glass, bricks, tiles, mosaic tesseræ, cements, artificial gems, and the like, may be designated Fictile Fabrics, in contradistinction to those of woollen, linen, silk, cotton, and other vegetable and animal fibre, which are strictly textile. The subjects thus embraced are numerous and important; of scientific importance, as involving at every step the deductions of chemistry and the principles of taste; and economically so, as elaborating from the crude and apparently worthless materials of the soil an almost infinite variety of articles of utility and elegance. Our limited space precludes the idea of a minute account, and restricts us merely to the leading features of the manufactures in question.

EARTHENWARE.

Pottery may be generally defined as the art of making vessels from clay, or from other mineral substances ground and rendered plastic like that body. The manufacture of porcelain or china is not included in this definition, inasmuch as it is semi-vitrified, and becomes translucent in the kiln. The fabrication of earthenware—that is, mere sun-dried or fire-dried vessels of clay—seems to have been one of the earliest of human arts; but pottery with a painted glaze was unknown till about the ninth century, when it was first attempted by the Arabs in Spain. Soon after, it found its way into the island of Majorca, where considerable progress was made in the art. From Majorca it was introduced into Portugal, Italy, and France, and thence into Holland. In the seventeenth century a pottery was established at Burslem, in Staffordshire, at which, however, only the coarsest articles of brown ware were manufactured. Subsequently, the glazing of this ware by the vapour of salt—obtained by throwing handfuls amongst the heated articles in the kiln—was introduced by Mr Palmer; and in this state the manufacture continued till 1690, when two Dutchmen of the name of Elers commenced at the same place the fabrication of red unglazed porcelain, of black or Egyptian ware—the tint of which was produced by manganese—and of brown ware of a higher glaze and finish than had hitherto been produced in England. Some years afterwards, Mr Astbury was led by accident to attempt the admixture of ground flint with the finest white clay—a composition which yielded not only a finer and whiter, but a more durable ware than had previously been manufactured. It is to the late Josiah Wedgewood, however, that Britain is mainly indebted for the vast improvements which have taken place since the middle of last century in this department of her manufacturing industry. It was he who erected the first large factories in Staffordshire, and who, from his extensive chemical and mechanical knowledge, conjoined with correct taste, has made the stoneware manufactures of this country superior to those of every other.

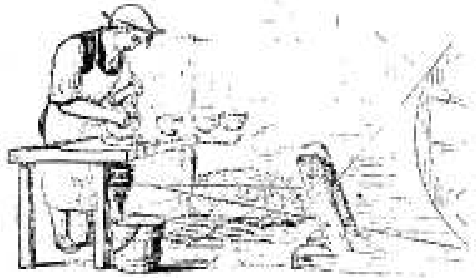
The best clay for pottery manufacture is obtained in Dorsetshire, and another of a quality somewhat inferior is found in Devonshire. These clays are both well suited for the potter, being easily worked, standing the fire well, and becoming very white when burnt. When dug, the clay should be cleansed as much as possible with the hand, and freed from stones. At the factory it is cut to pieces, and put into a cast-iron cylinder about four feet high and twenty inches in diameter. An upright shaft or axis revolves in this cylinder, from which knives radiate in all directions, being so placed, that the shafts with the knives attached somewhat resembles a screw. In the sides of the cylinder knives are also fixed, which reach nearly to the shaft, and remain inactive. When the shaft moves round, the active blades cross the passive, and operate like shears in cutting the clay, which is by this process reduced to a fine pulp. When well ground in this manner, the clay is of the consistence of cream, and is run off through sieves of wire, lawn, and silk, so that none of the grosser parts may enter into the composition of the ware. This clay-cream, or *slip*, as it is termed, is then diluted to a standard density, and set aside in cisterns, to be used as required.

Vessels made from clay alone, however, are found to crack upon being put into the kiln; and to prevent this, it is necessary to add some siliceous substance, incapable of contraction, to the clay. Ground flint is most commonly used for this purpose. It is prepared by cleaning the flint found imbedded in chalk, subjecting it to a red heat, and throwing it in this state into water, by which it becomes comparatively soft. It is then broken by being placed under an upright shaft, which moves up and down in a frame, and is called a *stamper*. The broken flint is next transferred to the flint-mill, which consists of a strong wooden tub, built round a circular bottom, composed of flat pieces of hornstone. On the top of these, similar flat stones are laid, which are attached to, and driven by, strong wooden arms projecting from an upright shaft in the centre of the box. Into this tub the flint is put, and a stream of water is constantly running in, which greatly facilitates the grinding. When the flint is reduced to about the consistence of cream, it is passed through sieves, in a manner similar to the clay. The story of the accidental discovery of this material by Astbury is worth recording:—While on a journey to London, this potter was compelled to seek a remedy for the eyes of his horse, which seemed to be rapidly going blind. The ostler of an inn near Dunstable burned a common black flintstone, pulverised it, and blew a little of the dust into the eyes of the horse, by which they were made to discharge copiously. Astbury having observed the white colour of the calcined flint, and the ease with which it was then reduced to powder, immediately conjectured that it might be usefully employed to improve the colour of his pottery. On his return home he availed himself of his observation, and soon produced a kind of ware superior to any that had hitherto been fabricated. The flints were at first pounded by manual labour in mortars; but an increased demand soon compelled the invention of grinding-mills as above.

The flint and clay liquids being properly prepared, they are next mixed together in such proportions that the flint powder will be to the dry clay as one to five or six, according to the plasticity of the clay. Sometimes a little Cornish stone is also added; and the following are the proportions generally adopted in one of the principal Staffordshire factories for what is designated *cream colour*:—Silex, or ground flint, 20 parts; clay, 100 parts; and Cornish stone, 2 parts. This mixture is put into oblong stone troughs called *slip kilns*, bottomed with fire-tiles, and placed above a furnace flue. Heat is then applied, and the water gradually evaporated, the liquid being constantly stirred during the operation. By this process the mixture is formed into a fine uniform doughy mass, which is cut into pieces, and heaped together in a damp cellar, where they lie for the space of about six months. The clay here becomes black, exhales a fetid odour, and is supposed to undergo a slight degree of fermentation. The longer the clay-paste is kept, the finer it becomes in the grain; and vessels made from it when old, are not so apt to crack as those formed from newer paste.

Another operation, called *slaying*, or *wedging*, greatly assists in forming a fine quality of clay. This consists in seizing a mass of clay in the hands, tearing or cutting it into two pieces, and striking them together again with a force sufficient to make them adhere. This is repeated about twenty or thirty times, by which the parts of the clay are completely intermingled. In large establishments, this operation is performed by means of a tub, with an upright revolving shaft, on which blades are fixed, the machine being similar to that used when the clay comes first from the pit. The clay is forced, by the downward pressure of the blades, through a pipe, and is cut into equal lengths, and again returned to the cylinder, until the parts are blended together. It is sometimes the practice to beat the clay with wooden mallets; this practice is common in France, and the stuff is afterwards trodden by the feet on a clean floor. In China and Sweden, oxen are made to tread upon the clay, to form it into a proper dough. A process called *slapping* is performed by cutting a large mass of clay with a wire, and striking the two pieces together with considerable force. This is generally done as the clay is to be used, either in the same apartment in which the manufacturing or moulding process is performed, or in an adjoining one.

The clay being thus completely kneaded, is put upon the potter's lathe, where it is formed into articles of various shapes. This lathe consists of an upright iron shaft, the lower point of which turns in a socket, and the upper is fixed in a broad wooden disk. Near the top the shaft passes through a socket attached to the framework of the lathe. In the centre is a pulley, with grooves of different circumferences, by which the speed of the shaft can be increased or lessened as circumstances require. This shaft is driven by a fly-wheel, from which an endless belt passes to the pulley. The clay is weighed out and handed to the workman at the



lathe, called the *thrower*, who dashes the mass upon the revolving wooden disk. He then dips his hands frequently into a dish of water placed beside the lathe, and pressing the clay with both hands, it gradually assumes an irregular conical form. By pressing one hand upon the top of this cone, it is again flattened down to a cake, by which operation all air-bubbles are extricated. He next lessens the speed of the shaft by shifting the belt from a small to a larger groove in the pulley, and forms the clay into the shape of the vessel required. This operation is called *throwing*; and when performed, the vessel is cut off from the disk by a wire attached at each end to a piece of wood. The vessel is then allowed to dry gradually, until it arrives at a certain point called the green state, after which it is put upon a turning-lathe, similar to that used by the worker in wood. Here it is turned to its proper shape by a sharp tool, which also smoothes it, and after this it is burnished with a steel surface.

In the green state, also, are attached handles and other appendages to vessels, this being the point at which the clay possesses its greatest tenacity, till it is burned. Handles of teapots, &c. are formed by squeezing the dough through different shaped orifices, which, as it issues, is cut into proper lengths, and bent into the desired forms. These being formed, are attached to the vessels by a paste called *slip*, and the seams are smoothed off with a wet sponge. The ware is next placed in an apartment heated to about 90° Fahrenheit, and fitted all round with shelving. When completely dry, they are rubbed over with hemp, and are then ready for the baking kiln.

The articles made in the manner above-described are all of a round form; but there are many which are of a different shape, and require a different process in the manufacture. Oval-shaped vessels are formed by what is called press-work, which is done in moulds made of plaster of Paris. One-half of the pattern is made in the one side of the mould, and the other half in the other side. The parts are formed to fit each other exactly, and are joined in the same manner as the handles are to vessels. Imitations of flowers and foliage are executed in moulds of plaster of Paris. The clay is poured into the mould in a thin state, and is there left for a certain time. The plaster soon absorbs the water, which renders the clay tough; and its thickness depends upon the time it is allowed to stand in the mould. These *furnishings*, as they are called, are then dried to the green state, and fastened on with slip.

When the ware is ready for the kiln, the articles are placed in baked fire-clay vessels called *sags*, or *saggers*. These vessels are made of inferior clay by the workmen during the intervals of their work, and are from six to eight inches deep, and from twelve to eighteen in diameter. The sags are packed full of the dry ware, and are then piled above each other in the kiln, the bottom of one sag forming the cover of another. These rude dishes are necessary, to prevent the ware from being suddenly and unequally heated, and also to protect it from the smoke and dust of the kiln.

The body of a pottery kiln is generally of a conical shape, and inside of this is the fire-kiln, which is circular and round at the top. When the kiln is filled with the sags, the doorway is built up, and fire applied to the furnaces. The heat is increased gradually, from the time the fire is put on till the ware is found to be properly burnt. To ascertain this, the workman draws from the kiln what is called a *watch*, and if this is found to resemble in colour a previously-burned vessel, he allows the kiln to burn a little longer, and then opens the doors of the furnaces carefully, so as to lower the heat by slow degrees. The burning, or *baking*, as it is called, usually lasts from forty to forty-two hours, after which the kiln is allowed to cool very slowly. When the ware is taken out of the sags, a child makes the pieces ring with the handle of a brush, used for dusting them, and then immerses them in the glazing material. The glaze is kept in a large tub, into which the articles are put by the child, and lifted out by a man, who shakes them in the air, and places them on a board, to be conveyed to the glazing kiln.

'Three kinds of glazes,' according to Dr Ure, 'are used in Staffordshire—one for the common pipe-clay, or cream-coloured ware; another for the finer pipe-clay ware, to receive impressions, called *printing body*; a third for the ware which is to be ornamented by painting with the pencil. The glaze of the first, or common ware, is composed of 53 parts of white lead, 16 of Cornish stone, 36 of ground flints, and 4 of flint-glass; of the second, 26 parts of white felspar, fretted with 6 parts of soda, 2 of nitre, and 1 of borax; to 20 pounds of this frett, 26 parts of felspar, 20 of white lead, 6 of ground flints, 4 of chalk, 1 of the oxide of tin, and a small quantity of the oxide of cobalt, to take off the brown cast, and give a faint azure tint, are added. As to the ware which is to be painted, it is covered with a glaze composed of 13 parts of the printing colour frett, to which are added 50 parts of red lead or litharge, 40 of white lead, and 12 of flint; the whole having been ground together.'

The above compositions make a very clear, hard glaze, which is not affected by vegetable acids, and preserves its lustre for an indefinite time. When covered with the glaze, the vessels are put into sags, which have been previously glazed, with a composition of 13 parts common salt, and 30 parts potash. They are then put into the glazing kiln, which is usually smaller than the biscuit kiln, the sags being piled in the same manner as at the first burning. The heat of the glazing kiln is very low at first, but gradually increases until it reaches the melting-point, when great care is necessary to prevent the temperature from suddenly falling. To ascertain when the temperature is high enough, balls of red clay, coated with fusible lead-enamel, are employed. When these balls become of a slightly dark-red colour, the temperature is sufficient to glaze ordinary pipeclay ware. The fire is kept on for about fourteen hours, after which very little fuel is added, and the kiln is gradually allowed to cool. The vessels are again tried by being slightly struck by a small wooden hammer, when, if they ring freely, they are sound.

The colouring of pottery is performed either by what may be called painting, or by printing. The colours used in producing the *dipt* or *sponged* ware are of a very cheap kind, as it is only for common purposes that this material is employed. In dipt ware, the colours are dropped on before the ware is burned; and in sponged ware, when it is in the biscuit state. A black dip is made from manganese, ironstone, and clay-slip; a drab by nickel and slip; a blue by cobalt and slip; a yellow by yellow clay alone, or by a compound of red and white clay; and a red by a natural red or brown clay, which will burn red.

The colours used for painting and printing on ware are similar to one another, excepting that the colours for printing are more expensive; both, however, form an important and extensive part of the materials of a pottery. The manufacturers of earthenware are much occupied with the improvement of the variety and beauty of the colours, as well as of the patterns or styles that are produced, and hence a great emulation exists among those employed in the trade. The blue colour in *printing* is produced from cobalt, which is used with flint, ground glass, pearl-ash, white lead, barytes, china clay, and oxide of tin in reducing its strength; the brown by ochre, manganese, and cobalt; the black by chromate of iron, nickel, ironstone, and cobalt; the green by chrome, oxide of copper, lead, flint, and ground glass; and the pink by chrome, oxide of tin, whiting, flint, ground glass, and china clay, which are mixed in various proportions, fused together at a high temperature, then pounded and mixed with oil. The colouring matter is ground upon a porphyry slab, with a varnish prepared from a pint of linseed oil boiled very thick, 4 ounces of rosin, half a pound of tar, and half a pint of the oil of amber. This transfer varnish is very tenacious, and requires to be liquefied by heat before being used.

The figure or design to be fixed upon the vessel is engraved in the usual way upon copper-plate, which is rubbed over with the colouring matter prepared as above, and the impression is taken upon a thin unsized paper made for the purpose. The printed paper is placed upon the vessel, and is rubbed with a roll of flannel about an inch and a half in diameter. After this the vessel is set aside for a little, to allow the figure to become fixed, when it is dipped in water, and the paper washed off with a sponge. The impression being transferred, the vessel is dipped in alkali to destroy the oil, and then immersed in the glazing matter. Printing above the glaze is performed by covering the copper-plate with the colouring matter as before, and brushing off what is superfluous. A cake of glue, stiff enough to be handled, is then laid upon the plate, which receives the impression of the figure. The glue cake must be very cautiously lifted off from the plate, and transferred to the surface of the glazed ware which it is intended to print. The same cake will answer for transferring a number of impressions, by simply washing its surface.

It is but recently since a new method has been applied to cause the colours to flow or spread over the surface of the ware. This object is effected by washing the saggars in which the ware is placed, previous to its being fired in the glost-kiln, with a mixture of lime, common salt, and clay slip. Dry flows are also used, which answer equally well, the mixture being sprinkled on the bottom of the saggar. The following are some of these flows:—Lime, sal-ammoniac, and red lead or litharge; lime, common salt, and soda; and whiting, lead, salt, and nitre.

The ornaments on common stoneware vessels are made in relief in France, and hollow in England, by means of a mould in relief which is made to pass over the article. These hollows are filled with a clay paste of the colour required, while the vessel is turning upon a lathe. Network and variegated decorations are made in this manner by passing different layers of coloured clay over each other.

Metallic lustres, from gold, platina, copper, iron, &c. are produced by dissolving any of these metals in aqua regia, and applying it to the vessels. Over the metallic solution a glaze composed of 60 parts of litharge, 36 of felspar, and 15 of flint, is put, and the vessels burned as before. These *lustres*, as the wares so coated are called, have a rich metallic appearance, and would be highly prized if they were not so cheap and common.

STONEWARE.

This is a ware intermediate between common earthenware and porcelain, and may be described as a coarse kind of porcelain, made from sandy clay, containing oxide of iron and a little lime, to which it owes its fusibility. The glazing is performed by throwing common salt into the heated furnace; this is volatilised and decomposed by the joint agency of the silica of the ware and of the vapour of water always present; hydrochloric acid and soda are produced—the latter forming a silicate which fuses over the surface of the ware, and gives a thin but excellent glaze. The salt is not thrown in until the kiln has been raised to its greatest necessary temperature. Ware of this kind, we have said, is generally made of sandy clay and a little sand, to keep the body open, or less compact; but for large vessels, potsherd (which is ware that has been fired, and then ground) is employed, to render the body still more open and porous, and also to give it a capability of withstanding sudden heats or colds. This ware is much used in public works for chemical purposes; it is exposed to the action of the flame during burning, whereas other kinds of ware are protected by saggars.

Stoneware of the Wedgewood colour is a semi-vitrified ware, which is not susceptible of a superficial glaze. It is composed either of barytic earths, which act as a flux upon the clay, and form an enamel, or by the clay being rubbed over with a compound-vitrifying paste. Semi-vitrified ware undergoes an operation called *smearing*, by which the vessels do not require to be immersed in glaze. They are merely put into the glazed sags, which communicate by reverberation a lustre nearly equal in brilliancy to glaze itself. 'About the year 1805,' we quote the Encyclopædia Britannica, 'an article was produced called *ironstone-ware*, in which, however, not a particle of ironstone was introduced, it being a compound principally of the Cornish materials above-mentioned. This ware has nearly all the properties of the Japan porcelain; it possesses great hardness and density; is sonorous, but is deficient in whiteness and transparency, although the vitrification is as complete as in that of the Japan. It continues to be made in great quantities; and being more durable, is perhaps, though higher in price, as economical as earthenware. It is a cheap substitute for porcelain, but does not admit of those fine paintings and splendid decorations which are applied with so much success on that more elegant production.'

In connection with this department of pottery, we may briefly allude to the manufacture of *crucibles*—vessels alike indispensable to the chemist, the worker in glass, and the metallurgist. In this branch of the art we are indebted to Wedgewood for numerous important improvements. 'Crucibles,' says Brande, 'composed of one part of pure clay mixed with about three parts of coarse and pure sand, slowly dried, and annealed, resist a very high temperature without fusion, and generally retain metallic substances; but where the metals are suffered to oxidise, there are few which do not act upon any earthen vessel, and some cause its rapid fusion, as the oxides of lead, bismuth, &c. Where saline fluxes are used, the best crucibles will undoubtedly suffer; but platinum may be employed in these cases, and the chemist is thus enabled to combat many difficulties which were nearly insurmountable before this metal was thus applied. Whenever silica and alumina are blended, as in the mixture of clay and sand, the compound softens, and the vessel loses its shape when exposed to a long-continued white heat, and this is the case with the *Hessian* crucibles; consequently the most refractory of all vessels are those made entirely of clay, coarsely powdered burnt clay (potsherd) being used as a substitute for the sand. Such a compound resists the action of saline fluxes longer than any other, and is therefore used for pots in glass furnaces. A Hessian crucible, lined with purer clay, is rendered much more retentive; and a thin china cup, or other dense porcelain, resists the action of saline matters in fusion for a considerable time. Plumbago is a very good material for crucibles, applicable to many purposes; when mixed with clay, it forms a very difficultly-fusible compound, and is protected from the action of the air at high temperatures; it is well adapted for small table furnaces.'

PORCELAIN.

Porcelain or china * is a fine-grained, compact, very hard, faintly-translucent ware, of which there are two kinds; one called hard, and the other tender. *Hard* porcelain is composed of a clay containing silica, which is infusible, and preserves its whiteness in a strong heat, and of a flux consisting of silica and lime. The glaze of this ware is earthy, and admits of no metallic substance or alkali. *Tender* porcelain consists of a vitreous frett, which is rendered opaque by the mixture of a calcareous clay. It is glazed with artificial glass, into the composition of which silica, alkalies, and lead enter.

Kaolin clay is the largest ingredient in porcelain ware. It is composed of alumina and silica, and is obtained in large quantities in China, Germany, France, and in the county of Cornwall in England. Kaolin is very friable in the hand, and is with difficulty formed into a paste or dough which will bear to be worked. That found in Cornwall is whiter than the foreign clays, and more unctuous to the touch. It is a decomposed felspar—one of the constituent minerals of granite—which has accumulated in vast quantities in certain localities, having been no doubt washed down by rains from the weathered and exposed surface of granitic rocks. At one time the use of this substance was unknown in England; but now about 38,000 tons, worth about £50,000, are annually exported from the south of England to the Staffordshire potteries, and for the manufacture of mosaic tesseræ, buttons, artificial gems, and the like. In some localities, the kaolin is found in the form of a fine sediment; in others, it is mingled with coarser alluvia, and requires to be prepared by running a stream of water over it—the water carrying off the finer particles, which are received into catchpools or ponds, and there allowed to subside. The water is next run off, leaving a fine sediment, which is removed, and exposed to the atmosphere for four or five months, when it is ready for export. In France, the clay is washed at the pit, which is repeated after it arrives at the manufactory, and it is also passed through fine sieves. When in this state, felspar rock is added, by the addition of which it is rendered fusible. The felspar is calcined, broken with stampers, and afterwards ground in a burrstone mill, to render it as fine as possible. This mixture is poured into shallow plaster pans, which absorb the water, leaving a thick paste, which is placed in damp cellars for some months to ripen. The paste is again put into the plaster pans, and cut into small pieces, which are thoroughly dried and ground to a fine powder. It is then moistened and trodden by workmen, who walk over it in every direction. The clay is now ready for working, which is done either upon the lathe or by casting in moulds. The materials for making porcelain ware are much less plastic than those of other pottery ware, and consequently greater care must be bestowed on its manufacture. When vessels are made upon the lathe, the operations are exactly the same as for earthenware, but they must be performed with greater caution. It is stated by Dr Ure that a good workman at Sevrès, in France, makes no more than from 15 to 20 porcelain plates in a day; whereas an English workman, with two boys, will make from 1000 to 1200 plates of stoneware in the same time.

When formed, the vessels are allowed to dry very slowly, and are then put into the kiln, which is nearly the same as that used for burning pottery. In this kiln they receive a certain degree of heat, by which the vessels are rendered capable of being handled, and the clay loses its property of forming a paste with water. The vessels are then dipped in the glaze, which consists of felspar rock ground to a fine powder, and formed into a paste with water mingled with a little vinegar. When taken out of the glaze, the vessels are inspected, and the glazing matter applied with a hair-brush to any parts which may remain uncovered. A quality peculiar to porcelain is, that it softens in the fire, for which reason one piece cannot be piled above another in the saggs, as is done with stoneware. Every porcelain vessel requires a sag for itself, with a piece of level stoneware in the bottom, covered with sand. This prevents the vessels from warping. The sags are piled above each other in the kiln, and wood put into the furnaces. The heat is gradually increased for fifteen hours, at the end of which time the inside of the kiln has a cherry-red colour. The temperature is then greatly increased by putting small chips of aspen wood into the furnace, which is continued for from thirteen to fifteen hours. The whole firing occupies from thirty to thirty-six hours, when the porcelain is baked. The kiln is allowed to cool gradually for three or four days; and when taken out, the bottoms of the vessels are covered with the sand put into the sag, which is removed by friction.

Unglazed porcelain has the appearance of white marble or alabaster, and presents none of that shining glassy surface which it acquires by the application of those vitreous compositions called *glaze*. In this state it is known by the name of *biscuit*, and is now employed for many ornamental purposes—such as the formation of small figures or statuettes, vases, medallions, and other imitations of sculpture. The celebrated manufactory at Sevrès in France has long been distinguished for works in porcelain biscuit; and of late years, so many improvements have been made in the English manufactories, that they are probably not inferior in the delicacy and accuracy of execution in this department of ornament. We have now before us some Staffordshire specimens which have all the sharpness and distinctness of the finest sculptures in marble, with a degree of translucency which reminds one of alabaster or picked specimens of Parian marble. In point of durability and non-liability to get tarnished

* The term *china* is evidently derived from the name of the country which originally produced the first specimens of this ware; but the etymology of the word *porcelain* is not so obvious. One authority says, 'The Portuguese traders were the means of introducing the fine earthenwares of China into more general use in Europe; and the name assigned to the fabric, as distinguishing it from the coarser kinds of pottery of domestic manufacture, was most probably given by them—*porcellana* signifying, in the Portuguese language, a cup.' Another authority states, 'It has been satisfactorily shown by Marsden that the word porcelain, or *porcellana*, was applied by Europeans to the ware of China, from the resemblance of its fine polished surface to that of the univalve so named; while the shell itself derived this Latin appellation from the curved or gibbous shape of its upper surface, which was thought to resemble the raised back of a porcella, or little hog.' The reader may decide.

or discoloured, ornaments of porcelain biscuit are vastly superior either to marble or alabaster.

In painting on porcelain, the same colouring materials are used as those employed in colouring glass or earthenware. In all the more delicate patterns, they are laid on with a camel-hair pencil, and generally previously mixed with a little oil of turpentine. Where several colours are used, they often require various temperatures for their perfection; in which case, those that bear the highest heat are first applied, and subsequently those that are brought out at lower temperatures. This art of painting on porcelain, or *in enamel*, is of the most delicate description; much experience and skill are required in it, and with every care, there are frequent failures; hence it is attended with considerable expense. The gilding of porcelain is generally performed by applying finely-divided gold mixed with gum-water and borax; on the application of heat, the gum burns off, and the borax vitrifying on the surface, causes the gold to adhere; it is afterwards burnished with bloodstone, agate, or other polishers.

Porcelain vessels are very brittle, and are easily damaged, which accounts in some degree for the high price at which they are sold. It is calculated that after being manufactured, one-third of the articles are damaged, most of which takes place in the kiln. English and foreign porcelains differ considerably in their composition, which accounts for their difference of transparency, brittleness, and fitness for chemical purposes. Thus an average of five analyses shows English porcelain to contain about 40 per cent. of silica, 24 alumina, 12 lime, 20 protoxide of iron and phosphate of lime; 3 of alkali, and a trace of magnesia; while Chinese and Berlin specimens yielded about 70 silica, 25 alumina and protoxide of iron, 2 lime, and less than 2 of alkali. The German manufacturers do not employ phosphate of lime or bone-earth; but use felspar instead, the alkali of which supplies the place of the phosphate. Their porcelain is thus better adapted for chemical purposes, as it is more vitrified, and less liable to be acted upon by acids, as well as being capable of withstanding a very high degree of heat. The principal materials employed by the Chinese are known to be *kaolin*, or decomposed felspar; *petuntze*, or quartz reduced to fine powder; and the ashes of fern, which contain carbonate of potash. From these materials the Chinese have long prepared a ware of the highest qualities—remaining perfectly white after exposure to heat, being able to withstand a very high temperature without fusing, exhibiting a semi-vitreous texture, and a peculiar degree of transparency and toughness. English and French manufacturers can produce the same degree of whiteness and translucency, but their ware is more fusible, is more apt to crack under sudden changes of temperature, and is altogether more brittle.

The extent to which the fabrication of pottery and porcelain wares is now carried on in Britain, together with its usefulness, and generally-acknowledged excellence, has rendered it a subject of great national importance. 'The raw materials,' says a recent writer, 'are of home production, and of little intrinsic value, the transport of which affords to the coasting-trade a freightage of from 40,000 to 50,000 tons annually. The manufactured articles are almost wholly produced by manual labour, which is not likely to be superseded by machinery, while the export of the bulky article of earthenware to all parts of the world, gives employment, to an immense extent, to the shipping of this and other countries. 'Nor is this interesting manufacture without some claim in furthering the progress of the fine arts, by the cultivation of painters, engravers, and modellers, many of whom have displayed talents of a superior order in their respective lines. In flower-painting, and in decoration generally, the work of English artists cannot be excelled; and in figure-painting it is to be hoped that the lately-instituted Schools of Design will soon raise them to the same superiority. There are some considerable manufactories of pottery-ware in the north of England, and one or two in Yorkshire; but the principal site of both porcelain and pottery-wares is in the modern borough of Stoke-upon-Trent, which contains a population of about 70,000 persons, engaged directly or indirectly in these manufactures.' The principal seats of porcelain manufacture in continental Europe are Sevrès near Paris, Tournay in Flanders, Dresden, Berlin, and Florence; the wares of Sevrès being as yet unequalled in their translucency, glaze, and gilding, and in the elegance and taste displayed in their shape and figure-paintings.

BRICKS—TILES.

The common superficial clay, which is so liberally spread over our island, must be familiar to every one. It is of various colours—yellow, red, or bluish, according to the amount of iron oxide which it contains—is more or less mixed up with sand and fragments of rock—and when softened, becomes plastic and tenacious. It is this variety that is ordinarily used for the manufacture of bricks, tiles, chimney-tops, flower-pots, drain-pipes, and the coarser sorts of earthenware. It will at once be perceived that the quality of the manufactured products must therefore depend upon the purity of the raw material, and upon the care with which it is wrought and tempered. Stones and other extraneous impurities can be readily separated by washing and screening, but admixtures of calcareous or magnesian earths cannot be so got rid of; and thus it happens, that what may appear a fine and available clay, is utterly worthless to the brick and tile-burner. What is chiefly necessary is a due admixture of alumina and silica—that is, clay and sand; for though pure clay may be made into extremely hard bricks, they are apt to shrink and crack in the burning; while too much sand renders them brittle and friable. Excellent natural brick-clay occurs in many localities; and where there is any deficiency of either ingredient, it can in general be cheaply supplied. As to the presence of a little lime, magnesia, or oxide of iron, it is rather liked than otherwise, these materials giving agreeable colours to the finished article. Thus the presence of iron confers on common bricks their red hue; magnesia a dullish gray; and lime a light cream or *malm* colour. These adventitious colours, however, cannot be procured without deterioration of quality, there being nothing so durable as the pure mixture of clay and sand, carefully tempered, and gradually but strongly fired. For bricks, slabs, crucibles, &c. which have to resist the action of fire, some of the coal-measure or stratified clays are generally had recourse to; these, from their greater purity, and a certain per centage of silica, being susceptible of a more thorough baking. In England, the Windsor, Stourbridge, and Welsh fire-clays are esteemed the best—the latter yielding those large square slabs employed in the construction of drying-kilns, brewers'-coppers, sugar-boilers, smelting-furnaces, and the like.

Bricks, formed of the materials above described, may be termed artificial stones; at least they have been used as substitutes for stones from the earliest periods, and often with greater advantage as to strength and permanency. *Sun-dried* bricks, though not durable, were formerly used in many places, as Egypt, Babylon, &c. and are still used in the East. There, under a dry and equable climate, they serve the purpose intended; but under the rains and frosts of our northern region they would be utterly useless. We have now before us a fragment of Egyptian brick in all probability more than three thousand years old, with a figure in fresco upon it as fresh and brilliant as that day it was painted by the artist. It is composed of an earthy clay, mingled with chopped straw, to give it greater consistence, and has evidently been subjected to no higher heat than that of the sun. Exposure in Britain for as many years as it has endured centuries in Egypt, would have reduced it to its original elements. *Kiln-drying*, or *baking*, is therefore necessary to render bricks sufficiently durable in Northern Europe; and according to the material of which they are composed, and the degree of heat to which they are subjected, so in general is their hardness and durability. The following is the ordinary process of manufacture:—'The clay is usually dug in September, and exposed in heaps of a few feet in height to the action of the frost of winter, which pulverizes and mellows it. The small stones are then separated by grinding it in water, and passing it through a grating. The clay thus reduced to paste is now mixed with chalk, ground with water to the consistence of cream, if any calcareous ingredient is to be added. After remaining till it has acquired sufficient consistency, it is finally tempered by working it in a pug-mill, when it is ready to be moulded. Before the pug-mill was invented, the clay was thrown into a shallow pit, and trodden by the feet of men or oxen. When the clay has been properly tempered, it is taken to the moulder's bench, and separated into small pieces. The mould is a box of a size fixed by act of parliament, but with the bottom loose. It is placed on the bench, sprinkled over with sand, to prevent the clay from sticking to it, a lump of the prepared clay is dashed in, and the top or superfluous portion scraped off with a flat stick. The newly-moulded bricks (with a little additional dressing where necessary) are carried on a wheelbarrow to a shed or open square, as the case may be, where, arranged on each other diagonally, with interspaces for the free passage of air, they are allowed to dry for a few days. When sufficiently firm to bear handling, they are removed to the kiln.' A clever workman, with proper assistance, will mould and dress about five thousand bricks per day.

The burning is performed either in *kilns* or in *clamps*—the latter being large square piles of bricks skilfully built up, with layers of fuel between, called *breeze*, and also with flues filled with coal, cinders, and wood, to facilitate still more the process of combustion. Baking in kilns, however, is preferable, as there is not only less waste, and less fuel consumed, but the bricks are sooner ready for the market. 'The kiln,' says Dr Ure, 'is usually 13 feet long by 10½ feet wide, and about 12 feet in height. The walls are one foot two inches thick, carried up a little out of the perpendicular, inclining towards each other at the top. The bricks are placed on flat arches, having holes left in them resembling lattice-work; the kiln is then covered with pieces of tiles and bricks, and some wood put in, to dry them with a gentle fire. This continues two or three days before they are ready for burning, which is known by the smoke turning from a darkish colour to transparent. The mouth or mouths of the kiln are now dammed up with pieces of bricks piled one upon another, and closed with wet brick earth, leaving above it just room sufficient to receive a fagot. The fagots are made of furze, heath, brake, fern, &c. and the kiln is supplied with these until its arches look white, and the fire appears at the top; upon which the fire is slackened for an hour, and the kiln allowed gradually to cool. This heating and cooling are repeated until the bricks are thoroughly burned, which is generally done in forty-eight hours. One of these kilns will hold about twenty thousand bricks.'

Bricks, whether clamp or kiln-burned, are of different qualities, according to the degree of baking they have been made to undergo. The most thoroughly burned are termed *stocks;* the inferior *samel*, or sandel bricks; and those vitrified, or over-burned, *burrs*. As in every other manufacture, there are numerous local designations, having reference either to the quality, colour, shape, or purposes to which the bricks are to be applied. Thus the *malms* of the London bricklayer are of a yellowish uniform colour and texture, prepared, as already stated, by an admixture of ground chalk; *seconds* are those less uniform in colour and texture; *cutters* are those made so soft, as to be cut into form for arches of windows; *fire* bricks are prepared to withstand the heat of fires and furnaces, and of such there are varieties known as *Welsh lumps*, *Windsors*, &c.; *paving* bricks, made for the purpose their name implies; *compass* bricks, of a circular shape, for lining walls and chimneys; *Dutch-clinkers*, at one time imported from Holland, but now made in England, a compact variety often used in stables, about 6 inches long, 3 broad, and only one in thickness; and *Bath-brick*, a soft variety, the powder of which is much employed in scouring bright many articles of furniture—as knives, forks, brass candlesticks, &c.

The *floating* bricks known to the ancients, and recently revived by M. Fabroni, are composed of a siliceous or infusorial earth, commonly known as fossil or mountain-meal. This substance is of organic origin, and consists of 55 parts siliceous earth, 15 magnesia, 14 water, 12 alumina, 3 lime, and 1 of iron; it is infusible in the fire, and though it loses about an eighth part of its weight, its bulk is scarcely diminished. 'Bricks composed of this substance,' according to the authority already quoted, 'either baked or unbaked, float in water; and a twentieth part of clay may be added to their composition without taking away their property of swimming. These bricks resist water, unite perfectly with lime, are subject to no alteration from heat or cold, and the baked differ from the unbaked only in the sonorous quality they acquire from the fire. Their strength is little inferior to that of common bricks, but much greater in proportion according to their weight; for M. Fabroni found that a floating brick 7 inches in length, 4½ in breadth, and 1 inch 8 lines in thickness, weighed only 14¼ ounces; whereas a common brick weighed 5 lbs. 6¾ ounces. The use of these bricks may be very important in the construction of powder magazines and reverberatory furnaces, as they are such bad conductors of heat, that one end may be made red-hot while the other is held in the hand. They may also be employed for buildings that require to be light; such as cooking-places in ships, and floating batteries, the parapets of which would be proof against red-hot bullets.'

Tiles are prepared much in the same way as bricks; only, from their being thinner, and of a more intricate form, they require to be made of finer and tougher materials, and are always burned in kilns. They are of different kinds, according to the use to which they are applied; as *plain* and *pan* tiles, *ridge* tiles, &c. In some instances they are glazed like brown ware; in others they are merely coloured red, blue, or cream-yellow, according to the taste of the purchaser. Tiles in many districts form cheap and durable materials for roofing, being less expensive than slates; and in reference to fire, a decided improvement upon thatch. For roofing, it has been proposed to lessen their weight by grooving their surface, whereby additional strength is also gained, and their appearance much improved. What are called *drain* tiles are of recent adoption, and are peculiarly available in districts where there is a scarcity of stones. These tiles are of very simple construction—consisting of flat soles, from 10 to 14 inches in length, with a highly concave tile placed above, so as to form a channel of 4 inches in width and 6 in height. From the highly concave shape of the cover, they are able to resist almost any degree of downward pressure; and the openings between each allow the water to percolate into the channel. As drain-tiles are not exposed to the action of the weather, the most common field-clay, if well worked and burnt, may be used in their manufacture. Besides clay, glass and various concretes (as mentioned under these heads) have been recently employed in the fabrication of tiles and water-pipes; but as yet, the data are too scanty to say with what degree of success.

Tiles and bricks, at one time made solely by the hand, are now extensively formed by machines which press and fashion the prepared material with wonderful rapidity. Thus the drain-tile machine invented by the Marquis of Tweeddale, throws out, when worked with one horse, from 1000 to 1500 per hour; and others have since been invented which exceed that rate; at the same time that the articles so moulded are greatly superior in shape and construction. In France, as well as in England, attempts have been made to produce bricks from dry pulverised clay by hydraulic pressure; but unless for mosaic tesseræ, and other ornamental purposes, the operation is said to be too tedious and expensive. In America, a common moulding machine will turn out about 30,000 bricks a day, not only of improved shape and compactness, but so dry, as to be ready for immediate burning.

The manufacture of tiles and bricks was, till recently, placed under the control of the Excise, and subject to a duty of 5s. 10d. per thousand; but now, only the latter are charged—producing an annual revenue of upwards of £450,000. We have no data as to the amount of roofing and drain-tiles produced in Britain; but England and Scotland manufacture upwards of 1,550,000,000 bricks per year, independent of Ireland, upon whose produce there is no duty. Makers of bricks must give notice of their intention to begin the manufacture, under a penalty of £100; and all bricks made for sale must be 8½ inches long, 2½ thick, and 4 wide. But for this absurd restriction and interference, vast improvements would speedily be effected both in the quality, shape, and appearance of British bricks; 'and when we consider,' laments an authority, 'the durability of the material, and the facility with which it may be moulded into any required form, it is much to be regretted that means are not found for preserving the revenue, without depriving the public of the advantages which might be derived from the inventions of architects.'

It seems almost unnecessary to advert to the fabrication of *flower-pots, chimney-tops, drain-pipes*, &c. which, in their usual forms, are manufactured from common clay, treated much in the same way as that for the finer sorts of tiles. It may be observed, however, that vast improvements have recently taken place in the preparation of these articles, not only in fashioning them into more elegant forms, but in constructing them of more varied materials, whereby they acquire colours and glazes, or are rendered compact or porous, according to the purpose they are destined to serve. For architectural decorations, figures, vases, &c. on a large scale, a variety of argillaceous compounds are now in use, the principal of which is known by the name of *terra cotta*—literally, baked clay. This composition consists of pipe or potters' clay, a fine colourless sand from Ryegate, and pulverised potsherds. These are worked into a homogeneous paste, which is modelled or cast into the figure required, then slowly dried in the air, and ultimately fired to a strong hardness in a proper kiln. We may also here allude to the manufacture of *tobacco-pipes*, which, from the too prevalent practice of smoking, has now become a considerable branch of national industry. These pipes are made of a finely-ground white plastic clay (to which they have given the name), chiefly found in the Isle of Purbeck and Dorsetshire. This clay being worked into paste and dough, in the same manner as the finer sorts of potters' stuff, is next rolled into cylinders for the stems and into balls for the bowls. These are then pressed to the desired form in metallic moulds, and pierced with a wire; dried for a day or two; scraped, polished, and dipped; and ultimately fired in a baking kiln for ten or twelve hours. A clever workman, aided by a boy, can easily make from five to six gross of plain pipes per day.—For *Meerschaums*, see No. 23.

MOSAIC WORK.

The term *Mosaic* is said to be derived from the Greek word *mousaikon*, elegant or polished; and is now applied to the art of imbedding or inlaying in a cement fragments of different coloured substances, so as to produce the effect of a picture. This art was practised at a very early period, and was introduced into Italy by the Byzantine Greeks. Magnificent specimens are to be seen in St Peter's at Rome, and in the chapel of St Lawrence at Florence, where precious marbles, agates, jaspers, avanturines, malachites, &c. constitute the coloured tesseræ. This art is now admirably imitated by the potter, tile-maker, and fabricator of pastes; thus bringing it fully within the scope of our present treatise.

Among the ancients, mosaic appears to have been confined to pavements, for which it is admirably adapted; since, notwithstanding its being frequently trodden upon and washed, it is not injured. At a later period, mosaics were executed upon walls; and more recently, extremely minute mosaics, either for the cabinet or for personal ornament, have been fabricated chiefly in Italy. For pavement, the tesseræ may either be individually coloured, and then so arranged as to produce a pleasing effect, or each tessera may be variously coloured and figured, and thus produce an independent effect, or an effect only when in combination with others, like the separate figures of a carpet. Till within the last ten or twelve years, tesselated pavements in Britain were generally very tame affairs, but now tesseræ of great beauty and delicacy are being fashioned at our potteries, and the laying of them in halls, and other public buildings, is greatly on the increase. The usual method of preparing them is thus intelligibly described by Mr Dodd:—'The tesselated tiles are formed of two differently-coloured clays, one imbedded in the other, and disposed so as to form an ornamental device. The tile is first made in clay of one colour, with a depression afterwards to be filled with clay of the other colour, and this depression is formed by the aid of a mould. In the first place, the modeller models in stiff clay an exact representative of one of the tiles, about an inch thick, cutting out to the depth of about a quarter of an inch the depression which constitutes the device. When this is properly dried, a mould is made from it in plaster of Paris, and from this mould all the tiles are produced one by one. The ground colour of the tile is frequently a brownish clay, with a yellow device; but this may be varied at pleasure. Let the colour be what it may, however, the first clay is mixed up very thick, and pressed into the mould by the aid of a spring press. On leaving the press, it presents the form of a damp, heavy, uni-coloured square tile of clay, with an ornamental device formed by a depression below the common level of the surface. The second coloured clay, so far from being made stiff like the first, has a consistence somewhat resembling that of honey; and herein lies one of the niceties of manufacture, for it is necessary to choose clays which will contract equally in baking, although of different consistence when used. The tile being laid on a bench, the workman plasters the honey-like clay on it, until he has completely filled the depressed device, using a kind of knife or trowel in this process. The tile in this state is then allowed to dry very gradually for the long period of eight weeks, to accommodate the shrinking of the clays to their peculiar natures. After this, each tile is scraped on the surface with an edge-tool till the superfluous portion of the second clay is removed, and the two clays become properly visible, one forming the ground, and the other the device. In this state the tiles are put in a "biscuit-kiln," where they are baked in a manner nearly resembling the baking of porcelain, but with especial reference as to time and temperature, to the quality of the two clays. From the biscuit-kiln they are transferred to the dipping-room, where they are coated on the upper surface with a liquid glaze by means of a brush. Lastly, an exposure to the heat of the glaze-kiln for a period of twenty-four or thirty hours, causes the glaze to combine with the clay, and the tiles are then finished.' Another mode of producing the tesseræ is by hydraulic pressure of pulverised clay, either uni-coloured or variegated.

The fabrication of those pretty ornaments generally known by the name of Roman mosaics, is altogether a different art. It is thus described by Mr Wyatt in a recent communication to the Society of Arts:—'A plate, generally of metal, of the size of the picture to be copied, is first surrounded by a margin about three quarters of an inch from its surface. This is then covered over with a coating of perhaps one quarter of an inch in thickness of mastic cement, composed of powdered travertine stone, lime, and linseed oil. This is, when set, entirely covered with plaster of Paris, rising to a level with the surrounding margin, which is intended to be exactly that of the finished mosaic. On this is traced a very careful outline of the picture to be copied; and with a fine chisel, just as much is removed, from time to time, as will admit of the insertion of the little pieces of glass, or, as the Italians call it, "smalto." This smalto is composed of glass, and is made in rounds about six or eight inches in diameter, and half an inch thick. The workman then proceeds to select from the great depository—wherein are preserved in trays nearly 10,000 varieties of colour—those he may require, which he works to the necessary shape. This is done by striking the smalto with a sharp-edged hammer directly over a similar edge placed vertically beneath. The concussion breaks the smalto to very nearly the shape required; and it is then more perfectly ground, by application to a lead wheel with emery powder. The piece thus shaped is then moistened with a little cement, and bedded in its proper situation; and so on until the picture is finished; when the whole is ground down to an even face, and polished.' Several regularly-trained artists are now constantly employed in the fabrication of these mosaics at the Vatican.

GLASS.

The origin of glass manufacture is involved in the greatest obscurity, and has given rise to much ingenious speculation, upon which little or no dependence can be placed. Glass beads have been found on the bodies of Egyptian mummies, which are known to have been embalmed three thousand years ago. Pliny says that the art of glassmaking was accidentally discovered by some shipwrecked Phœnician mariners, whose vessel was laden with fossil alkali, a component part of glass. On kindling a fire on the sand to prepare some food, and placing their cooking vessels on pieces of the substance just named, the sand, by the agency of the fire and its union with the alkali, became vitrified; hence, according to this authority, the discovery of the art.

The first glass manufactory of any note was established at the village of Murano, near Venice. The glass produced here was superior to any in Europe, and for a long time the principal supply was obtained at this place. The Venetians were long celebrated for making mirrors, which they brought to considerable perfection. Window-glass appears to have been made in England in the middle of the fifteenth century, but it was of an inferior description. In 1557, the finer sort of window-glass was manufactured at Crutched Friars in London. The first flint-glass was made at Savoy House in the Strand; and the first plate-glass for mirrors, coach-windows, and the like, was fabricated at Lambeth in 1673, by Venetian workmen, brought over by the Duke of Buckingham.

A glass-house is usually built in the form of a cone, from 60 to 100 feet high, and from 40 to 80 feet in diameter at the base. The furnace is placed in the centre of the building, and is generally of an oblong figure, although sometimes circular. Below the furnace is an arched gallery, extending right across the building, and terminating in folding-doors, large enough to admit a barrow for carrying out the ashes. In the sides of the furnace are apertures called working-holes, through which the materials are put into the pots, and the blowing tubes inserted. In a crown-glass manufactory, the furnace generally contains from four to six pots; but this will altogether depend upon the size of the building. The stone used in constructing glass furnaces must be of the finest quality; that called fire-stone, got from Coxgreen, in the neighbourhood of Newcastle, is considered the best for this purpose.

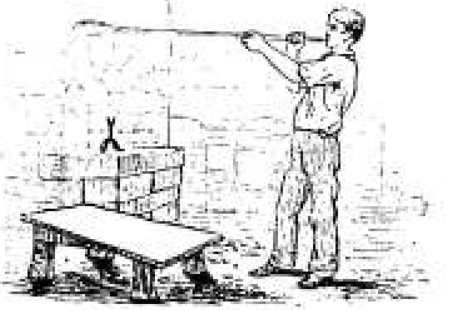
Crown-Glass.

Crown or window-glass is usually composed of pearl-ash, or other alkalies, and fine white sand. The best sand for glassmaking is that which contains most transparent particles, and this is found in large quantities in that brought from Lynn Regis in Norfolk, and the western coast of the Isle of Wight. The sand is put into a large vat, and boiling or cold water poured upon it until the water runs off clear. It is then subjected to a red heat for twenty-four hours, and immediately on being taken out is plunged into cold water, which divides the particles of sand, and makes it unite more readily with the alkali. Some put nitre amongst the sand during this process, which consumes any sulphur or other extraneous matter which may be present. The sand and kelp are next mixed together, in the proportion of eleven parts of the former to seven or eight of the latter. Since the manufacture of soda from common salt, the use of carbonate of soda and lime, instead of kelp, in the manufacture of crown-glass, is almost universal; and from these alkalies being much purer, a better article is produced.

When the sand and alkali are properly mixed together, the compost is put into the calcining arch, or reverberatory furnace, where it is reduced by heat to a semi-fluid state. This process requires from three to four hours, and the *frett*, as it is now called, is taken out, placed upon an iron plate, and cut into cakes before it becomes quite cold. The calcining furnace is generally about ten feet long, seven feet wide, and two feet high. The sides and top are built of fire-brick, and the rest of common brick; and the bottom must be carefully cemented, to prevent the frett from oozing through the seams. It is the opinion of most glass manufacturers that the frett should be kept for about six months before it is used. If glass is made from new frett, it is full of what are called seeds, the presence of which depreciates the quality of the ware.

The frett is next put into the melting-pot, along with a proportion of what is called *cullet*, which is nothing more than broken crown-glass. The melting-pot is formed of the finest clay, that obtained at Stourbridge, in Worcestershire, being considered the best adapted for this purpose. The clay is freed from all extraneous particles, which, if allowed to remain, would injure the pot, and about a fourth part of old crucibles ground into a fine powder is added. Pots made from this mixture resist heat much better than when altogether formed of the virgin clay. The pots are very gradually dried, being generally kept for nine or twelve months at a temperature of about fifty degrees. They are afterwards tested in a furnace before being used, and last upon an average for from eight to ten weeks.

When the frett and cullet are put into the pots, the furnace is heated to as high a temperature as possible, until the metal is reduced to a liquid state. It is then skimmed of all extraneous substances which may be floating on the surface, and is fit for the operations of



the workmen. An iron tube, six or seven feet in length, thicker at one end than the other, is heated and dipped into the liquid metal. A portion of glass adheres to the end of the rod, which, being allowed to cool a little, is again dipped in, and gathers more. The rod is then taken out and hung perpendicularly, that the metal may be equally distributed on all sides, and also that it may be lengthened out beyond the rod. The metal is next rolled upon a smooth iron plate called the *marver*, and afterwards blown out slightly, so as to resemble a pear in shape. The blower then heats the metal twice, blowing it out between the heatings, when it is brought to a globe shape. The glass is then allowed to cool a little, and a rod of iron, called the *punty rod*, is attached to the side immediately opposite to the tube. This is done by dipping the end of the rod in the liquid metal, which adheres readily to the half-cooled glass, and the tube is detached by touching it with a piece of iron dipped in cold water, leaving an aperture in the glass about two inches in diameter. The glass is again put into the furnace until it has become sufficiently ductile to yield readily to any impression. The workman then twirls the globe round, slowly at first, but afterwards with great velocity, during which the aperture formerly mentioned gradually widens, until it reaches a certain point, when the globe suddenly flies open with a loud ruffling noise, and becomes a plane or circular sheet of glass, about fifty inches in diameter. This is an exceedingly beautiful operation, and requires considerable skill on the part of the workman. The circular motion is still continued, until the sheet is sufficiently cool to retain its form, when it is carried to the annealing arch to be tempered. The punty rod is detached by means of large shears, and the sheet of glass is lifted on a wide-pronged fork, and set up edgewise in the kiln. A kiln will hold from four to six hundred sheets. When full, the mouth is built up, the fire withdrawn, and the kiln allowed to cool as gradually as possible. This process of gradual cooling is known by the name of *annealing*—a process without undergoing which, glass, as well as several of the metals, would be so brittle, as to break on the application of the slightest force. The glass is then taken out, the circular sheet cut into halves, and assorted into different qualities, known by the names of *firsts*, *seconds*, and *thirds*.

Sheet-Glass.

The process we have described is altogether applicable to crown or window-glass, but the manufacture of sheet-glass is somewhat different. In making sheet-glass, the same materials are used as in crown-glass, the difference being in the manner of forming the sheet. When the metal is melted, the workman dips his tube into the pot, and when he has gathered a sufficient quantity of the liquid glass upon it, he places it in a horizontal position upon a hollowed block of wood. He turns the rod round in his hand, with the metal resting upon the hollowed block, which forms it into a solid cylindrical mass. Water is poured upon the block during this operation, the action of which upon the glass gives great brilliancy to its surface. If the glass was only red hot, on coming in contact with the water it would crack; but at the great heat at which it must be kept so as to be ductile, no injury takes place. When the metal is sufficiently formed and cooled, the workman blows into the tube until he perceives the diameter to be of the dimensions required, which depends upon the size of the sheet to be made. The metal is again put into the furnace, and when softened, the workman swings it round his head, reheats, and continues to swing it, until the cylindrical mass has attained what he thinks a sufficient length. He then fills the tube with air, and closes up the hole, so that none may escape; after which the metal is again put into the furnace, and as it becomes soft, the air bursts from the end opposite to the tube, leaving an aperture. The cylinder is then turned round very quickly, which renders it perfectly straight; and then, by applying cold iron to the end of the glass next the tube, a sudden contraction takes place, which separates the cylinder of glass from the iron tube. The cylinder thus formed is allowed to cool for about five seconds, and it is then split up lengthwise by drawing a red-hot iron rod along the inner side. The glass has next to be flattened, which is done by softening it in a furnace upon a smooth plate, where, as it begins to melt, it gradually opens, and is smoothed with a piece of charred wood. It is then carried to the annealing furnace to be tempered, in the same manner as crown-glass.

Sheet-glass may be made of any thickness, and possesses considerable advantages over crown-glass. It has none of that wavy appearance too often seen in crown-glass, and a larger square can be obtained when the sheet is formed. It is difficult to get a sheet of crown-glass which will yield a square 34 inches by 22, whereas the common size of sheet-glass is 40 inches by 30.

Plate-Glass.

The manufacture of plate-glass requires greater care than either of the two preceding kinds, and the process is different—the plate-glass being moulded, and not blown, as is the case with other kinds of glass-ware. The sand made use of must be the finest that can possibly be obtained, and requires to be well washed, to free it from impurities, and passed through a fine sieve, previous to being mixed with the other ingredients. At St Gobin, in France, crystallised carbonate of soda is used as the alkali; and at Ravenhead, near St Helen's, Lancashire, the soda is obtained by treating sea-salt with pearl-ash, the result of which is carbonate of soda and muriate of potash. The latter body is easily got rid of, as it crystallises at a higher temperature than the carbonate of soda. The soda thus prepared is exceedingly pure, and well adapted for glass manufacture. To these are added dry slaked lime carefully sifted, and cullet, as in crown-glass-making. The following proportions are stated by Dr Ure to have uniformly yielded a beautiful glass:—'Sand, 7 cwt.; quicklime, 1 cwt.; dry carbonate of soda, 2 cwts. 37 lbs.; and about the same quantity of cullet as there is sand.' Mr Parkes somewhat varies the formula—namely, siliceous sand, washed and sifted, 720 lbs.; alkaline salt or soda, 450 lbs.; quicklime, 80 lbs.; nitre, 25 lbs.; and broken glass, 425 lbs.—in all, 1700 lbs.; from which about 1200 lbs. of good plate is generally obtained.

These materials are usually fretted before being melted; but at St Gobin, in France, this is sometimes dispensed with. Two kinds of crucibles are required in the manufacture of plate-glass; namely, the pots in which the materials are melted, and the basins from which it is poured upon the moulding plate. These crucibles are made from a clay entirely free from iron and lime, and which is dried, ground, picked, washed in water, and passed through a fine hair sieve. Old crucibles ground to a powder are mixed with the clay in proportions according to its quality. This composition, when prepared, is called *slip*, and is also used for cementing the furnaces.

The materials of which the glass is composed are first put into the pots to be fused, which occupies about sixteen hours, and then transferred to the basins. The transfer of the melted glass from the pots to the basins is called *lading*, and is performed by ladles of wrought iron furnished with long handles. This second melting is called *refining*; and the glass is allowed to remain other sixteen hours, which is necessary for the disengagement of the air-bubbles introduced by the transferring, and for giving the metal the proper consistence for casting. For three hours previous to the casting, all the openings in the furnace are closed—an operation called *stopping the glass*, or *performing the ceremony*. The glass is tried; and if found of the proper consistence, and free from air-bubbles, the basins are carried to the casting table.

This table was formerly made of copper or bronze, but cast-iron is now found to answer the purpose better. It is about ten feet long, five feet broad, and from six to seven inches thick, supported by a wooden frame which rests on iron wheels. Along the sides of the table are two parallel bars of bronze, which support the roller in its progress, and determine the thickness of the glass. The roller is made of bronze, and is run along the table after the glass is poured on, to spread it equally. When the liquid glass is poured upon the table, two men run the roller slowly and steadily from one end to the other; and after two plates have been formed, the roller is allowed to cool. The plate of glass is next inspected, and if any air-bubbles appear, it is cut through, and is then put into the annealing furnace, where it remains for fifteen days.

When tempered and cooled, the rough edge is cut off the glass by means of a diamond, and the plates are sorted according to their sizes; it being necessary, when air-bubbles occur, to cut a larger piece from one than from another. The next step is the grinding of the surface, which is done by cementing the glass upon a horizontal table made either of freestone or wood. One plate is then reversed and suspended over another, and ground flint or sand is introduced between them. The suspended plate is fastened upon a conical stone, with a ball at the top for the workman to hold it by. When machinery is used for this process, the upper plate is fastened to a square of cast-iron, which receives a rotatory motion similar to that communicated by the hand. When one side has been sufficiently ground, the plates are reversed, and the same operation performed upon the other. By this grinding, the plates have been rendered perfectly level, but they have still to be smoothed before receiving their polish. For this purpose, they must be again ground with emery powder, of increasing degrees of fineness. The glass is then polished on both surfaces, by means of wooden blocks covered with layers of woollen cloth. The glass is fixed, as before, upon the stone table, and a quantity of the red oxide of iron (the colcothar of commerce) is laid on, and the surface rubbed with the covered blocks till a perfectly smooth and transparent plate has been obtained.

Plate-glass is not always fashioned by casting. The process of *blowing* a plate of this kind is very similar to the mode of blowing sheet-glass; the differences observable in the manipulation in these processes being chiefly occasioned by the weight and bulk of the mass of glass operated on. It is very difficult to blow a plate of glass of sufficient thickness for grinding to a level surface, and polishing of a size larger than fifty inches by forty; whereas, by the process of casting, plates are produced one hundred and sixty inches by eighty—this, we believe, being the largest attempted at Ravenhead.

Plate-glass is extensively manufactured into *mirrors*, which has hitherto been done by applying a layer of tinfoil, alloyed with mercury, to the posterior surface of the glass. The workshop for executing this operation is provided with a number of smooth tables of fine freestone or marble, truly levelled, having round their contour a rising ledge, within which there is a gutter, or groove, which terminates by a slight slope in a spout at one of the corners. The glass-tinner, standing towards one angle of his table, sweeps and wipes its surface with the greatest care, along the whole breadth to be occupied by the mirror-plate; then taking a sheet of tinfoil adapted to his purpose, he spreads it on the table, and applies it closely with a brush, which removes any folds or wrinkles. The table being horizontal, he pours over the tin a small quantity of quicksilver, and spreads it with a roll of woollen stuff; so that the tinfoil is penetrated, and apparently dissolved by the mercury. Then taking the plate of glass, he lays it carefully on the smooth bed of tin and mercury, which adheres to the glass in obedience to the law, that bodies contract a close adhesion when they touch at all points. The glass is then removed from the table, and placed under heavy weights for twenty-four hours, so as to make the adhesion more perfect and durable. Even after this, a portion of the superfluous lackering remains on the glass, and has to be gradually drained off by placing the plate on a frame sloped like a writing-desk. This is a very nice and difficult operation, and requires the most minute care to prevent the glass from contracting during the operation, in which case the whole process must be recommenced. Moreover, the bed of tin is easily cracked, and every one knows with what rapidity the action of the sun, or the least humidity, spoils the best looking-glasses. Such, till within a recent period, was the tedious and expensive mode of 'silvering' plate-glass for mirrors.

Towards the end of 1843, Mr Thomas Drayton, of Brighton, sealed a patent, the subject of which was a mode of silvering looking-glasses without the employment of quicksilver; and this by chemical instead of mechanical means. The material used is composed of coarsely-pulverised nitrate of silver, spirits of hartshorn, and water. This, after standing for twenty-four hours, is filtered, and an addition is then made of spirit of wine and a few drops of oil of cassia. The glass to be silvered with this solution must have a clean and polished surface; it is to be placed in a horizontal position, and a wall of putty or other suitable material formed around it; so that the solution may cover the surface of the glass to the depth of from an eighth to a quarter of an inch. A deposition of the silver then takes place in two hours or less, and when the required deposit has been obtained, the solution is poured off; and as soon as the silver on the glass is perfectly dry, it is varnished with a composition formed by melting together equal quantities of bees' wax and tallow. This serves as a protection to the residuum which adheres closely to the glass, and affords a more clear and brilliant reflection than the old process; besides being done in infinitely less time, and with no risk of failure. The term 'silvering' looking-glasses is rendered by the new plan quite correct, for it is silver, and nothing but silver, which converts the glass into a mirror. M. Tournasse has lately improved the minutiæ of Mr Drayton's process, so that mirrors may be now made in half an hour, and this in any shape or form—a result rendered impossible by the old pressure system, which could be applied only to flat or plane surfaces.

Still more recently (August 1847), Mr T. Fletcher of Birmingham has patented a process for silvering mirrors, or rather for coating, by the electrotype, mirrors already silvered, whereby the quicksilver is protected from injury, and a stronger reflecting power given to the speculum. The silvered plate is lightly and carefully coated on the back, or silvered side, with a varnish composed of two ounces of shellac, half a pint of highly-rectified spirits of wine, and half an ounce of the best lampblack; this varnish protects the quicksilver from damp, and from the acid used in the subsequent process. Before the varnish is quite hard, shake over it, from a muslin bag, finely-pulverised plumbago, black oxide of manganese, or any other metallic powder, or cover it with metal foil, so that the whole surface may receive a perfect but thin metallic coating; after which it is submitted to the electrotyping process, and by this means a thin coating of copper, or other metal, will be precipitated over the entire back of the mirror.

Flint-Glass.

Flint-glass, or crystal, is composed of Lynn sand—which is calcined, sifted, and washed for the purpose—red lead, or litharge, and refined pearl-ash. It was formerly made of calcined flint, but the finest Lynn sand has been found to produce a clearer ware, and is therefore preferred. The proportion of these materials varies in almost every manufactory; but the following proportions were long ago recommended by M. Loysel, the fuel employed being coal:—Fine white sand, 100 parts; red lead, 80 to 85; pearl-ash, 35 to 40; nitre, 2 to 3; and manganese a little more than $\frac{1}{6}$ a part. The mixture used by most manufacturers of the present time does not differ greatly from the above. With a coal fire, the following may be taken as the average:—White sand, 9 parts; red lead, 6½; and pearl-ash, with a little nitre, 4½. An excellent crystal may be obtained, however, with a much smaller proportion of red lead, but a higher temperature is then required for working the glass. A mixture of this description, recommended by Mr Aikin, consists of—White sand, 100 parts; purified pearl-ash, 40; red lead, 35; nitre, with a small quantity of manganese, 13 parts. When a flint-glass of first-rate quality is required, purified carbonate of potash is always employed instead of pearl-ash. We may also mention that a considerable quantity of cullet or broken crystal is in most cases made use of—to the extent perhaps of a fourth of the whole weight of the melting.

A flint-glass furnace varies little from those described for other kinds of glass, except that it is round in the top. The pots in which the glass is melted are larger at the top than the bottom; and the top is arched over, that no dust may fall in, with a hole at the side for the insertion of the tube. When the glass is sufficiently melted, the tube is inserted, and a quantity lifted out upon its point in the same manner as for crown-glass. After being rolled upon the marver, the glass is blown out to a globe shape, when the punty rod is attached, and by means of an instrument resembling a pair of sugar-tongs, the glass is moulded to the form required. The shapes into which flint-glass is manufactured are so numerous, that it would be almost impossible to describe them all. The operations are extremely simple and beautiful, and are performed with a rapidity which is truly astonishing. The workman is furnished with a pair of compasses, and a graduated scale, to measure the articles which he is making, by which they are kept of a uniform size. When finished, the articles are all weighed, to see that the right quantity of glass has been used in their manufacture, and after this they are put into the annealing furnace.

Optical glasses are made from crystal, in which case the utmost care is necessary to keep the metal entirely free from waves, otherwise the glasses will be useless. An *achromatic* object-glass for a telescope or microscope; that is, an object-glass which does not produce coloured fringes around the edge of the image—distinguished as chromatic aberration—must consist of two lenses made of different kinds of glass, differing in the proportion which their refractive bears to their dispersive power. Flint-glass and crown-glass are well adapted for being formed into such a compound lens, the dispersive power of the former being nearly double that of the latter, while the mean refractive powers of the two kinds are nearly the same.

Bottle-Glass.

Bottle-glass is composed of the coarsest materials, generally soap-boilers' waste and sand. The following receipt is recommended by Dr Ure as producing a fine dark-green glass:—Dry glauber salts, 11 lbs.; soaper salts, 12 lbs.; half a bushel of waste soap ashes; sand, 56 lbs.; glass skimmings, 22 lbs.; green broken glass, 1 cwt.; basalt, 25 lbs. The composition of bottle-glass, however, is by no means uniform, it being varied not only in different establishments, but in the same establishment at different times. The basis of the manufacture, nevertheless, is always a triple silicate of soda, alumina, and lime, the place of a portion of the lime being generally occupied by some magnesia and protoxide of iron, and that of a part of the alumina (clay) by peroxide of iron. A very worthless and deleterious article is occasionally produced, with a view to facilitate the formation of 'crust,' in port-wine bottles. This is said to be managed by an over-proportion of lime, or sulphate of lime, upon which the free acid of the wine acts, and forms a crust in a very short period. The practice is highly reprehensible, as is the introduction of soluble silicates in any form.

The furnaces for preparing bottle-glass are similar to those used for crown-glass; and the raw materials are treated much in the same way—being generally fretted, before they are introduced into the glass pots, in arches attached to the principal furnace. As the mixture always contains a very small relative proportion of the alkaline ingredient, its vitrification requires a high temperature; but it is usually complete in eighteen or twenty hours. After the undissolved matter has subsided, the sandiver skimmed off, and the glass cooled down to blowing consistency, the mass may be worked up into bottles. For this purpose the workman introduces his tube, and when sufficient is gathered upon the end, he rolls the glass upon a stone, blowing into it at the same time. He then puts the metal into a brass or iron mould of the shape of the bottle to be made, and blows through the tube until it comes to the desired form. This mould is so contrived as to open down the middle by means of a spring which the blower works with his foot. The mould is open when he puts in the metal at first; it is then immediately closed, and opened again when the bottle is formed, which is handed over to the finisher. The finisher detaches the tube from the mouth of the bottle, and fixes the punty rod to the bottom. He then warms the bottle at the furnace, and takes out a small quantity of metal, which is turned round the upper part of the neck, and forms the rim usually seen on bottles. The finisher next employs a pair of shears to give the right shape to the neck: on one of the blades of the shears is a piece of brass resembling a cork, by which the inside of the neck is formed. The bottles thus finished are sent to the annealing arch, which is kept a little below melting-heat until full, when the fire is allowed to die out.

Cutting—Grinding—Etching.

The instrument universally employed in *cutting* window-glass is the diamond, which is set into a metal socket attached to a wooden handle for this purpose. The cutting point of the diamond must be a natural one; artificial points, as well as those produced by breaking the diamond, only scratch the glass, without producing the deep cut which is necessary. The best diamonds for cutting glass are called *mother sparks*, which are sometimes cut down into a number of small sparks, with a natural point to each. It is thought better that a cutting diamond should be made of a large spark, for when one point is worn out, it can be turned and reset, when another fresh point is obtained. The diamonds used are known by the technical name of *bort*—that is, all such pieces as are too small to be cut, or have a bad colour, and are consequently unfit for ornamental purposes.

What is called glass-cutting, or *grinding*, is a separate trade from blowing in all glass manufactories. The cutting-wheel is driven by means of a belt proceeding from a large drum attached to an engine or other moving power. Above the cutting-wheel is a conical box, from which wet sand drops upon it, while another is placed below, to receive the sand as it falls from the wheel. The wheels used are three in number; the first is made of cast-iron, by which the rough glass is ground; the second of Yorkshire stone, by which the vessel is smoothed; and the third of willow-wood, by which the final polish is communicated. For this latter purpose, the wooden wheel is dressed with rotten-stone or pumice-stone; and for imparting the highest degree of polish, putty powder is used. These wheels are of various forms, according to the shape of the vessel to be cut. They may be broad or narrow, flat-edged, two-edged, concave, convex, &c. The cutter holds the glass to the wheel while it is revolving, and the most beautiful and regular figures are engraved in this manner with astonishing rapidity. Imitations of cut-glass vessels are made by blowing the soft glass into a polished metallic mould, the form of which it acquires with as much faithfulness as wax.

As stated under CHEMISTRY, the vapour of hydrofluoric acid acts energetically on glass, and is sometimes employed for the purpose of *etching* on this material. 'The art,' says Parnell, 'may be practised on all kinds of glass, but the most proper description is good crown-glass. The facts on which the art is founded are, that glass becomes powerfully corroded by exposure to the acid in question, and that certain parts of the glass may be easily protected by a resist varnish, on which the acid exerts no action, except at a high temperature. The varnish usually employed by artists for this purpose is either common turpentine varnish, mixed with a little white lead, or a strong aqueous solution of isinglass. In performing the process on a small scale, purified bees'-wax will be found to form a convenient varnish. The piece of glass to be etched is first of all warmed in a convenient manner, and one of its surfaces is then rubbed over with the wax—the temperature of the glass being high enough to cause the wax to melt, and be distributed uniformly over the entire surface. The glass is then set aside to cool; and when the wax has become quite solid, the design may be traced with a pointed, but not very fine instrument, such as a bodkin. Care must be taken to cut through the entire thickness of the wax, so as to lay the glass quite bare through the whole length of the line. The next part of the process consists in the application of the acid vapour. The vessel employed for this purpose is a shallow basin of lead, or of Wedgewood's ware (no glazed vessel should be employed), large enough to include within its area every part of the design when the prepared glass is placed over it. The materials for generating hydrofluoric acid, consisting of one part powdered fluor-spar, and two parts highly concentrated oil of vitriol, are introduced into the basin, and well mixed; the glass plate is then laid over the basin, with the waxed side undermost, and a moderate heat (generally a spirit-lamp) applied to disengage the vapour. Care must be taken to prevent the heat becoming high enough to melt the wax. After being exposed to the acid fumes for a few minutes, the glass plate may be removed and cleaned, when the design will be found perfectly etched upon the surface of the glass—the depth of the lines being proportional to the time the glass was exposed to the acid vapour.'

Staining—Colouring—Enamelling.

The art of staining or colouring glass is believed to be coeval with the discovery of the article itself. It is certain that it was known in Egypt several thousand years since, and tradition gives the honour of the discovery to an Egyptian king. The art of combining colours so as to produce pictures is of more recent date. The early specimens of stained glass exhibit a series of different pieces of various colours, joined together like mosaic work, so as to bring out the representation desired. This can now be done on one entire sheet. For a long period, the pictured glass used in cathedrals, &c. was merely painted on the surface, and was consequently liable to be rubbed off. The colours now are incorporated by fusion, and cannot be obliterated but by the destruction of the glass itself. The discovery of this art is ascribed to a painter in Marseilles, who went to Rome during the pontificate of Julius II. It was afterwards greatly improved by the celebrated Albert Durer and Lucas of Leyden.

All the pigments used in painting on or staining glass are oxides of metals or minerals—as gold, silver, cobalt, manganese, &c.—which, after being laid on, are subjected to a strong heat, until they penetrate into the body of the glass, or become fixed on its surface, and thus give out their fullest brilliancy and transparency. Animal and vegetable matters, which are freely used as colouring in ordinary painting, are wholly excluded in this, as the operation of the fire would entirely destroy their colouring properties. The colours that are meant to penetrate into the glass for the purpose of staining it, are wholly transparent, while those which are merely fixed upon the surface are only semi-transparent. Any colour or tint can be communicated to the glass in this way, and the art is at present practised with great success. The description of glass best adapted for painting upon or staining, is the finest crown or window-glass.

Thus the black oxide of copper imparts either a bright blue or a full green, according to the manner in which it is applied, while the red oxide of the same metal tinges glass with a beautiful ruby-red, the intensity of which is increased by the addition of peroxide of iron. Several different colours may be communicated by means of the protoxide and peroxide of iron: the former alone yields a dull green, which may be made so deep as to appear black; while the latter affords a variety of hues, from yellow to dark red. The greenish colour of common bottle-glass is due chiefly to the presence of protoxide of iron, introduced as an impurity in the materials. Oxide of cobalt is the principal vitrifiable colouring matter employed for the production of blue glass. 'No other metallic oxide,' says a chemical authority, 'possesses so intense a colouring power as this—one part being sufficient to afford a deep blue to one thousand parts of glass; and if the oxide is applied in a little larger proportion, the colour becomes so deep as to appear black. All kinds of glass may be coloured blue by this oxide with equal facility, and the colour is not in the smallest degree deteriorated by exposure to the highest temperature of a wind-furnace.' Oxide of chromium, which is the natural colouring matter of the emerald, imparts a beautiful and delicate grass-green; oxide of manganese, which is now extensively employed, a variety of shades, from a delicate amethystine to a deep violet, or even black. The delicate lemon-yellow, at present so fashionable, is produced by the peroxide of uranium; a good yellow by the chromate of lead, or by the oxide of silver, which is now, however, seldom employed. The splendid ruby, purplish-red, and rose-coloured hues are generally imparted by the oxide of gold, in combination with the oxide of some other metal—as lead, tin, bismuth, antimony, or zinc; gold by itself imparting no hue to the glass.

'The substances employed,' we quote from Parnell's Applied Chemistry, 'for rendering colourless and some coloured glasses more or less opaque, like enamel, are phosphate of lime, fluor-spar, arsenious acid, peroxide of tin, phosphate of lead, and phosphate of antimony. Phosphate of lime, which is the only one of these materials commonly employed at present, with the exception of fluor-spar, is introduced in the form of finely-powdered calcined bones, to the amount of one-twentieth to one-thirtieth of the weight of the glass. A very beautiful opaline crystal is obtained in this way.

'To colour glass uniformly throughout its whole substance, it is essential that the colouring oxide be intimately mixed with the glass, and both be brought into a state of complete fusion. But glass vessels and panes for windows are coloured very commonly merely on their surface, the body being an ordinary colourless glass, such as good crown-glass, containing a small proportion of alkali. For this purpose the metallic oxides, mixed with vitreous bodies which are easily fused, and with certain fluid vehicles, as oil of turpentine, are applied to the surface of the pane, commonly where a design is required, by means of a brush; but the pigments may also be transferred from a metallic plate or wooden block by gentle pressure; the pane is then exposed in an oven, or muffle, to a temperature sufficient to fuse the vitreous flux, and dissolve the colouring matter. In another method of obtaining a sheet of glass coloured on one of its surfaces, the glass-blower first collects the proper quantity of colourless glass on the end of the blowing-iron, then dips this lump for a moment into a pot of melted coloured glass, and blows out the two together into a cylinder or globe, which is extended into a flat plate in the ordinary manner. This method has been long practised in Bohemia, and is now become very general for colouring crown-glass red by means of the red oxide of copper. Ornamental vessels of flint-glass are also coloured on their outside in a similar manner, and colourless facets may be produced on such vessels by cutting through the layer of coloured glass into the substratum of the colourless.

'A patent has been recently obtained for a method of ornamenting glass, as well as earthenware and porcelain, by a process similar to that for painting or staining glass. The glass vessel or plate to be coloured is first of all covered with a thin layer of some adhesive matter, for which purpose essence of lavender is said to be preferred by the patentee; and on this coating the colouring oxides, in a state of very fine powder, and mixed with proper fluxes, are carefully dusted. The colour is then permanently fixed by the usual process of "firing." Articles of flint-glass are sometimes ornamented with delicate white argentine incrustations, formed of dry porcelain clay, cemented into a solid by means of a little plaster of Paris. These figures being thoroughly dried, are placed on the red-hot bulb of flint-glass, and are immediately covered with a thin layer of glass in a very liquid state. The polished external layer of glass gives the white figures a very agreeable silvery appearance, and they may be easily coloured, if required, before being applied to the glass. Flint-glass vessels, with coloured enamel figures on their external surface, are sometimes prepared by placing the figure in its proper place on the mould into which the vessel is to be blown. The glass, at this stage, being very hot, the enamel figure becomes firmly cemented to the surface.'

The applications of glass prepared and ornamented as above, are almost innumerable. Its use for windows, mirrors, bottles, decanters, drinking-glasses, and other vessels of domestic utility; for optical lenses, and the construction of chemical and philosophical apparatus; for decorative mouldings, chandeliers, and articles for the boudoir; for beads, spangles, gems, and other personal ornaments—must be familiar to every British reader. Since the abolition of the duty in 1845, its use has been extended in horticulture and in the dairy; it has been proposed to use it in the fabrication of transparent roofing-tiles, and pipes for the conveyance of water; and it is not too much to predict its application, on a large scale, to other economical purposes for which, by its beauty and durability, it is so eminently adapted. The manufacture of glass, in all its departments, is one of high national importance, giving employment to many thousands of our population, and converting into sources of wealth, comfort, and civilisation, the crudest and commonest materials of our soil.

PASTES—ARTIFICIAL GEMS.

In gem sculpture, *paste* is the term for a preparation of glass, calcined crystal, oxide of lead, and other ingredients for imitating gems. This art appears to have been well known to the ancients, and after being lost, was restored, at the end of the fifteenth century, by a Milanese painter. The general base of artificial gems is a vitreous compound known as the 'Mayence base' or Strass (from the name of its inventor.) It is prepared, according to Fontanieu, in the following manner:—8 ounces of pure rock-crystal or flint in powder, mixed with 24 ounces of salt of tartar, are to be baked, and left to cool. The mixture is to be afterwards poured into a basin of hot water, and treated with dilute nitric acid till it ceases to effervesce; and then the frett is to be washed till the water comes off tasteless. This is to be dried, and mixed with 12 ounces of fine white lead, and the mixture is to be levigated and elutriated with a little distilled water. An ounce of calcined borax being added to about 12 ounces of the preceding mixture in a dry state, the whole is to be rubbed together in a porcelain mortar, melted in a clean crucible, and poured out into cold water. This vitreous matter must be dried, and melted a second and a third time, always in a new crucible, and after each melting poured into cold water, as at first—taking care to separate the lead that may be revived. To the third frett, ground to powder, 5 drachms of nitre are to be added; and the mixture being melted for the last time, a mass of crystal will be found in the crucible of a beautiful lustre. Another very fine white base may, according to the same authority, be obtained from 8 ounces of white lead, 2 ounces of powdered borax, ½ grain of manganese, and 3 ounces of rock-crystal mixed and treated as above.

A base being thus prepared, the peculiar colours are obtained from the metallic oxides. We transcribe the proportions given for the fabrication of a few of the more familiar gems:—*Yellow diamond*—1 ounce strass, and 24 grains of chloride of silver, or 10 grains of glass of antimony. *Colourless diamond*—3 ounces rock-crystal, 8 ounces white lead, 2 ounces borax, and ½ grain of manganese. *Oriental ruby*—to 16 ounces strass, add a mixture of 2 drachms, and 40 grains of the precipitate of cassius, the same quantity of peroxide of iron prepared by nitric acid, the same quantity of golden sulphuret of antimony and of manganese calcined with nitre, and 2 ounces of rock-crystal. Manganese alone, combined with the strass, is said to yield a ruby colour. *Sapphire*—24 ounces of strass, 2 drachms and 26 grains of the oxide of cobalt. *Emerald*—to 15 ounces strass add 1 drachm carbonate of copper, and 6 grains glass of antimony; or to 1 ounce of base add 20 grains glass of antimony, and 3 grains oxide of cobalt. *Common opal*—1 ounce strass, 10 grains chloride of silver, 2 grains calcined magnetic ore, and 26 grains of an absorbent earth (probably chalk marl). *Topaz*—10 lbs. strass, and 1½ ounce of calcined iron. *Garnet*—2 lbs. strass, 2 lbs. glass of antimony, and 2 drachms of manganese. *Amethyst*—5000 parts strass, 20 oxide of manganese, and 1 oxide of cobalt. The preceding proportions, under the hands of an experienced manipulator, are said to yield imitations so like the natural gems, that none but lapidaries or mineralogists could detect the deception. In general, the artificial products are softer, more readily scratched, and of less specific gravity than the real gems; while their power of refracting light is also different—a test that can be applied without unsetting them.

In the above preparations, it will be observed that the fabricator produces a mere amorphic mass, which must be subjected to the wheel of the lapidary before it assumes the ultimate polish and facets of the natural crystals. Attempts have been made, however, to produce regularly-crystallised products from aqueous solution, by the agency of electricity; and in several instances the result has been so satisfactory, as to induce the hope of accomplishing in the laboratory of the chemist what nature has produced in the crust of the earth. More recently, M. Ebelmen has adopted a method to effect crystallisation based on the property which boracic acid possesses of dissolving metallic oxides in the dry way, and the volatility of this acid at a high temperature. It occurred to him that, by dissolving alumina and magnesia, mixed in the proportions which constitute spinelle (for example) in fused boracic acid, and exposing the mixture in open vessels to the high temperature of a porcelain furnace, the affinity of the alumina for the magnesia might cause the separation of a crystallised aluminate, and the expulsion of the boracic acid. By this means he has succeeded in producing artificial spinelle, cymophane, emerald, and other minerals possessing nearly all the hardness, transparency, colour, &c. of the natural product. M. Ebelmen is now hopefully engaged in prosecuting experiments in this interesting department of chemical knowledge.

CEMENTS—CONCRETES—STUCCOES.

Under this section we rank those compositions generally known as cements, mortars, concretes, plasters, and stuccoes. Their preparation, for the most part, involves a knowledge of chemical principles, and their practical application as ornamental mouldings, substitutes for sculpture, and the like, is an art as strictly fictile as the fabrication of earthenware or porcelain.

The *mortar* or cement employed to unite stones and bricks into a compact mass in building, is composed of quicklime, sand, and water. Quicklime is procured by roasting or calcining limestone in kilns, into which moderate-sized fragments of the rock are placed in alternate layers with coal or turf. By this process, water and carbonic acid are expelled, and the limestone converted into what is called *shell* or unslaked lime. The shells are then reduced to powdery quicklime by *slaking*—that is, by pouring as much water upon them as will suffice to destroy the cohesion of their particles. When intended for mortar, the quicklime should immediately be incorporated with sand, and used without delay, before it imbibes carbonic acid from the atmosphere. Lime, thus mixed with sand, becomes harder, and more cohesive and durable, than if it were used alone. It is found that the sand used in common mortar undergoes little or no change; while the lime, seemingly by crystallisation, adheres to its particles, and unites them together. The cement formed in this manner continues to increase in strength and solidity for an indefinite period, the hydrate of lime being gradually converted into a carbonate. Such is the strength which mortar thus acquires by time, that in some old buildings the lines of cement remain entire, while the stones have decayed. Indeed, in the removal of many old ruins, it is found necessary to employ the explosive force of gunpowder; and in such cases the stones more frequently give way than the lines of mortar.

In making mortar, fresh sand from a pit is to be preferred to that taken from the sea-shore, the salt of which is liable to keep the building moist, and to weaken the strength of the cementing property. The sand most proper for mortar should consist of angular particles, not rounded by attrition. The proportions of the lime and sand to each other are varied in different places; the amount of sand, however, always exceeds that of the lime. The more sand that can be incorporated with the lime the better, provided the necessary degree of plasticity be preserved; for the cement becomes stronger, and it also sets or consolidates more quickly when the lime and water are less in quantity, and more subdivided. The purer the lime, and the more thoroughly it is beaten or worked over, the more sand it will take up, and the more firm and durable does it become. In many cases, modern builders pay little or no attention to the slaking and preparing of their mortar, which, from whatever cause, is very inferior to the ancient cements.

When common mortar is made so fluid with water as to be poured on a course of brick or stone-work, it is known by the name of *grout*. Where great strength and durability are required, the practice of grouting the hearting or packing of the walls is usually adopted; as by this means the interstices are filled, and the whole rendered, by the hardening of the lime, a solid compact mass. Foundation *concretes* are generally formed of small angular stones well packed and grouted. Such concretes are proof against all moisture and decay; and on indifferent subsoils form more resistant foundations than isolated blocks of stone, however large and heavy. A concrete of quicklime and well-sifted gravel, with a small proportion of some absorbent earth, has been applied with success by Lord James Hay to the fabrication of drain-tiles or drain-tubes—the chief merit of the invention consisting in the facility with which the object can be accomplished. The composition setting with great rapidity, it may be worked round a mould in the bottom of the drain, and almost immediately covered with the arable soil.

Hydraulic or water cements, also called *Roman cements*, are those which have the property of hardening under water, and of consolidating almost immediately on being mixed. Common mortar, although it stands the effect of water very well when perfectly dry, yet occupies a considerable time in becoming so, and dissolves or crumbles away if laid under water before it has had time to harden. It is found that certain rocks which possess an argillaceous as well as siliceous character, if mixed with lime or mortar, communicate to them the property of hardening in a very few minutes after the mixture has taken place, as well under water as out of it. Substances of this sort have therefore been made the basis of water cements. The ancient Romans, who practised building in the water, and particularly in the sea, to a great extent, first availed themselves of a material of this kind. They erected their villas, not only on the sea-shore, but in artificial quays and islands constructed in the water. To enable them to erect these marine structures, they fortunately discovered, at the town of Puteoli, a peculiar earth, to which they gave the name of *Pulvis puteolanus*, and which is the same as that called by the modern Italians *Pozzolano*, chiefly obtained from Pozzuoli, near Naples. This earth is a light porous friable mineral, various in colour, and evidently of volcanic origin; mineralogically, it may be designated a calcined ferruginous clay. When reduced to powder by beating and sifting, and thoroughly mixed with lime, either with or without sand, it forms a mass of great tenacity, which, in a short time, cements to a stony hardness, not only in the air, but likewise when wholly immersed in water. To give the composition greater tenacity, it is occasionally mixed with bullocks' blood and oil. *Dutch trass* is a somewhat similar substance, which used formerly to be imported from Holland, where it is extensively used in hydraulic works. It is made from a light vesicular lava found near Andernach, on the Rhine.

Of late, a vast number of compositions have come into use as hydraulic cements, many of them possessing all the properties of the old Roman cement, and procurable at much less cost. The precise composition of several is kept secret by the manufacturers; but it may be stated generally, that lime, such as the lias, which contains about 12 per cent. of clay and iron, 5 clean sand, and occasionally brick or pottery dust, constitute the chief ingredients. Thus Parker's cement, which is known under the name of *compo*, and much used for facing houses, water-cisterns, setting the foundations of large edifices, and the like, is described as follows in the 'Engineers' Journal:'—This valuable cement is made of the nodules of indurated and slightly-ferruginous marl, called by mineralogists 'septaria,' and also of some other species of argillaceous limestone. These are burnt in conical kilns, with pit-coal, in a similar way to other limestones, care being taken to avoid the use of too much heat, as, if the pieces undergo the slightest degree of fusion, even on the surface, they will be unfit to form the cement. After being properly roasted, the calx is reduced to a very fine powder by grinding, and immediately packed in barrels, to keep it from the air and moisture. For use it is tempered with water to a proper consistence, and applied at once, as it soon hardens, and will not bear being again softened down with water. For foundations and cornices exposed to the weather, it is usually mixed with an equal quantity of clean angular sand; for use as a common mortar, with about twice as much sand; for coating walls exposed to cold and wet, the common proportions are three of sand to two of cement; and for walls exposed to extreme dryness or heat, about two and a half or three of sand to one of cement. For facing cistern-work, water frontages, &c. nothing but cement and water should be employed. The same authority gives several recipes for the preparation of similar cements, of which we may transcribe a few by way of example:—*1st*, Good gray clay 4 parts; black oxide of manganese 6 parts; good limestone reduced to powder with water 90 parts: mix, calcine and powder. *2d*, Mix manganese iron ore 15 parts, with lime 85 parts: calcine and powder. Both this and the preceding must be mixed up with a little sand for use. A piece thrown into water will rapidly harden. *3d*, Fine clean sand 1 cwt.; quicklime powder 28 lbs.; bone ashes 14 lbs. For use beat up with water as quickly as possible. *4th*, Three gallons of clay mixed with one of slaked lime, and exposed for three hours to a full red heat, are given as the constituents of Bruyere's water-cement. *5th*, The following preparation, and the last which we shall quote, is said to yield a very durable artificial pozzolene:—Expose a mixture of clay or loam, broken pottery, flints, or siliceous sand, or broken bottle-glass, with wood ashes, to a considerable heat in a furnace, until it becomes partially vitrified. Next grind to a fine powder, sift and mix with one-third of its weight of quicklime, also in fine powder. Pack in barrels, to preserve it from the air and moisture. For use this composition must be mixed with water, and applied like Roman cement.

Plaster, or the material which is used to spread smoothly over walls, is of various kinds. That which is applied to inner walls or partitions, is formed of certain proportions of slaked lime, fine sand, and water, with mixture of cow hair, to assist in giving cohesion. The lime requires to be sifted finely, and the more free it is of small lumps the better, as such lumps are apt to swell in the walls, and cause blisters, it is usual to allow plaster to remain some time made before using. The best plaster is now prepared by the pug-mill, by which the ingredients are more thoroughly incorporated than by the old process of hand-beating. Spanish white, ochre, and other colouring matters, are added when any peculiar tint is wanted; but we may here remark, that the most durable of all plasters, and that which answers best, even for fresco-painting, is composed simply of well slaked lime and sifted river sand. The surface of plaster is now seldom finished with a view to permanent exposure—whitewashing, sizing in colours, oil painting, and, above all, papering, being the prevalent fashions of the day.

Stucco is the name ordinarily given to plaster of Paris, which is gypsum reduced to a powder by heat and grinding; but the term *stuccos* is further extended to embrace all those compositions with which walls are coated or ornamented, in imitation of stone. Gypsum, which is found in roundish hard masses, is properly a sulphate of lime; and like all other varieties of lime, it has a strong power of absorbing water. The practice is to put the masses into a heated oven, and when duly baked, to take them out and grind them to powder in a mill. This powder, when sifted, is a beautiful white substance, resembling flour. A quantity of powder being put in a vessel, water is poured upon it, and immediately the stuff thickens in a surprising manner, and becomes a hardened mass. While still thickening or setting, it is poured into a mould for any required shape; or it may be applied along with a little lime as a fine plaster, which it is desirable should dry speedily. It is used largely for all kinds of casts from pieces of sculpture, mouldings for cornices, and is indispensable in stereotyping. There are none of the artificial stuccos which yield so sharp or delicate a cast; but most of them excel it in hardness and durability. Of these we shall notice a few of the more important:—

Mastic is a resinous substance, obtained from incisions made in the branches of the *Pistacia lentiscus*, a small tree or shrub growing in the Levant, and other countries bordering on the Mediterranean. It abounds in Scio, where it has long been cultivated. The gum being chewed or used as a *masticatory* by women in Turkey, for the purpose of cleansing the teeth, and imparting an agreeable odour to the breath, hence its European name of *mastic*—a term by no means appropriately applied to certain architectural cements or mortars. One of the most durable of these is *Hamlin's mastic*, thus described in the 'Pharmaceutical Times:' 'To any given weight of well-prepared pit or river sand, or any other sand of the same nature, or pulverised earthenware or porcelain, add two-thirds of such given weight of pounded Portland stone, Bath stone, or any other stone of a like nature. To every 500 lbs. of these earths so prepared, add 40 lbs. of litharge, and 2 lbs. of powdered glass or flint. To this admixture add 1 lb. of minium, and 2 lbs. of gray oxide of lead. When this composition is intended to be made into cement, to every 605 lbs. there should be added 5 gallons of vegetable oil—as linseed, walnut, or pink oil. When applied to walls in imitation of stone, the surface of the building should be previously washed with oil.' *Martin's patent cement* is another composition possessing durable properties, and less expensive than Hamlin's. It is made to imitate Bath, Portland, and other kinds of stone, as well as marble. It is generally employed as a plain coating, but can likewise be formed into ornamental mouldings. *Chunam* is the term for a durable Indian stucco, the basis of which is obtained from calcined shells.

Keene's patent marble is a recent invention, which appears to be approved of. It is described in the proceedings of the London Society of Arts as a combination of sulphate of lime and alum. The gypsum undergoes the same preparation as for plaster of Paris, being deprived of its water of crystallisation by baking. It is then steeped in a saturated solution of alum; and this compound, when recalcined, and reduced to a powder, is in a fit state for use. The cement has been already extensively employed as a stucco; but the finer qualities (when coloured by the simple process of infusing mineral colours in the water with which the cement powder is finally mixed for working) being susceptible of a high degree of polish, produce beautiful imitations of mosaic and other inlaid marbles, scagliola, &c. The cement is not adapted to hydraulic purposes, or for exposure to the weather, but has been used as a stucco in the internal decorations of Windsor and Buckingham palaces. From its extreme hardness, it has been found serviceable when used for imbedding and setting the tiles of tesselated pavements, &c.; and has been adopted for this purpose in several of the public buildings in London. The coarser qualities are said to form an internal pavement not distinguishable from stone in colour and hardness, and at less cost.

Scagliola is the Italian term for a composition intended to represent various marbles, porphyries, serpentines, &c. It is composed of fine plaster of Paris, with colouring matters, cemented by glue or isinglass, and is sometimes studded with chips of alabaster, &c. to imitate verd-antique. It is laid on like common stucco, moulded into the desired forms, and allowed to set. When thoroughly set, it is smoothed with pumice stone, and washed; then polished with tripoli and charcoal; next with tripoli and oil; and finally with pure oil, laid on with cotton wool. The result is a surface of unusual richness; but from the nature of the ingredients, it is only fitted for internal decoration, and even then requires to be kept dry.

Another composition, under the name of *intonaco* (literally wall-plaster), has recently been patented by Mrs Marshall of Edinburgh. We have seen nothing beyond hand specimens of the cement, but judging from these, it has all the requisites of hardness, susceptibility of polish and colour, and capability of resisting either fire or water. A writer in 'Chambers's Journal' for March 18, 1848, has 'seen walls in sunk flats (done with it more than two years ago) which had been streaming with damp, noxious and offensive in its effluvia, so as to be quite uninhabitable, rendered perfectly dry, and the apartments offering a peculiarly comfortable sensation to the feelings on entering, as if a fire had recently been in them. This arises from the intonaco being such a remarkably slow conductor of heat, that the atmosphere in all apartments plastered with it is kept at an even temperature—warm in winter, and cool in summer; whereas common lime, being a very rapid conductor of heat, speedily robs the air of all warmth in winter, and throws in great heat in summer—effects which we but partially obviate by covering it with paint or paper. The cement,' continues the same writer, 'also resists fire to a very high degree. Half an inch depth of it has been known to protect lath from intense fire for two hours; and even when it reaches the wood, neither flame nor spark is ever emitted—it merely smoulders slowly into a light-white ash. The intonaco does not, even under a red heat, crack or fly off from the wall; but if water be thrown upon it at this time, its substance and cohesion are destroyed, and it requires removal.' It can be employed with equal facility as a cement or plaster, a paste for casts and ornamental mouldings, or a concrete for the fabrication of artificial marble and other stones.

Various *artificial stones*, besides those for ornamental purposes, have recently been brought under the notice of the scientific. Thus a French mechanic has proposed the running of iron dross into moulds, and thereafter subjecting it to the slow cooling process which is known to produce such a total change in the nature of glass—the object being to impart to the dross the compactness and hardness of granite, and at the same time to save the cost and labour which the hewing of the real stone requires. To this end he contrives to let the iron refuse, and while in a fluid state, run into iron forms, which are previously brought to a red heat by being placed so as to receive the superfluous flame which issues from the mouth of the furnace; and in order to insure the slow cooling, these forms are provided with double sides, between which sand is introduced, which is well known to be a bad conductor of heat; the whole is then brought to a glow of heat, and in like manner again cooled off. By this procedure, it is asserted, the ingenious discoverer has succeeded in forming paving-stones, flags, large building blocks, and even pipes, of any given form, of a degree of hardness and polish equal to the best hewn natural granite, and at the most trifling conceivable cost. A composition of the same class has also lately been invented by M. Möser of Berlin, and employed in the fabrication of statues, vases, and ornamental mouldings under the title of *cast-marble*. The nature of the composition is a secret, but from its cheapness (2s. 6d. per cubic foot), it must consist chiefly of very common materials. The figures exhibited at the factory of the inventor are of various ingredients, presenting gradations from a compact reddish sandstone to the finest translucent Carrara marble.

Moulding compositions for making architectural ornaments in relief are now extremely common, and in most instances well fitted for the object in view. A very cheap one is formed of glue, chalk, and paper-paste, the paper aiding the cohesion of the mass; another of paper-paste, finely-powdered plaster of Paris, and size, which requires to be used as soon as mixed. Both of these are extremely light, and receive a good polish, but will not stand exposure to the weather. *Papier-maché*—a substance to be more fully noticed under Paper-Making—is also much employed for forming ornaments, as a substitute for carving, and casts in plaster of Paris. It is made, as its name imports, from paper or rags reduced to a pulp with gum or size, pressed into moulds and afterwards dried. It is extremely light and durable; and from its susceptibility of being varnished and painted upon, is now coming largely into use, not only for architectural ornaments, but for the fabrication of finger-plates, door-handles, tea-boards, trays, fire-screens, work-boxes, and a variety of articles for the boudoir.

Asphalte, so called from its adhesive nature, has lately been adopted to a large extent, both in the formation of a pavement concrete, and as waterproof roofing for buildings. Asphalte, or asphaltum, is a bituminous mineral, allied in its nature to pitch, and is found in the form of rocky masses in different parts of the world. The chief quarries for it in continental Europe are in the Val de Travers, province of Neufchatel, the excavations being in the Jura range of mountains, which are calcareous in their nature. An inferior kind is a species of bituminous molasse, which exists in various parts in what must be called lakes, or vast semifluid masses. The true asphalte, or asphaltic cement of Neufchatel, is procured by boring and blasting the bituminous rocks, and the pieces being brayed and then melted in large boilers, the hot fluid is poured out so as to form conveniently-sized cakes. When needed for smearing on roofs, it requires to be only melted and spread; and when dry, it remains impervious to the weather, neither cracking in winter nor melting in summer. If designed for pavement, it must be mixed with sifted gravel, pounded iron slag, or river sand, which gives it more stability, and a degree of roughness that is not unnecessary. The composition is prepared in portable boilers or caldrons, and spread while hot on a properly-prepared bed; and being rendered smooth on the surface, it offers an exceedingly agreeable resistance to the foot, being not so hard as stone, nor so soft as a mud pathway. Wherever stone is expensive, asphaltic pavement may be advantageously employed, not only for streets, but floors of dairies and other out-houses, garden-walks, and terraces.

A cheaper and equally durable pavement may be formed of gas-tar and gravel, the following formula for the preparation of which we find given in the 'Builder,' by Mr Shearburn of Dorking:—'Take ten gallons of gas-tar, two bushels of gravel, sifted through a half-inch sieve, and two bushels of sharp washed sand; the whole of this composition to be heated in an iron furnace, and kept stirring until it is found to set quickly; after which it is taken out, and spread upon the surface intended to be covered about two inches thick, with a wooden handfloat, such as is used by plasterers for stucco work. A heated iron or spatula is passed over it, which brings the tar to the face; after this sift over it some smiths' ashes—refuse from the forge. In a short time it will set, and appear like cast-iron, and resist all impressions and wet. Gutters may be formed in a similar manner. Care should be taken the materials are dry before being added to the tar; for this purpose I have used an old hot-plate, and dried them at the same time and expense as heating the tar. All can be done by labourers, excepting one man handy with a trowel; and the material will cover a large surface, at a comparatively small expense. I have used it for the covering of bridges, terraces, stables, and sheds for feeding cattle; and also on an area of 300 yards, covering basement rooms to a nobleman's mansion in the north of England; no wet has penetrated. I have seen it used on roads, with the exception of the tar being heated, and the materials of a heavier metal. The best road that I know of is out of Nottingham to Lincoln, for about two miles, and is of this description.'

Adhesive cements and *lutes* have already been briefly noticed under the head of 'Applied Chemistry:' we may here observe generally, that they are exceedingly varied both in their composition and application. Thus the engineer, plumber, jeweller, cabinetmaker, and mender of broken china or glass, have their own peculiar compounds; and the manner in which they apply them, so as to combine strength with neatness, and at the same time make them appear like the material united, is often truly ingenious. As a general rule, it may be remarked, that the closer any two bodies can be brought together, consistent with the uniform distribution of the cement, the more firmly will they be united. A few of these compositions may be transcribed, merely by way of example:—4 parts of iron-filings, 2 of potters'-clay, and 1 of pounded potsherds, mixed into a paste with salt and water, if allowed to concrete slowly on iron joints, forms a very hard cement. Another used by coppersmiths and engineers to secure joints, consists of boiled linseed-oil and red-lead mixed into a putty. White of egg, thickened with finely-powdered quicklime, is employed to mend earthenware, china, glass, &c.; but it does not resist moisture. Isinglass dissolved in mastic varnish is often used for the same purpose; it resists moisture, and dries colourless. Glue, and the various cements into which it enters, are well known; the celebrated *marine glue*, the adhesive powers of which are invincible, is a totally different substance, said to be composed of caoutchouc dissolved in naphtha or oil of tar, with a certain proportion of shellac. So powerful is this compound, that the hull of a vessel might almost be constructed by its assistance, without the aid of bolt or trenail!

Caoutchouc and *gutta-percha*, two remarkable substances of vegetable origin—to be afterwards treated at length—can scarcely be omitted in any account of modern fictile fabrics. The former, being highly elastic, reducible by heat, soluble only in certain liquids, and capable of chemically uniting with several substances, is applicable to a thousand purposes of utility and ornament. The same remark may be applied with equal propriety to gutta-percha, which is also soluble only in certain liquids, is reducible by heat, and though inelastic, is much more ductile and plastic than caoutchouc. In our textile fabrics, both now occupy a prominent part; while as fictile materials, they may be formed into ligatures and belts, tubes, bottles, springs, boots and shoes, waterproof vessels, knobs and handles, ornamental mouldings, and as ingredients in pavements and floorings of a very durable kind.

TEXTILE MANUFACTURES.

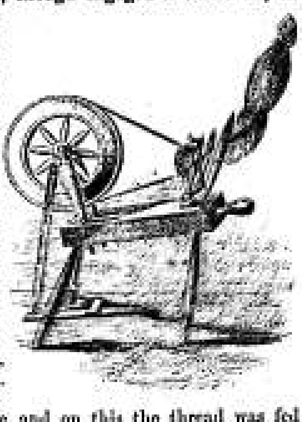
By *Textile Manufactures*—as generally defined—are meant those in which filaments of flax, of cotton, of silk, or of wool are wrought into linen, cambric, calico, muslin, silk, satin, flannel, broadcloth, and the numerous modifications of these now so well known to every British reader. In the present instance, we extend the definition so as to embrace every variety of fabric—as paper, felt, straw-plait, and the like—essentially composed of vegetable or animal fibre. In the preparation of these, from the rearing of the raw materials to their ultimate stage as articles of utility and luxury, there is involved a vast amount of labour, of mechanical and chemical skill, of capital and enterprise—so much so, that, as a class, they rank second to none of the manufactures which come within the scope of our national industry. In the following pages we aim at a very general account, seeing that details of any particular process would be not only inconsistent with our limits, but unintelligible without the aid of numerous diagrams, and also a certain amount of practical acquaintance with the subject under review.

LINEN.

The fabrication of linen cloth, which is of high antiquity, and to which we may first advert, commences by the preparation and spinning of the raw material—lint. Lint is the fibrous bark of the flax-plant (*Linum usitatissimum*), which grows in temperate climates to a height of from three to four feet. It is an annual, having a slender, smooth, hollow stem, rising undivided till within a few inches of its full height; its several branches are then terminated by small blue flowers, to which succeed roundish seed-vessels, each enclosing ten smooth shining seeds replete with meal and oily matter. As a crop, flax is cultivated less or more in most European countries, and succeeds best in a rich deep loam, with a good deal of moisture. That produced in Holland and Belgium is said to be best; but our chief supplies are obtained from Russia, Prussia, and other countries bordering the Baltic. Egypt, anciently so celebrated for its fine linen, is beginning to yield a portion of our supply, and promises well for the future. Owing to the cheapness of foreign flax, comparatively little is reared at home, notwithstanding the endeavours which have lately been made to extend its culture in Ireland, and in certain districts of England and Scotland. The seed is sown broadcast, and harrowed down early in April; and if in clean, well-prepared soil, requires no farther attention. When the crop is ripe, which usually happens about the end of summer, it is pulled and laid in bundles to dry. It is then *rippled*, or deprived of its seed-vessels, either by drawing the stalks through a kind of comb with iron teeth, or by beating them. The capsules are next thrashed and winnowed to obtain the seed, from which linseed oil is procured by pressure—the refuse forming the oil-cake of the cattle-feeder and farmer.

The next process is to obtain the flaxen fibre or lint free from the woody core, or *boon*, of the stem. This is effected by steeping the bundles in water till the boon begins to rot, in which state it is readily separated from the fibre. This operation is called rotting, or *retting*, and requires to be managed with great care, as by continuing it too long, decomposition might extend to the fibre, and render it useless; while by discontinuing it too soon, the separation could not be effected with sufficient ease. The time is generally determined by the nature and temperature of the water, and the ripeness of the flax—decomposition taking place more rapidly in soft stagnant water than in running streams, in which the retting is sometimes conducted. After being sufficiently steeped, the flax is spread out on the grass, to rectify any defect in the retting, and ultimately to be dried for the breaking. In some districts it is the practice to conduct the retting entirely on the grass—a process known as dew-retting, in contradistinction to water-retting. This is a safer and less offensive method, but it requires much longer time, and in a country where land is valuable, would become very expensive. On the whole, the mixed method of retting is preferable—that is, to steep till decomposition of the boon is well advanced, and then to complete the process on the grass. It has been attempted to separate the fibre by machinery, without subjecting the flax to retting; but the material so produced has hitherto been rejected as inferior in quality to that produced by the old process. Being retted and dried, the flax is now *skutched*, or bruised, to free the external fibres from the waste of the stalk. This was formerly effected, first by the *hand-brake*, which bruised or broke the dry brittle core; and secondly by the *skutch*, a sort of wooden knife with which the operator switched the waste from the fibre. A system of rollers to bruise, and flying arms to skutch, now constitute the preliminary dressing apparatus, which is moved by steam or water power. *Hackling* is the next process in flax-dressing, still partially performed by the hand, but chiefly, we believe, by machinery. The hackle is a strong comb composed of several rows of steel teeth, four or five inches in length, fixed upright in a block of wood as a base, and made fast to a bench. The workman taking a handful of skutched flax, strikes it against the pointed summits of the teeth, and draws it through—repeating the process till the requisite fineness is obtained. Coarser and wider-toothed hackles are first used, and then others progressively closer as the fibres become finer by separation. The fine lint so obtained is called *line*; the refuse left on the hackles, *tow*. Supposing the hackling to be performed by hand, the line is now ready to be spun into the finer sorts of yarn; the tow into the coarser sorts, for sacking and similar fabrics.

The mode of *spinning* is now very different from what it once was. In ancient times it was customary to spin by the distaff, an exceedingly simple apparatus, consisting of a spindle or bobbin, twirled by the twisting of the lint, as it came from a staff of lint held by the operator; the finger and thumb were the sole instruments for twisting. A female could not twist a spindleful of thread, though engaged a whole day in the labour. This rude process was at length superseded by the introduction of a machine called the *spinning-wheel*, a representation of which is given in the annexed engraving. A female sat with her left hand towards the *rock*, or staff, on which the lint was placed; her right foot moved the paddle-board below, and this affecting the upright crank, turned the wheel. A band communicated to the spindle, and on this the thread was fed from the rock. In drawing out the lint, the finger and thumb were frequently wetted by touching the lips, and this had an effect in consolidating and smoothing the thread, which no purely mechanical process has



since been able to imitate. An improvement on this, in point of celerity, was the double-thread spinning wheel, which was furnished with two spindles, the spinner forming a thread with each hand. Although the motion of the wheel was rapid in comparison of the feeble operation of the distaff, the process was very insufficient, except for home-made linens, and something very different was required for manufactures conducted on an extensive scale.

The introduction of machinery in the manufacture of cotton led to the application of similar mechanism in the linen manufacture; and for many years hand labour has been entirely abandoned. Hand-spinning may now be said to live only in the songs and ballads of our country, and spinning-wheels to be preserved merely as relics. All steps in the preparation and spinning of the flax are on a large scale. The flax is imported in vast quantities from the countries already mentioned, and is dressed and spun in factories at Leeds, Dundee, or some other great seat of manufacture. The machinery is extremely beautiful and ingenious, and the making of it alone is a principal trade. On being brought to one of these factories, the flax is from thirty to thirty-six inches in length, and the first step 'is to take a quantity of it'—we quote the Encyclopædia Metropolitana—'and divide it into three lengths; the part nearest to the root being coarse and strong, the middle part fine and strong, and the upper part still finer, but not so strong. Thus each length being divided into three, and all those of the parts from the bottom, middle, and top, being collected into separate heaps, three distinct qualities of yarn are to be formed. The separation of these first lengths into three is effected by a very ingenious machine, consisting of a number of vertical wheels, and a centre wheel, furnished with a kind of teeth. The length of flax is held transversely against these wheels, and is passed between two, one on either side, while the centre wheel tears it across by separating but not cutting the fibres. This cuts off the bottom part of the length of flax; the remaining part is then submitted to the same process, and the middle part cut from the top, each sort being collected in one heap, so as to effect a separation of the three qualities above named. Each division will be of course about ten or twelve inches in length.

'In the next stage—the dressing or hackling—these lengths are fixed in a sort of vice at one end, spread out to a breadth of six or seven inches; several of these are fixed on a sort of revolving drum, at distances of about a foot from each other, their unsupported ends falling on an internal drum covered with strong cards, the internal drum revolving one way with considerable velocity, and the external in the opposite direction rather slowly, and thereby the lengths of flax are rendered very smooth and straight; they are then dexterously removed by an attendant, generally a girl, and placed with their other side downwards in the next machine, and again removed. It should be remarked that these only pass over the upper part of the internal drum; for it is obvious, if they passed below, their weight would cause them to fall away from, and not upon the carding-roller.

These several operations being performed, the next step is to place these pieces of flax, one just reaching the other, on a feeding cloth, and by the hand slightly to combine their ends; the first end is then passed between two card-rollers, or rollers furnished with teeth, which carry the whole forward, while the extreme end passes between two rollers of iron, the latter moving with considerably greater velocity than the former, in some cases 30 to 1, and consequently the flax is now lengthened 30 to 1, and its thickness reduced accordingly. In passing from the roller the flax receives no twist, but comes out flat, and of about the breadth of narrow tape, and is caught in a cylindrical tin can placed below to receive it; when a certain length has been received sufficient to fill the can, a bell rings, an attendant breaks the flax, removes the can, and places another. The flax in the full can is then taken to another machine, where it is again lengthened, and so on, to different degrees, according to its intended fineness. After it is properly reduced in the flat state above described, it receives in its last stage a very slight twist, so as to reduce it to a round thread. It is then received on bobbins, and is in a proper state for spinning; the process of which differs only in degree from that described in relation to the cotton manufacture.' The yarn thus produced is now ready for the weaver, who converts it, either by hand or by steam power, into the various fabrics of linen, damask, cambric, &c. to be afterwards described.

Weaving is an art of great antiquity, and has undergone little improvement till recent times. The process is founded on a simple principle. A certain number of threads drawn out alongside of each other constitute the *warp*. This is evenly wound on the beam of a loom, and is thence extended to another beam at the opposite end. The warp is two threads in depth, and by means of heddles and other apparatus, these are caused to rise and fall, so as to cross each other vertically. Every time that the threads are opened, a shuttle, containing the *woof* or *weft*, is thrown across from one side of the warp to the other, and the thread of woof thus left is driven home by a lay, or properly by a comb-like process of reeds called a *dent*, which the lay brings forward. A reversal of the warp makes another opening, which is similarly crossed by the shuttle, and so on, the fabric gradually assuming the character of cloth. Plain cloth of all descriptions is formed by this simple species of operation, whether the loom be driven by hand or by steam power. In preparing *warps* and *woofs* on an extensive scale, machinery has also been called in to supersede that of manual labour. The former are now prepared by the *warping-mill*, an apparatus consisting of a number of spindles on which the bobbins containing the yarn are placed, and a drum or reel, round which they are simultaneously wound. The quantity of warp being determined, the warper proceeds to unwind from these bobbins the requisite amount, observing that none of the threads get broken, and taking care to supply the spindles with new bobbins as the first set are wound off. In filling the pirns for the shuttle, machinery also lends its aid; and though almost automatic—stopping when the thread breaks, or when the pirn is full—yet human skill is still, and ever will be, necessary to superintend and direct.

The only changes of pattern which can be readily produced by plain weaving are *stripes* or *checks*—the former generally depending upon the colours of the warp, and the latter upon the colours of both warp and weft. Thus stripes in the direction of the cloth may be produced by using warp of various colours, or a warp composed of threads of different sizes and substances; stripes across the web may be formed by using shuttles containing various colours and substances; chequered patterns by varying both warp and weft; and figures to a certain extent by raising and depressing alternately certain portions of the warp. *Twills* are formed by causing the thread of the weft to pass alternately over four and one of the threads of the warp, and performing the reverse in its return. Plain twilling is adopted in various linen fabrics—in silk it is called satin, in cotton fustian or jean, and in woollen serge or kerseymere. In ornamental or *figure* weaving, an expensive, or at least complex, harness is required, the warp being of various depths, several sets of heddles being also in requisition, and it may be a number of shuttles, each having its own system of thread or threads. It is easy to see how, by these means, a great variety of figures may be produced; and in order that the weaver may clearly understand the intended texture of his piece, all the threads are drawn on cards before he begins, in a manner peculiar to themselves; and these he reads as he proceeds, just as a musician plays from his sheet of music. Formerly, a number of boys or assistants were required in damask and other ornamental weaving; but now, by the aid of wheels, cranks, springs, and levers—in fact, by a system of clock-work—the weaver in general proceeds by himself. Looms of this kind, whether for linen, silk, cotton, or carpet fabrics, are known as draw-looms, the most perfect of which is that invented by M. Jacquard, a practical weaver at Lyons. With modifications adapted to the object in view, the Jacquard loom has now superseded all others for figure weaving—the skill and labour required to work it being little more than that necessary for plain weaving. *Pile* fabrics—as velvets, fustians, corduroys, &c.—are produced by using another set of threads besides the warp and weft. In the process of weaving, these threads are looped on one side of the fabric, and are afterwards cut and flushed into pile. For the weaving of ribbons, gauze, lace, and other fancy textures, a variety of ingenious machines are constantly being invented, some of which have little in common with the loom, and would require to be examined minutely to be properly understood.

The *fabrics manufactured from flax*, or linen yarn, are known in commerce by various names, according to their fineness, patterns, uses, and other particulars. Any of them may be bleached or unbleached, and bleaching may take place either in the yarn or in the fabric. In all of them the fineness and strength depend upon the original quality of the yarn, the closeness of the dent or reed, and the regularity with which the weaver drives the weft home. An excellent fabric may be left rough and unfinished in surface, while a worthless material may be made to assume the most captivating appearance by smoothing, starching, singing, watering, calendering, and other ultimate processes. Of *linen*, there are various subordinate sorts—as *Irish*, *Scotch*, and *English*; *Holland*, a fine kind brought from the Low Countries; *dowlas*, a coarse undressed fabric; *drill*, a stout twilled linen; *Silesia*, a fine brown holland, glazed for window blinds, &c.; and *Hessia* and *Forfar*, both coarse varieties used by upholsterers and others. *Linen damask* is the name given to twilled and figured sorts used for tablecloths and napkins, often of great beauty and intricacy of pattern; *diaper* is a damask of smaller figure and pattern used for napkins, towels, and the like; and *union*, a damask formed of linen and cotton, or even of linen and woollen. *Cambric* is the well-known finest fabric which can be produced from flax; and *lawn*, a variety intermediate between linen and cambric. *Tick* is the twilled and striped fabric used for bed, bolster, and pillow cases; *huckaback*, *dorrock*, *Osnaburgh*, &c. are coarse varieties of dowlas; and *canvas*, the general term for the coarsest fabrics produced from flax. Canvas of still coarser texture is manufactured from hemp and other fibrous material, to be afterwards noticed.

Bleaching and *calendering* are the processes which follow the weaving, and in both there are now great improvements. The principles of bleaching have been already explained under 'Applied Chemistry'—whether by the old process of sun-bleaching on the grass, or by the application of chemical detergents. We shall here merely allude to the process adopted by the Irish manufacturers, as detailed in 'Hall's Ireland,' premising that the cloth in this case is woven of unbleached yarn; it being perhaps now the more common plan to submit the yarn to perfect or to partial bleaching before committing it to the hands of the weaver. 'Being first unfolded from the firm and compressed shape in which each *piece* or web is received from the manufacturer, the cloth is cast, loosely knotted, into a wooden boiler, capable of containing some two or three hundred pieces, and nearly filled with a weak solution of potash or barilla. After it has been boiled in this liquid for several hours, it is removed from the boiler by a crane and network of rope, and almost immediately transferred, in separate quantities, to the *wash-mills*. Here it is placed in a trough, through which jets of spring-water are constantly passed, and kept fully exposed to the action of the water by means of two large beams suspended above the troughs, and termed *feet*, the lower ends of which are alternately drawn back, and permitted to fall against the linen with considerable force. This motion is produced by the revolving of a cylinder situated directly beneath, and having projecting spars which catch and raise, at intervals, the extremity of the feet. From the wash-mills the linen is removed to the green, where it is carefully spread upon the grass, the several pieces being attached together, and their ends secured to the ground by small wooden *pins*. After remaining two or three days upon the grass, it is again brought to the bleach-house, to be boiled and washed as before. The operations of boiling, washing, and spreading upon the green continue, thus successively repeated, till the linen has fairly assumed a whitish hue, when two additional forces are introduced. The first is that of passing the linen through the *rub-boards*. These boards, which are fixed in a frame, and moved by simple machinery, have portions of their inner surfaces furnished with plates of *lignum-vitæ*, or other hard material, completely channelled with narrow parallel grooves, the plates of the upper board being placed immediately over those of the under. Between these plates the linen, having been first plentifully soaped, is slowly passed, so that the entire web is submitted to the friction. The second process is that of steeping, for a certain number of hours, in *kieves*, or cisterns, containing water acidulated with sulphuric acid. After the introduction of the additional processes, the earlier continue unchanged, excepting that the use of the former alkalies in boiling is abandoned, soap-lye being now employed.

'By these several means, the bleaching is at length completed, when the *finishing* or preparing for market immediately begins. The linen is first starched and blued, after which it is suspended in a *drying-loft*, where it is exposed to the air till completely dry. It is then taken down and stretched, and submitted to the *beetles*. These are a succession of weighty wooden billets, ranged in a frame, above a slowly-revolving cylinder, round which the linen is wound. The machinery being set in motion, the billets are raised and successively dropped, with great rapidity and force, on the cylinder beneath. This is continued for several hours, and the operation repeated till the fabric is sufficiently compressed, and the requisite smoothness obtained. The linen is then *lapped*, or folded, and sent to the assorting-room. Here each piece is carefully measured, again firmly lapped, and subjected to the pressure of a hydraulic press. The peculiar stamp of the merchant is finally applied, and the linen is ready for the market.' Of course every manufacturer has his own mode of 'finish;' some smoothing by heated cylinders, others using starch and similar ingredients to stiffen the fabric, and not a few employing more objectionable methods of stretching, smoothing, and producing an artificial gloss, with a view to make an inferior fabric assume the appearance of one of superior quality.

It may be here observed that new modes of bleaching have recently (July 1847) been patented by Mr Sandeman of Perthshire, which, from their simplicity, cheapness, and safety, are likely to supersede in a great measure the old hot or boiling processes. Mr Sandeman's methods are termed the 'cold,' 'thermal,' and 'binary,' and are founded on the peculiar property of hydrates of lime—a property possessed, we believe, by no other aqueous solutions whatever—namely, that the colder the water, the greater is the quantity of solid matter (lime) which they absorb. He employs in the main the same detergents that are used in the boiling process, but in different proportions; while he manages to dispense with several of the alkaline solutions, nearly all the expense of furnaces and fuel, and effects a considerable saving in point of time. 'Moreover,' to quote his own words, 'yarns, threads, or twist which have gone through this cold process, are found to retain more of their original strength, firmness, levelness, and weight, and to be much freer from oaziness of fibre, than those which have been treated according to the ordinary hot or boiling processes. In like manner, all cloth bleached by this process retains more of its original strength, firmness, elasticity, and weight, than that which is bleached by the processes heretofore pursued.'

The *Linen Manufacture* has been long prosecuted, especially in England and Scotland; but until of late years, its progress has been inconsiderable, compared with that of our other manufactures. No very accurate statistics of the trade can be obtained, in consequence of hand-power being employed to a large extent both in the spinning and weaving of the material. In 1839, there were 169 flax factories in operation in England, 183 in Scotland, and 41 in Ireland—employing respectively sixteen, eighteen, and nine thousand hands. According to Mr M'Culloch, the entire value of the linen manufacture of the United Kingdom does not exceed ten millions.

Hemp and other Ligneous Fibre.

Hemp is the fibrous bark of the *cannabis sativa*—a plant supposed to be a native of Persia or India, but which has long been naturalised and extensively cultivated in Europe, particularly in Italy, Russia, and Poland, where it forms an article of primary commercial importance. It is also cultivated to a considerable extent in many parts of America; but in Britain it is but little grown, except in a few districts of Suffolk and Lancashire. Its fibres are prepared for spinning in the same way as flax, and is made into yarn for the fabrication of canvas-bagging, sailcloth, ropes, and cordage. The common cultivated *hop*, some species of *nettle*, and other plants belonging to the same natural order (*Urticaceæ*), as the hemp, yield also a tough elastic fibre, from which coarse fabrics are occasionally woven. Indeed the elaboration of a tough elastic product seems to be characteristic of the whole order—making its appearance in the stem of the hemp, in the inspissated sap of the Indian-rubber tree, and in silk, the best of which is derived from silkworms that feed on the leaves of the mulberry. Several of the members of another natural order (*Liliaceæ*) yield fibre strong enough to be worked into cloth and cordage; but in these the fibre resides in the leaf, and not in the bark of the stem. Of these may be mentioned the *New Zealand Flax* (*Phormium tenax*), whose toughness rivals that of hemp, and the Sansevieras, from which is obtained the still stronger substance called *African* or *bowstring hemp*. *Coir*, which is extensively worked into mats and cordage, is the dry fibrous pericarp of the cocoa-nut. The inner bark of various trees is sufficiently tough in fibre to form material for fishing-lines, nets, rice-bags, a coarse kind of linen, and the well-known matting called *bast*. The linden-tree may serve as an example, its inner bark furnishing the Russian or bast mats so largely employed for commercial purposes. The most of the coarse fabrics so composed are either woven or plaited; ropes and cordage are twisted on the same principle as common thread, either by hand labour, or perhaps now more generally by machinery.

COTTON.

Cotton is the wool produced in the pods or seed-vessels of the cotton plant (*gossypium*), which is indigenous to all the tropical regions of Asia, Africa, and America. Three great distinctions are generally observed in treating of cotton—namely, the herbaceous, the tree, and the shrub species. The first and most useful is the *herbaceous*, which is an annual plant, cultivated in the United States, India, China, and other countries. It grows to the height of eighteen to twenty-four inches, and has leaves somewhat lobed, of a bright dark green, and marked with brownish veins. Its blossom expands into a pale yellow flower, like that of a mallow; and when the flower falls off, a three-celled, triangular, capsular pod appears. The pod increases to the size of a large filbert, and becomes brown as the woolly fruit ripens; the expansion of the wool then causes the pod to burst, when it discloses a ball of snow-white or yellowish down, consisting of three locks, one in each cell, enclosing and firmly adhering to the seeds. The seed is planted in March, April, and May, and the cotton is gathered by hand, within a few days after the opening of the pods, in August, September, and October. In America, it is planted in rows five feet asunder, and in holes eighteen inches apart, in each of which several seeds are deposited: careful weeding of the ground is necessary, and the plants require to be gradually thinned, so as ultimately to leave only one or two for each hole; they are also twice pruned, in order to make them put out more branches, and yield a larger quantity of blossom and fruit. The *shrub cotton grows* in almost every country where the annual herbaceous cotton is found. Its duration varies according to the climate: in some places, as in the West Indies, it is biennial or triennial; in others, as in India, Egypt, &c. it lasts from six to ten years; in the hottest countries it is perennial; and in the cooler countries where cotton is grown, it becomes an annual. The *tree cotton* grows in India, China, Egypt, the interior and western coast of Africa, and in some parts of America. As the tree only attains the height of from twelve to twenty feet, it is difficult to distinguish the tree cotton and the shrub cotton from the mention made of them by travellers.

The cotton plant, in all its varieties, requires a dry and sandy soil. This is the uniform testimony of travellers and naturalists. It flourishes on the rocky hills of Hindostan, Africa, and the West Indies, and will grow where the soil is too poor to produce any other valuable crop. A mixture of siliceous and argillaceous earth is the most desirable, with a preponderance of the former. A marshy soil is wholly unfit for the plant, and so little congeniality has it for moisture, that a wet season is destructive to the crops. The plant flourishes most, and produces cotton of the best quality, on the sea-coast, as is well known by the planters of South Carolina and Georgia, who raise the finest cotton known—namely, the 'Sea Island,' on the sandy coasts and low islands of the sea, and who find the same cotton degenerate in length of staple and in quality when grown inland.

After the cotton is gathered—which is done by degrees, as the pods do not get ripe all at once—it is exposed to the rays of the sun till it is perfectly dry; the seeds are then separated by a peculiar skutching apparatus; and being picked and compressed into bales, the wool is sent to Europe. The chief seats of import are Glasgow and Liverpool, where it arrives in large oblong bales, and in this state is carted off to the factories in which it is to be spun.

The relative value of raw cotton depends on the length of its staple, the delicacy of its fibre, and its freedom from dirt and seeds. The cleanest, we believe, is the American; but however careful its preparers have been, 'it never comes to England in a state fit for immediate use; some seeds remain after the most careful cleaning, and the pressure to which it is subjected in packing, forms hard matted lumps, and some of the coarser and heavier wool is unavoidably mixed with that of superior quality. The first operation in the process of manufacture is consequently the cleaning of the cotton. It is put into the blowing-machine, where the cotton is torn open by revolving spikes, and subjected to the action of a very powerful blast, produced by the rapid turnings of a fan; the light wool is thus blown to some distance from the heavier portions—the dirt, seeds, &c. This process is continued in the skutching-machine, where the cotton is beaten by metallic blades making from 3000 to 5000 revolutions in the minute; these completely open the fibre, and separate the fine wool from the waste, which falls to the ground through a frame of wire-work.

The cleaning process is generally called *willowing*, which is either a corruption of *winnowing*, or perhaps derived from the willow frames on which the cotton was cleaned by beating, before blowing-machines were invented. Previous to this improvement, the cotton was placed upon willow hurdles, or upon cords stretched over a wooden frame, and then beaten with smooth switches. This operation, technically called *batting*, though very fatiguing, and we believe unwholesome, from the dust, &c. which was scattered about, was usually performed by women; it is now very rarely practised, except when some remarkably fine cotton is required for the manufacture of lace, when it is of importance to preserve the length of the staple, which might be injured by machinery.

The Hindoos open the fibres of their cotton by a bow similar to that which hatters use in raising wool; the same contrivance appears to have been employed in America, for we find the term *bowed cotton* still employed in the language of commerce. Judging from its effects on wool and fur (see Hat-making), we should think that the bow is an effective machine for cleaning and opening the fibres, but it would be far slower and less productive than the willow.

When cleaned, the cotton is brought to the lapping or spreading machine, where a given weight of the wool is spread over a determinate surface of cloth; and being then slightly compressed by a cylinder, it is lapped round a roller, so as to be in a fit state for feeding the carding-machine. It is a singular fact, illustrating the accuracy with which machinery works, that the weight of the cotton spread on the cloth in this process regulates the fineness of the thread ultimately produced, and that there is rarely any great amount of error in the calculation.

The next process—that of carding—is one of the most beautiful in the whole of the cotton manufacture. An explanation of the object to be obtained, is necessary for those who have not paid some attention to the subject. In order that any material should be spun—that is, should have its fibres twisted together—it is essential that these fibres should be straight and parallel with each other. After having been subjected to the action of the willow, the fibres of the cotton are blown about in every direction, and if compressed, would be entangled with each other. This, which is the object to be gained for the process of felting, is precisely that which must be carefully avoided for spinning. In order to straighten the fibre, the cotton is made to pass between cards or brushes of wire, one of which is stationary, and the other in motion; the wire teeth catch the fibres, and by their continued action pull them into nearly parallel directions.

This process was anciently, and in some rural districts both of England and Ireland is still, effected by hand-cards, which might be described as two brushes with handles, having short wires instead of hairs. The labour was usually performed by women, who placed one of the cards on the knee, holding it firm with the left hand; and then spreading the cotton or wool in small quantities over the wire, drew the other card repeatedly over it with the right hand, until the fibres were deemed sufficiently straight. When thus prepared, the cardings were taken off in a roll by the hand, and laid so as to be united into a continuous roving by the spinning-wheel.

The first great improvement in this process was to fix one of the cards to a table, and suspend the other from the ceiling, so that the workmen could move it without having to sustain its weight. Such a contrivance allowed *stock-cards*, as they were called, to be made of double the size of hand-cards, and consequently to double the quantity of work produced. We have seen stock-cards in some rural districts, where there is still a domestic manufacture of woollens; but they are daily becoming of more rare occurrence. In nearly all manufactures they have been superseded by the cylindrical cards, which Mr Baines has shown to be the invention of Mr Lewis Paul of Birmingham, about the year 1748. About 1760, the process, which seems to have been either neglected or disused, was revived by Mr Morris of Wigan, and applied to the carding of cotton. The perfecting of the machine has been claimed for Sir Richard Arkwright, but the originality of his invention has been very fiercely contested. Without entering into the controversy, we shall proceed to describe briefly the machine in its present state.

The *carding-machine* has the appearance of a cylindrical box, into which cotton is given by the roller, round which it was wrapped in the spreading operation. Its wooden covering is a series of narrow panels; and if one of these be lifted, it will be seen that each of them is a card, and that a cylinder covered with cards occupies the interior of the box, between which and the panel-cards the cotton is rapidly passed. At the opposite side of the box is a second cylinder, the cards on which, instead of being placed horizontally, are wound spirally round the cylinder, which is called a *doffer*, so as to remove the carded cotton in a continuous fleece. The cotton is slipped from the doffer by the action of a slip of metal, finely toothed like a comb, which being worked against the cylinder by means of a crank, beats or brushes off the cotton in a fine filmy fleece. The cloud-like appearance of the carded cotton, as it is brushed from the doffer, or finishing cylinder, by the crank and comb, is singularly beautiful—a breath seems to disturb the delicacy of its texture, and to the touch it is all but impalpable. The filmy fleece is gradually contracted as it passes through a funnel, by which it is forced to assume the shape of a roll or sliver. It then passes between two rollers, by which it is compressed into the shape of a ribbon of considerable tenacity, in which state it coils itself up in a deep tin can—there to await the subsequent process.

Looking at the various parts of this interesting machine, the attention is first engaged by the feeding cylinder, which supplies the cotton to the cards more regularly and continuously than could be effected by hands. The successive cards on the concave and convex cylinder are seen to subject the wool to several successive cardings at each revolution of the wheel; and to prevent the necessity of stopping the machine to remove the carded cotton, it is stripped off by the doffer, which removes the cotton, not in successive portions, but in one continuous fleece. Again, the removal of this fleece from the doffer, which would be both tedious and imperfect if attempted by hand-cards, is completely accomplished by the simple agency of the crank and comb.

Carding is not the only operation employed to straighten the fibre of the cotton. It may easily be conceived that the teeth of the cards will frequently lay hold of a fibre by the middle, and thus double it together, in which state it is unfit for spinning. This evil is corrected in the *drawing-frame*—an important part of the spinning machinery, for it executes work which could scarcely have been effected by human hands. The essential parts of the drawing-frame may be easily understood from description. Each drawing-head consists of three pairs of rollers, the upper one of each pair being smooth and covered with leather, the lower being fluted longitudinally. They are placed at a distance from each other, which is regulated by the staple of the cotton; that is to say, the distance between each pair of wheels is generally a very little more than the length of the fibres subjected to their action. The loose ribbon formed by the carding-machine is pulled through these rollers, and as they revolve with different velocities, the fibres pull out each other, and reciprocally extend each other to their full length.

But a not less important object of the drawing-frame is to equalise the consistency of the cardings. One carding, notwithstanding all the precautions that have been taken, will be found to have more or less of substance than another, and it is necessary to counteract this inequality by combining several of the carded ribbons, technically called *card-ends*, into one sliver. Eight card-ends are usually brought to the first drawing-head, and after passing through the rollers, they combine to form one sliver of the same density as each of them separately, thus increasing eightfold the chances of uniformity in the sliver. Four of these slivers are again subjected to the same process, and thus the chances of uniformity are thirty-two-fold those of the original card-ends; and this is continued until the last sliver may be regarded as containing parts of

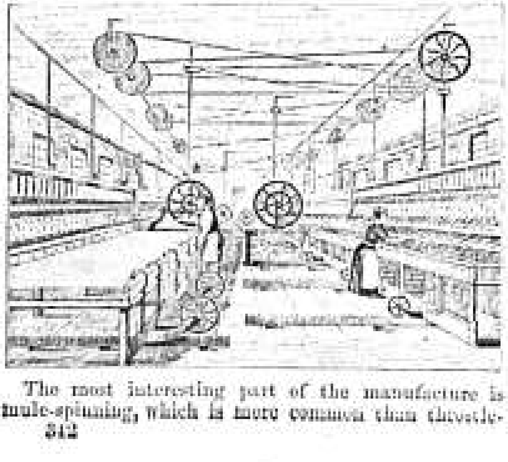
300 card-ends; but for very fine spinning, the doubling of the fibres, as the process is called, is multiplied more than 60,000 times.

The drawing-frames are fed from the tin cans containing the card-ends, and the chief duty of those who attend them is to mend or piece the feeding slivers when one of them is broken, or when one of the cylindrical cans is exhausted. A contrivance has been recently introduced to abbreviate this labour; a cylindrical weight is made to fall at intervals into the receiving can, and by pressing down the sliver, to force it to hold more than double the quantity which it would contain if the sliver were left to coil itself loosely. In the mills for fine spinning, great attention is paid to this process, because any defects left by the drawing-frame cannot be cured in subsequent operations. The labour of attending to the machines is the lightest in the cotton mill, but there are few parts which require more vigilance and care.

The next operation is the making of a roving or thin sliver about the thickness of candlewick, and giving it only so much of a twist as will enable it to hold together. The attenuation of the sliver is accomplished by rollers acting in the same way as in the drawing process, but various contrivances have been devised to give the roving just so much tension as is necessary, and no more. Arkwright invented the can-roving-frame, in which a slight twist was given to the roving by making the receiving-can revolve upon a pivot. It was necessary that the rovings, after this operation, should be wound off upon bobbins, a process injurious to their delicate texture; to obviate this evil, the jack-frame, or jack-in-the-box, was contrived, which wound the roving on a bobbin as it received its twist, instead of leaving it to coil in the can. At present, the process of roving is generally performed by the bobbin and fly-frame, an ingenious piece of mechanism.

It is not necessary to enter into any examination of the many ingenious contrivances which have been devised to render the roving-machines more perfect and automatic; the reader will best appreciate the difficulty of the operation, by bearing in mind that the process of twisting by the spindle, and winding on the bobbin, though connected in fact, are quite independent in principle, and that there is therefore a necessity for the nicest adjustment, in order that the one should be accommodated to the other.

Twist of low numbers, called *water-twist*, because it was originally worked in Arkwright's water-frame, is spun by the throstle, a machine probably deriving its name from its singing noise. It is in principle nearly the same as the drawing-frame which has been just described; it extends the rovings by the action of rollers into slender threads, and twists them by the rotation of spindles and flyers. The machinery, however, is far more simple, because the hard-twisted throstle thread does not require such tender manipulation as the delicate roving.



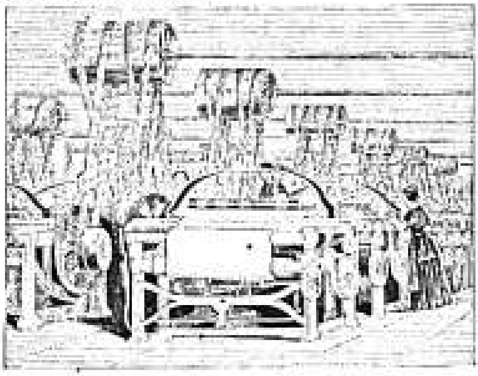
The most interesting part of the manufacture is mule-spinning, which is more common than throstle-spinning. 'Let the reader,' continues our authority, 'imagine himself in the room, a part of which is represented in the preceding cut, and it is probable that the circumstances worthy of his notice will present themselves in nearly the following order:—He will see a carriage about a yard in height, and of very considerable length, varying in different mills, bearing a row of spindles between its upper rails; it has generally three wheels, which traverse on the same number of iron guiding bars, so as to allow of its drawing out to a distance of more than four feet from the stationary frame; as it recedes from the frame, it draws with it and elongates the threads, or rather rovings delivered to it through rollers, by a series of bobbins in the creels or stationary rails. The threads, as they are elongated, are twisted by the spindles; and should any of them break, it is the duty of a boy or girl, called a piecer, to join the disunited ends as the carriage moves from the upright frame. A girl in the act of piecing the yarn is represented in the cut. When the carriage has receded to its full extent, the spindles continue to revolve until the requisite quantity of twist is communicated to the yarn. The spinner then causes the spindles to revolve backwards, until he has unwound the portion of thread which has coiled spirally round it from the point to the nose of the cop, and at the same time he lowers a faller wire, supported by hooks, as seen in the cut, so as to regulate the winding of the yarn on the cop in a proper spiral. There is great nicety required in regulating the pushing back of the carriage, for it is necessary that its rate of travelling should be commensurate with the revolution of the spindles. Three simultaneous and delicate movements have thus to be effected by the spinner as the carriage returns—he must guide the faller wire so as to insure the regular winding of the yarn on the cop; he must regulate the rotation of the spindles, of which there are often a thousand to one mule; and he must push the carriage at such a rate as to supply precisely the exact amount of yarn that the spindles can take up.

'The little piecers can only take up the ends when the carriage is within a foot or two of the delivering-roller, and they have therefore an interval of rest while the carriages traverse backwards and forwards.' The spinner, too, has a brief respite while the carriage is moving outwards from the frame. The time taken to make a stretch—that is, to draw out a thread equal in length to the range of the carriage—increases with the fineness of the yarn, and varies also according to the completeness of the machinery and the skill of the operative. The breaking of the threads depends not merely on the machinery, but to a very great extent on the atmosphere and temperature. We were in a mill during the prevalence of a sharp drying east wind, and found that it produced such an effect on the fibres of the cotton, that the threads broke faster than the piecers could mend them, and that the spinning of very high numbers at such a time was all but impossible. The rooms in which fine yarn is spun are kept at a temperature of from 70 to 80 degrees, which is not so high as to produce much inconvenience.'*

By the processes now described, the cotton has been attenuated into fine yarn on bobbins, and is now ready for being *warped*, or made into webs for the weaver. Formerly, all was wove by the hand; but the introduction of the power-loom, by which the work is altogether done by machinery, has superseded hand-loom weaving, except for some particular fabrics. 'In one respect,' observes the above authority, 'the power-loom has a very obvious advantage over the hand-loom; the batten, lathe, or lay, to which the reed is attached, drives home the weft to the rest of the web, after it has been shot from the spindle; now a weaker or stronger blow of this lathe alters the thickness of the cloth, and after any interruption, the most experienced weaver finds it difficult to commence with a blow of precisely the same force as that with which he left off. In the

* England in the Nineteenth Century—Lancashire. London: Howe and Parsons. 1842.

power-loom, the lathe is easily adjusted to give a steady certain blow, and when once regulated by the engineer, it moves with unvarying precision from the beginning to the end of the piece. Hence power-loom cloth is always of a more equable and regular texture than that woven by hand. Power-looms are generally placed in long apartments, and lighted from the top by a single range of windows to every row of looms. The weavers, or rather the tenters, have very little to do besides watching the machinery, and correcting any defects in the materials to be woven. As the labour is light, it is usually performed by women, or young persons; and we were informed that the business is so simple, as to be easily learned in a month or six weeks.' In the annexed engraving is presented a view of the interior of a power-loom apartment. All the looms are of iron, and moved by belts from shafts, the shafts being turned by steam or water power.



The subsequent processes of bleaching, dyeing, and printing have been already adverted to (pp. 311 and 339); and here we need only observe, that it is customary to *singe* the majority of calico fabrics, with a view to remove from their surface all loose and superfluous fibres. This is effected before printing by passing the web with rapidity over heated copper rollers, or by bringing it in contact with the flame of gas, as in Hall's beautiful singing apparatus. In printing, the reader will remember that the patterns are transferred to the surface of the fabric by blocks, copper-plates, or engraved cylinders, by which the colours are directly printed, or by which mordants are so applied, that when the calico is immersed in a colouring-bath, the colour only adheres upon the parts to which the mordant has been previously applied. Calico-printing in all its departments—from the preparation of the dyes and designs, to their ultimate finish on the fabric—is an art of the highest ingenuity and perfection. The old practice of *block-printing* by hand was slow, expensive, and imperfect; the new mode of *cylinder-printing* is rapid, cheap, and undeviatingly accurate. The one bears to the other the same relation that hand printing does to the steam printing-press; the one producing yards merely, while the other is throwing off miles! To be fully comprehended, the process would require to be seen—the original execution of the designs, the transferring and engraving of them on cylinders of steel, the multiplication of these engraved cylinders by Perkin's method, the mode of applying the colouring matter with such nicety and perfection, the subsequent processes of getting rid of all superfluous hues and stains, and the imparting of the ultimate gloss—are all triumphant manifestations of chemical and mechanical skill.

The *Cotton* manufacture, notwithstanding that the raw material can be obtained only in distant parts of the earth, has risen in Great Britain, during seventy years, from about two hundred thousand pounds of annual produce, to the enormous sum of thirty-six millions, of which about two-thirds is exported. Cotton goods are manufactured chiefly by means of machinery, in large factories, of which, in 1839, there were 1603 in England and Wales, 192 in Scotland, and 24 in Ireland; the chief seats of the manufacture being Manchester, Glasgow, and Paisley. These factories gave employment, in the same year, to two hundred and fifty-nine thousand persons, of whom upwards of twelve thousand were below thirteen years of age. Cotton goods are also manufactured by hand-loom weavers, of whom a considerable number continue to strive against the overpowering competition of machinery.

SILK.

This beautiful and unrivalled material is the produce of a plain-looking, greedy, leaf-devouring insect—the caterpillar of the silk-moth or *Bombyx mori*. It is thus directly of animal, though indirectly of vegetable origin; the glutinous caoutchouc principle of the leaves furnishing the insect with the basis of its silken fabric. The silk-worm is supposed to have been indigenous to China, at least the discovery was there first made, that the product of this little creature's operations could be elaborated into articles of human attire, richer and more beautiful than any to be derived from other sources. At an early period, a considerable commerce was established in silk between eastern and western Asia, from which latter quarter it was conveyed to Europe; but not until the sixth century of the Christian era, was it distinctly known by Europeans that the splendid tissues which they had worn for more than a thousand years, and which they had even partially manufactured from the raw transported material, were the product originally of a caterpillar. The first silk-worms seen in Europe were brought from China in the year 552, by two Persian monks, who had gone thither as Christian missionaries, and who contrived to secrete a number of the eggs in a cane, and to escape with them to Constantinople. From these few eggs have sprung all the successive generations of the insect which have supplied silk to Europe from that period to the present time.

Like many other insects, the silk-worm passes through the successive stages of egg, caterpillar, chrysalis, and moth. The eggs when dropped are about the size of a grain of mustard seed; their colour being then yellow, but afterwards becoming of a bluish hue. In temperate climes, and with proper precautions, these eggs may be preserved a long time without hatching or rotting. When first hatched, the caterpillar or larva has the appearance of a small black worm, about a quarter of an inch in length. On being brought forth, it almost immediately begins searching for its natural food (the leaves of the mulberry tree), which it devours with avidity. In about eight days, the head grows much larger, and the larva is attacked by its first sickness. This lasts for three days, during which time it refuses food, and remains perfectly motionless. It then begins to cast its skin, which it accomplishes after much pain and exertion. So complete is this moulting, that not only the covering of the body, but of the feet, the skull, the jaws, and even the teeth, are cast off. The insect then begins to feed with recruited appetite, and continues for five days, when a second moulting takes place, exactly like the first; and so on through a third and fourth course, the animal progressively increasing in size. After the last moulting, it feeds voraciously, and increases rapidly in size during ten days, when it has attained its full growth—being then generally from two and a half to three inches long. At this period it begins to leave off eating, and soon entirely ceases—becomes restless and uneasy, and looks out for a convenient place to commence its spinning labours. Its colour is now a light green; but as the material for forming the silk gets digested, it becomes glossy, and somewhat transparent. The silky substance is secreted in the form of a fine yellow transparent gum, in two vessels, which are wound, as it were, on two spindles in the stomach.

When the animal has found a suitable corner or hollow for the deposition of its silken ball, or cocoon, it begins to spin thin and irregular threads at first, the silk being drawn through two minute apertures beneath the jaws. In four days the cocoon is completed, the labourer remaining of course always on the inside of the sphere it is forming. The cocoon resembles a pigeon's egg in shape and colour, but is not quite so large. As may be imagined, the insect, from the continual emission of the gummy silk, together with the want of food, gradually contracts in size; and if the cocoon be opened after it is finished, the animal will appear in the form of a chrysalis, with a smooth brown skin—its former covering lying beside it. The silk-worm goes through all the transformations above-mentioned in the space of from twenty-two to thirty days, according to the temperature to which it is exposed. The cocoons containing the insects intended to be preserved for laying eggs are left undisturbed, and the chrysalis gradually undergoes a transformation into the state of a moth. This change is accomplished in the space of about twenty days; and the moth, by great labour and ingenuity, works its way through the cocoon. It then appears as a large moth, of a grayish-white colour, furnished with four wings, two eyes, and two black antennæ, or feelers, of a feathery appearance. This moth enjoys its existence only a very short time. It remains almost entirely fixed to one spot, the wings never being used for the purpose of flying, but only in assisting it in fluttering while seeking its mate. When this object is attained, the female deposits her eggs, and both end their being in the course of two or three days afterwards. The number of eggs laid by the female varies from 300 to 500; and these eggs, in about six months after, produce larvæ as before. It will scarcely be credited, but is nevertheless true, that in a few short weeks—that is to say, from its being hatched to the period of its full-grown size—the weight of the silk-worm is increased more than nine thousandfold.

The product of the silk-worm's labours, such as they have now been described, was a thing of too much value and importance not to attract the attention of man to the means of improving and increasing it. The Chinese have long pursued artificial modes of insuring the regularity of the silk produce; in Europe, and in many other parts of the world, for the last thousand years, it has also been the object of the most anxious and unremitting attention. It has been stated that these insects feed on mulberry leaves alone: the culture of the mulberry tree (*morus*) by pruning, grafting, and the like, is therefore an essential preliminary. Mulberry trees have often two crops of leaves in the year, and indeed, in very warm climates, the tree produces foliage all the year round, thus permitting the artificial breeders of silk-worms to obtain several crops of silk a-year. About thirty pounds of foliage may be procured from a healthy well-grown tree. Having an ample provision in expectancy of mulberry leaves, the silk-worm itself is the next object of care. The attention required in the management of these insects is indeed great and incessant. If the eggs, for example, from which the brood of the season is expected, be hatched a few days too soon, by a slight mismanagement of temperature, the whole hopes of the cultivator will be ruined. His leaves and his worms must be ready for one another to an hour almost. It is by confinement of the moths to particular spots that the eggs are procured, the insect being necessitated by situation to deposit them on paper or on cloths. They are then gathered, and placed in such situations as may prevent them from being hatched until the mulberry leaves are ready. When the proper season for bringing on the hatching arrives, the eggs are separated from one another by washing. They are then dried, and taken to the store-room, where they are exposed to a gradually increasing temperature, until they grow white, which is the signal of the approaching outbreak of the worm. Muslin is now laid over the eggs, and above this muslin a quantity of mulberry leaves. As soon as the larvæ are hatched, they crawl through the muslin, and attach themselves to the leaves.

The feeding-room is the place to which the worms are now conveyed. This apartment should be dry and well ventilated, but at the same time closed against the access of ordinary insects. It should contain proper shelves also for the reception of the worms. Young and tender leaves are given to the worms at first. Through the whole period of their transmutations, their food is chopped small, a great saving of leaves being thus effected. They are fed regularly three or four times a day, and consume, during the period of their moultings, a quantity of food which would appear wonderful, did not one remember the vast increase which takes place in their bulk. The same number of worms which will be satisfied with one pound of leaves previous to their first moulting, will consume one hundred and eighty-three pounds during their last feeding interval, before the commencement of their spinning. For their convenient performance of the latter operation, bushes of broom or brushwood are erected on the shelves, being usually bent over in an arched form. In clefts of these bushes the worms arrange themselves, and there they go through the process of manufacturing their cocoons. In three days their labour is finished, and in a few days afterwards the cocoons are carefully gathered from the bushes. One-sixtieth part of them is set aside for breeding, and the remainder are exposed to a strong heat, in order to extinguish the vitality of the chrysalis within, previous to reeling off the silk. When the moth breaks out, care is taken to make it deposit its eggs where they can be gathered, and laid aside for the next season. * The moth soon dies, having fulfilled its object—no mean one—in creation. It seldom exists beyond a couple of days, taking the while no food that can be observed.

It has been stated that one cocoon sometimes yields filaments a mile in length. More commonly, however, six hundred yards is about the extent of the largest cocoons. Twelve pounds of cocoons yield one pound of silk, by the ordinary computation. The silk differs considerably in quality, and the cultivators sort the cocoons, accordingly, into distinct lots, being guided by the observation of colour and other circumstances. The cocoons being prepared and assorted, the material is ready for being *reeled*. The great point in reeling is to make the thread of as even a thickness as possible: *perfect equality* is scarcely attainable. An experienced reeler, with the assistance of a girl to turn the wheel, can with ease wind off a pound of silk in a day. Six or eight pounds may be wound off in a day, but a coarse, foul, and ordinary silk will be the produce. The modes of reeling silk in Italy and France are very different, but that of the former is reckoned the best. The *floss*, or inferior silk, of the cocoons is not reeled, but spun, after being mixed with the silk of the injured or inferior cocoons.

After reeling, the next process for preparing the raw silk for the weaver is that of *throwing*. It has already been mentioned that this branch of the art was introduced by Sir Thomas Lombe into England in 1718, from models surreptitiously obtained by him at Piedmont. Considering the remarkable perfection now attained in this country in the science of mechanics, it will not appear strange that these throwing-mills have been long since superseded in Great Britain by subsequent improvements.

Raw silk, preparatory to weaving, must be made to take one of three forms—respectively termed *singles*, *tram*, or *organzine*. *Singles* is merely the raw silk twisted, in order to give more firmness to its texture. All raw silk, for whatever manufacture designed, must undergo this process. *Tram* is formed by twisting together, not very closely, two or more threads of raw silk, and this generally forms the weft, or transverse threads of the web. *Organzine*, which is principally used for warp, is produced by a very elaborate process, of which it would be impossible to convey any correct idea to the general reader without the aid of a diagram. The principle of the process, however, may be generally stated to be like that of making rope, where the combined strands are twisted in an opposite direction to that given to the separate threads, and this is accomplished by giving a reverse motion to the machinery; whereas singles and trams are twisted only in one direction, similarly to twine, or to the individual strands of which the larger rope is made. Silk thread intended for organzine is in the first process twisted in a left-hand direction. The organzine, when finished, is transferred to reels instead of bobbins, whence it is made up into skeins, and sorted for sale or use. Previously to this, however, the reels are subjected to a process of steaming for two or three minutes, in order to prevent any after-crinkling. The silk thus thrown is called hard silk, and must be boiled for some hours, with a quantity of soap, in order to discharge the gum, and thereafter well washed in a current of clear water to discharge the soap, after which the silk appears soft and glossy. Besides these varieties, there is another called *sewings*, which are compound threads of silk, wound, cleaned, doubled, and thrown, with especial reference to their ultimate use for sewing. *Marabout* is a peculiar kind of thrown silk, generally formed of three threads of raw silk; and being white as it comes from the cocoon, it takes the most delicate shades of colour at once without the discharge of its gum.

Silk is woven into various fabrics, plain and figured, by the Jacquard loom, and also into velvets. The fine soft pile of *velvet* is produced during the process of weaving, by inserting short pieces of thread doubled under the shoot or weft, and which stand upright in such a way, and so close together, as entirely to conceal the interlacings of the warp and shoot. In the production of every yard of velvet, six yards of pile at least are used. The loops of the doubled threads intended for the pile are supported by grooved wires, and the loops are afterwards divided by running a sharp instrument, called a *trevat*, along the groove. This is done by the hand, and of course requires great dexterity, as the slightest deviation from the proper line would infallibly injure, if not wholly destroy, the silk. It is considered a good day's work for one man to weave one yard of plain velvet, for which he is paid about five times as much as for weaving plain silks. *Damasks* of the most exquisite and elaborate patterns are of course produced by the Jacquard loom, and in some instances as many as 1200 or 1400 changes or cards are required for their completion. *Satin* and *satinette* are peculiar kinds of silk-twill, and exhibit in the most perfect manner the lustre of the material of which they are composed. *Brocade* is the general term for tissue of silk with gold or silver threads—a stuff of exceeding richness, and at one time much in fashion, but now seldom or ever sought after. *Lutestring*, *Gros de Naples*, *Persian*, &c. are names given to plain fabrics of silk, differing little from each other except in their thickness, or in the quality of silk. *Tabbaret*, *tabine*, *serge*, *levantine*, &c. are twilled fabrics, occasionally relieved with satin-stripes and checks; they are to be had of all qualities and colours. *Crape*, crisped or smooth; *gauze* in all its varieties; *ribbons*, of whatever fabric; and *bandanas*, are too well known to the English reader to require description. In fact, it is almost impossible to enumerate the various stuffs woven from silk, either for the purposes of clothing, upholstery, or ornament; but an idea of its importance may be formed from the fact, that scarcely an individual, even in humble life, but can boast of using it to some extent, either for the purposes of dress or of ornament.

In Britain, the annual value of the silk manufacture is estimated at nearly ten millions sterling—more than nine-tenths of which are for home consumption. We draw our chief supplies of the raw material from Bengal; from Italy, which produces about eleven million pounds annually; from China, where, next to tea, it is the staple article of export; from Turkey; and in smaller quantities from Holland, the United States, and other countries. The foreign states in which the manufacture chiefly exists are China, India, Italy, Switzerland, and France; the latter kingdom alone producing fabrics to the annual value of about eight millions sterling. There are no very accurate data as to the amount of silk stuffs consumed in the various countries of the world; but considering how generally they are worn in Oriental as well as in European countries, and reflecting upon the increasing demand by a civilised population in the Americas, we cannot be far wrong in stating that a million and a half of human beings derive their sole support from the culture and manufacture of silk, and that it creates an annual circulating medium of between thirty and forty millions sterling! So much for the importance of a humble insect which, if it had been shown to our ancestors a few hundred years ago, would have been as little valued as the earth-worm beneath their sandals.

WOOLLEN.

Wool, if we accept the definition of a recent authority, 'is a kind of soft hair which forms the external covering of several ruminating animals, particularly the sheep, llama, Angora goat, and the goats of Thibet. The distinction between wool and hair is rather arbitrary than natural, consisting in the greater or less degrees of fineness, softness, and pliability of the fibres. When the fibres possess these properties so far as to admit of their being spun and woven into a texture sufficiently pliable to be used as an article of dress, they are called wool.' The sheep, according to this definition, is the wool-bearing animal par excellence; different breeds yielding wools of different degrees of length and fineness, and this dependent, in a great measure, upon the food, climate, and other external conditions they enjoy. The finest of all wools is that from the goat of Thibet, of which Cashmere shawls are made; the finest of European wools is the produce of the Merino sheep—the Spanish and Saxon breeds taking the precedence; the Merino sheep, as now naturalised in Australia, furnishes also an excellent fleece; but all varieties of sheep-wool, reared either in Europe or Australia, are inferior in softness of feel to that grown in India, and also to that of the llama of the Andes. The best of our British wools are inferior in fineness to any of the above-mentioned (being nearly twelve times the thickness of the finest Spanish Merino); but for the ordinary purposes of the manufacturer they are unrivalled. Wool shorn from the living animal is known as *fleece-wool;* while that pulled from the skins of those slaughtered is termed *pelt-wool*. *Lambs'-wool* is generally softer than that of the full-grown animal, and is of course applied to finer purposes. The fineness of the fleece varies on different parts of the animal, and therefore requires to be 'sorted,' which may be considered the first process in the manufacture of woollen fabrics. The next step is to free it from dirt and foulness of various kinds, and in particular from the grease or oil with which it is naturally imbued. For this purpose it is repeatedly washed and combed, after which it becomes soft, clean, and elastic.

Independent of the quality of fineness, there are two sorts of wool which afford the basis of different fabrics, and are somewhat differently treated in the process of spinning, for which the combed material is now ready: these are the *long* wool and the *short*. Long wool is that in which the fibres are rendered parallel by the process of combing; it is also known by the name of worsted, and is the material of which camlets, bombazines, &c. are fabricated. Short wool is prepared by carding, like cotton, and is used in different degrees of fineness, for broadcloths, flannels, and a multitude of other fabrics. This wool, when carded, is formed into small cylindrical rolls, which are joined together (or by improved machinery into one continuous roll), and stretched and spun by a *slubbing* or *roving* machine, and a jenny or mule, in both of which the spindles are mounted on a carriage, which passes backwards and forwards, so as to stretch the material at the same time that it is twisted. On account of the roughness of the fibres, it is necessary to smear them with oil, to make them move freely upon each other during the spinning and weaving. After the cloth is woven, the oily matter is removed by scouring, in order to restore the roughness to the fibres, preparatory to the subsequent process of milling. In articles made of long wool, the texture is complete when the stuff issues from the loom. The pieces are subsequently dyed, and a gloss is communicated to them by passing them between heated metallic surfaces. But in cloths made of short wool, which is generally dyed before being spun, the weaving cannot be said to complete the texture. When the web is taken from the loom, it is too loose and open, and consequently requires to undergo another operation, called *fulling* or *milling*. This is performed by a fulling-mill, in which the cloth, being first freed from its oil by the use of fullers' earth and other detergents, is immersed in water, and subjected to repeated compressions by the action of large beaters, formed of wood, which repeatedly change the position of the cloth, and cause the fibres to felt, and combine more closely together. By this process the cloth is reduced in its dimensions, and the beauty and stability of the texture materially improved. This tendency to become thickened by fulling, is peculiar to wool and hair, and does not exist in the fibres of cotton or flax. It depends on the fibres or hairs being branched or serrated, which admits motion in one direction, but not in another. It thus promotes entanglements of the fibres, which serve to shorten and thicken the woven fabric.

The nap, or downy surface of broadcloth, is raised by a process which, while it improves the appearance, tends somewhat to diminish the strength of the texture. It is produced by carding the cloth with the barbed or hooked fruit-cone of the common teazle (*Dipsacus fullonum*), which is cultivated in England for the purpose. This operation extricates a portion of the wool, and lays it in a parallel direction on the right surface of the fabric. Machinery has been employed as a substitute for the teazle, but hitherto with very indifferent success. The nap thus formed is then cut off to an even surface by the process of *shearing*. This is performed in various ways; but in one of the most common methods, a large spiral blade revolves rapidly in contact with another blade, while the cloth is stretched over a bed or support, just near enough for the projecting filaments to be cut off at a uniform length, while the main texture remains uninjured.

The manufacture of cloth, as thus described, is carried on in three different modes in England—that of the master clothier, who buys his own wool from the importer, and afterwards gives it out to be manufactured, either in factories or at private houses; the factory system, by which every process of the manufacture is carried on under the same roof; the last is the domestic system, in which private weavers purchase wool from the dealer, and employ themselves, wives, children, and sometimes several journeymen, in the various manufacturing processes under their own roofs. The factory system is evidently the one best adapted for carrying the manufacture to its utmost extent. The mode of disposing of the various woollen cloths is different in Yorkshire and the west of England, but in both upon a scale in keeping with the magnitude of the manufacture and the commercial importance of the kingdom. In the west of England, the goods are exposed at periodical markets or fairs; in Yorkshire, in cloth-halls, of which there are three at Leeds, besides others at Halifax, Bradford, Huddersfield, Wakefield, &c. These halls consist of long walks or galleries, through the whole length of which the master-manufacturers have their stands in double rows. Between these the merchants pass, and make their purchases. At a certain hour a bell rings, and the market closes, those goods which are purchased being then carried to the merchants' quarters, and those unsold remaining in the stands. The goods are bought in their undressed state, the merchant afterwards getting them finished off himself. Dressing and finishing has of late years become a business entirely distinct from the manufacturing department, and in which, to attain perfection, has been the chief aim of the Yorkshire merchants. So proficient, indeed, have they become, as to defy any but experienced judges to distinguish their cloths from the more costly fabrics of the west of England.

Woollen fabrics manufactured as above are generally known by the name of *cloths*, of which there are several varieties in common use, as broad, narrow, and habit-cloths; all of which are worked plain, and only differ in width or in quality. When twilled, they are termed *kerseymeres, kerseymerettes, pelisse-cloths, &c.*; and when peculiarly finished—as, for example, with long, tufted, or velvet naps—they are known by such designations as *dreadnought, frieze, swanskin, plush*, and *duffle*. *Tweed* is a light structure, now largely used for trousering; *flannels*, of whatever variety, are all loosely woven; *baize* is a kind of flannel with a tufted nap; and *blankets*, of which there are many varieties manufactured in different parts of the country, are also loosely woven and finished with a long nap raised by rollers covered with brass pins. Besides the manufacture of cloths, blankets, and flannels, the department of woollen fabrics comprehends *carpets* and *hosiery*, two very distinct but important branches. Three kinds of carpets are usually made—Venetian, Kidderminster, and Brussels. Venetian carpeting is a plain fabric, composed of thick linen woof on a woollen warp, and is employed chiefly for stair or lobby coverings. The Kidderminster carpeting is by far the most common. It consists of two woollen webs, woven together, and intersecting each other at particular parts, so as to produce definite figures of different colours. The manufacture of this species of carpets has been long carried on with advantage in different parts of Scotland. Brussels carpets possess a basis of strong linen threads, on which the pattern in woollen is thrown up in loops, which are kept firm by small rods. When the web is woven, the rods are pulled out, leaving a soft surface of the closed ends of loops. Latterly, a great improvement has been made in Brussels carpet-weaving, and which has also been adapted for shawls. Instead of using threads of any particular colour throughout, and throwing up the threads as they were required to form the pattern, the custom is now to dye the threads with different colours, suitable to the pattern required. Thus a single thread may be dyed in patches of red, yellow, black, or any other colour, and it performs its part in the pattern through its entire length; the saving of material by this ingenious mode of dyeing is immense.

When long or combing wool is twisted to a certain degree of hardness, it receives the name of *worsted*; and the manufacture of certain fabrics of this kind is as extensive as that of soft woollen goods. Many of the variegated cloths called *tartans* are made of worsted; and so likewise are *tapestries*, and some kinds of *stockings*. The stocking or hosiery manufacture, generally, is conducted by means of stocking-frames and hand labour; the frame having been in universal use since it superseded knitting on the large scale about seventy years ago. Stocking-knitting or weaving is a distinct art from cloth-weaving, inasmuch as the fabric is not formed of a warp and woof, but consists of one continuous thread, which is formed into a series of loops in successive rows, the loops of each row being drawn through those of a former row, and so on. Besides stockings and socks, waistcoats, nightcaps, drawers, and other under-clothing are made in this manner—all coming under the general designation of *hosiery*, from the Saxon word *hosa*, hose or stockings. Though stocking-weaving has in a great measure superseded the old process of knitting, the latter is still largely prosecuted by females in Germany, in the Pyrenees, in the north of Scotland, and especially in the Shetland isles, whence shawls, plaids, hose, and other articles of exceeding softness and beauty, are exported to the large towns of the kingdom. In this list may be added what are termed *stuffs*—a term which properly includes all the thin fabrics of worsted, as shalloons, florenteens, moreens, calimancoes, camlets, merinoes, &c. They are woven either plain, twilled, or figured, and differ from other woollen cloths in having no nap or pile. After the operation of weaving, each side of the piece is drawn rapidly over a convex plate of red-hot iron, to singe off the superfluous fibres of the wool; it is then rolled tight, soaked in hot water, and boiled. Afterwards it is scoured, stocked, or milled, and pressed between rollers to take out the moisture; it is then dyed; dryed by passing between heated cylinders; and ultimately subjected to hydraulic pressure.

Of *ornamental fabrics*, such as tapestry, sewed-work, knitting, netting, and crotchet, our space will not permit any lengthened description. The first of these is more of a textile nature than the others, although still closely allied to the achievements of the needle. The following is given as the mode of fabrication at present practised in the celebrated manufactory of the Gobelins:—The frame or loom is formed of two upright pieces, at the top and bottom of which two large rollers are fixed horizontally: round the upper of these rollers are wound the longitudinal threads, or warp, composed of twisted wool—the work, as it is executed, being gradually wound round the lower. On the inner side of the upright pieces, several contrivances (here unnecessary to describe) are placed at different points, for separating these threads more or less from one another, in order to admit the cross threads or woof, which are to form the picture. As a sort of guide for the artist to introduce the cross threads in their proper places, he traces an outline of his subject on the threads of his warp in front, which are sufficiently open to enable him to see the painting behind.

For working the tapestry three instruments are required—a broach, a reed or comb, and an iron needle. The first is formed of hard wood, about seven or eight inches in length, and two-thirds of an inch thick, ending in a point with a small handle, round which the wool is wound, and serving the same purpose as the weaver's shuttle. The reed is also of wood, eight or nine inches long, and an inch thick at the back, whence it gradually decreases to the extremity of the teeth, which are more or less divided, according to the greater or less degree of fineness of the intended work. The needle is in shape similar to a common needle, but much larger and longer; it is used to press close the wool, when there is any line or colour that does not set well. The artist places himself behind the frame, with his back towards the picture he is about to copy; he first turns and looks at his design, then taking a broach of the proper colour, he places it among the threads of the warp, which he brings across each other with his fingers, by means of the coats or threads fastened to the staff; this he repeats every time it is necessary to change his colour. Having placed the wool, he beats it with his reed; and when he has thus wrought several rows, he passes to the other side to see their effect, and to properly adjust them with his needle, should there be occasion.

Knitting, netting, crotchet, and sewed work, now so universally practised by ladies as a light and elegant employment, depend upon the principle of looping one continuous thread, or system of threads, and not upon that of fabricating by warp and woof. The articles so produced admit of an almost infinite variety of design and pattern; and where the colours are in harmony, and the figures in keeping with the character of the piece, effects of a very wonderful kind—considering the simple nature of the materials—are not unfrequently obtained.

As to the *statistics* of British woollen manufactures, it is very difficult to arrive at anything like accurate data. The goods pass and repass through so many hands that the real amount is apt to be exaggerated; while knitting, both of useful and ornamental articles, is still too largely carried on to be altogether overlooked. In 1839, the manufacture was carried on by 86,411 persons; in 1738 factories, of which 1595 were in England and Wales, 112 in Scotland, and 31 in Ireland—jointly realising an annual value of about twenty-five millions. This amount includes of course all sorts of woollen and worsted stuffs—as broadcloths, tweeds, blanketings, flannels, carpets, hosiery—in fine, all articles into which wool enters as the main ingredient. Of such goods, to the value of eight and a quarter millions are now annually exported.

FELT—HATS—STRAW-PLAIT.

Felting is the process by which different kinds of hair, fur, or wool, are blended into a compact texture, without undergoing either spinning or weaving. It depends upon the serrated structure of the fibre—a structure which has already been noticed under 'milling,' and which may readily be observed by passing a hair through the fingers in opposite directions. This peculiar structure allows the fibres to glide amongst each other; so that when the mass is agitated, the anterior extremities slide forward in advance of the posterior half, and serve to entangle and contract the whole together. Vegetable fibre being of a smooth linear texture throughout, cannot be felted; and among animal fibres, those are best adapted for the process which are naturally curled or wavy, and have the deepest serratures. Felting is best seen in the making of beaver or stuff hats, to which we shall shortly advert.

The materials commonly used for *hat-making* are the furs of the beaver, seal, hare, and rabbit, and the wool of the sheep. The furs of most animals are mixed with a longer kind of hair, from which they have first to be separated; they are then cut off with a knife, and 'sorted' by a blowing machine, which carries the lightest and finest fibres to the extremity of a hollow trunk or funnel, while the heavier and coarser are left at proportionate distances from the fanners, or source of the current. The materials to be felted are next intimately mixed by the operation of *bowing*, which depends on the vibrations of an elastic string; the rapid alternations of its motion being peculiarly well adapted to remove all irregular knots and adhesions among the fibres, and to dispose them in a very light and uniform arrangement. This texture, when pressed under cloths and leather, readily unites into a mass of some firmness. A piece sufficient to form a hat is next taken up, and dipped in warm water, containing a little sulphuric acid, and moulded into a large conical shape, which is afterwards reduced in its dimensions by working it several hours with the hand, for the purpose of further thickening and fulling it. At this stage any knots are removed, and fresh felt here and there added; the hat is then shaped, water-proofed by a lac varnish, tied upon a block, dyed, stiffened by the application of a solution of glue, steamed, brushed, and ironed. The brim is then trimmed, and it is ready for lining and binding. The material felted as above described generally consists of a variety of furs, as those of the hare, rabbit, and beaver, lambs'-wool, goat and camels' hair, cotton, and silk. Most manufacturers make what they term a foundation of coarser material, to which they apply beaver or other fine furs as a *plate* or finish. What are called *beaver* hats are thus completed with the fur of that animal; while in *stuff* hats this fur is altogether omitted. *Silk* hats have a foundation of felt, chip, straw-plait, whalebone, or pasteboard, upon which silk-plush is afterwards applied. From their cheapness, durability of colour, and lustre, they have lately come much into use, though scarcely so durable, or so soft and elastic for the head, as the old beaver. The best variety of the silk hat is that in which a fine Paris plush is fixed upon a beaver body. *Gossamer* hats, for summer wear, are those in which the foundation or body is of willow-chip or other light material, with a plush of floss-silk.

Felt cloth, manufactured much in the same manner as felt for hats, is a fabric employed for several economical purposes. At one time it excited considerable expectation as a substitute for woven woollen-cloths, and perfect imitations of these were produced, but they were found deficient in firmness and durability. More recently a pneumatic process of felting was introduced, of which better hopes are entertained. The mode is as follows:—Into an air-tight chamber is put a quantity of flocculent particles of wool, which, by a kind of winnowing wheel, are kept floating equally; on one side of the chamber is a network, or gauze of metal, communicating with another chamber, from which the air can be abstracted by an exhausting syringe or air-pump; and on the communications between the chambers being opened, the air rushes with great force to supply the partial vacuum in the exhausted chamber, carrying the flocculent particles against the netting, and so interlacing the fibres, that a cloth of beautiful fabric and close texture is instantaneously made. The only objection to cloth of this kind was its rawness, or liability to shrink after being wetted; and for this reason, we believe, it has never come into anything like use for clothing. Coarse feltings, variously treated, are used for roofing, underlaying copper-sheathing, and other analogous purposes; and for these ends their cheapness renders them specially available; but where elegance and durability are sought to be combined, as in dress and household furnishings, woven fabrics must ever take the precedence.

Straw, plaited, or otherwise worked into a fabric, is in use in almost every country as a material for a light and ornamental head-dress. Many of the tropical grasses are eminently fitted for this species of manufacture, and thus navigators often bring from the Indian Archipelago and South Sea Islands hats, fans, baskets, and other articles, exhibiting a beauty of texture and intricacy of design which the most expert straw-plaiter in Europe could scarcely surpass. It is to straw-plaiting as a branch of civilised industry, however, that we would now direct attention; and for this purpose present the following abridged exposition from the 'Encyclopedia of Domestic Economy:'—*Dunstable* hats are made of whole straw, plaited in long narrow stripes or ribbons, which are afterwards sewed together in the form of a hat or bonnet. The weight and clumsy appearance of these bonnets first suggested the idea of splitting the straw into stripes; but it was a considerable time before a method was invented of performing this in a perfect manner. *Split straw* is an elegant manufacture brought into use about forty years ago, and has now become very general for women's bonnets. The straw of wheat or of rye is cut at the joints; and the outer skin being removed, it is sorted into small bundles, and is next split by means of a very simple instrument, and delivered to be plaited. The plait is sold by the score yards, and about three-score and a half will make an ordinary-sized bonnet. It is sewed by the bonnetmakers, and then blocked, which is a laborious process; and after being pressed, wired, and lined, is ready for sale. There are markets in the plait-districts for the sale of straw, plait, and bonnets; the best market for the latter is St Albans. The various forms of bonnets into which the straw-plait is worked up, varying continually with fashion, baffles all description, and is a subject well understood. Straw is bleached, and straw-hats cleaned, by putting them into a cask into which a few brimstone matches are placed lighted. The fumes of the sulphur have the effect of destroying the colour, or whitening the straw. The same effect may be produced by dipping the straw into the chloride of lime (common bleaching powder), dissolved in water, an article which may now be procured at any large chemist's. Of the straw-hats, the *Leghorn* are the most highly prized, as the finest in the world; these are made in the neighbourhood of Florence, Pisa, the district of Sienna, and the upper part of the vale of the Arno, and are exported from Leghorn. The straw is produced from a small kind of wheat, cultivated on a poor soil, and bleached like flax; it is remarkable for its strength and whiteness; the plait is extremely regular, and the straw is not split. Attempts have been made to grow this kind of wheat in England; but hitherto without success. About twenty years ago a firm established straw-plaiting in the Orkney Isles, and adopted rye-straw as the material. At first there seemed some prospect of success; but it does not appear that the competition of foreign-grown straw could be successfully met. Various other materials besides straw are used for making light hats. *Chip*, which is thin strips of wood made by a plane, is employed; the *willow* is found to answer well, and these strips are woven with a loom into a kind of twill or diamond tissue, and afterwards bleached like straw.

Of straw-plait as a branch of industry, it has been observed that 'there is perhaps no manufacture more deserving of encouragement and sympathy, as it is quite independent of machinery, and is a domestic and healthful employment, affording subsistence to great numbers of families of agricultural labourers, who, without this resource, would be reduced to parish relief. By the estimate of an intelligent individual, intimately acquainted with the manufacture, it is considered that every score of plait consumes a pound of straw, in the state of which it is bought of the farmer; that, on an average, every plaiter makes fifteen yards per day; that in the counties of Hertford, Bedford, and Bucks, there are, at an average, 10,000 scores brought to market every day, to make which 13,000 persons, women and children, must be employed. In Essex and Suffolk it is estimated that 2000 scores are the daily produce; to make which about 3000 persons more must be employed to convert these quantities into bonnets. Including other places where the manufacture is carried on in England, there are perhaps in all about 30,000 persons engaged in it.'

PAPER.

The earliest kind of paper, or material on which writing was performed, of which we have any account, was the *papyrus*, used by the ancient Egyptians, and hence our modern word *paper*. The papyrus was a plant, from which thin fibrous membranes were stript, and being pressed together, they formed a rude species of small sheets. The Chinese are said to have understood the art of making paper from the pulp of rags in very early times; but whether the European mode of making paper was derived from that quarter, is not clearly known. The art was introduced amid the obscurities of the middle ages, and most likely through the ingenuity of the Arabians. In the beginning of the fourteenth century, a paper-mill was established at Nuremberg, in Germany; and in 1588, a mill was erected at Dartmouth, in England. Little progress was made, however, in the manufacture of paper in this country, it being supplied, till within the last seventy years, principally from France and Holland.

The principle on which paper is made is very simple. A portion of linen cloth is ground to pulp; this pulp is shaken in a fine wire sieve, so as to settle in a thin cake, or sheet; the sheet is pressed, in order to squeeze out the liquid; and when dry, we have a sheet of paper. Instead of new linen cloth, rags, for the sake of economy, are always employed; and the more substantial the rag, so is the paper the stronger in texture. The quantity of rags produced in Great Britain and Ireland being altogether insufficient to supply the demand for paper, large importations take place from continental Europe, chiefly Germany. Cotton rags, or the refuse cotton of factories, are also employed in the paper manufacture; but only for inferior sorts, or as an alloy, which is not always justifiable. Any vegetable fibre, indeed, may be used in the fabrication of paper, and attempts (of which we have now a fair specimen before us) have recently been made to manufacture it from the straw of the oat and barley. The processes of preparing the rags, making by hand, and making by machine, may be respectively noticed:—

Preparation of the Rags.

After the rags arrive at the mill, they are picked and sorted into four or five qualities. All substances not suited for paper-making, or which might injure the machinery—such as pins, buttons, pieces of silk and woollen cloth—must be carefully removed. This greatly facilitates the work of the cutters, who have also to see that the rags are sorted into their proper parcels. In cutting, small table frames are used, the upper surfaces of which are composed of wirecloth, containing about nine meshes to the square inch. In the centre of these tables a knife or short scythe is fixed, in a slanting direction. Against this knife the females at the table draw the rags, cutting them into pieces of about four inches square, when they are put into boxes according to the fineness of their texture. During this operation, much dust is beat out of the rags, which falls through the meshes of the wirecloth. It is calculated that a woman will cut a hundredweight of rags by this method in a day. After the rags are cut, they are put into a cylinder of wirecloth, measuring about four feet in diameter and five in length. An axis runs through the centre of the cylinder, which is furnished with spokes about a foot long, attached at right angles to the axis. The machine being set in motion, the spokes beat and toss the rags about, which frees them from any dust that may remain after the cutting. When the rags are very dirty, it has been found advantageous to put them into the duster before being cut, which renders that operation easier and more cleanly for the people engaged at the work.

The next operation is that of boiling the rags in an alkaline lye. Sometimes this is done by simply putting the rags into open vats containing the lye, with a fire underneath. Others, however, use close boilers, into which steam is admitted by means of a pipe from the top. The alkaline lye is composed of from four to ten pounds of the carbonate of soda to the hundredweight of rags, according to their quality, and a third part additional of quicklime, to render it caustic. Some manufacturers use lime alone, and others pot and pearl ashes, for the purpose of bleaching; but soda and quicklime are the substances generally employed. The rags are boiled for about eight hours in this solution, and are then allowed to cool gradually, it having been found that when the cooling takes place too rapidly, any dirt upon the rags is apt to be indelibly fixed.

After being boiled, the rags are carried to the first washing-engine, which consists of a large oblong stone trough, into which a stream of water is allowed to flow and to escape by the other end. This cleans the rags most effectually, the run of water carrying away any impurities that may still adhere to them. On one side of this trough is an engine, which again washes and grinds the rags, and is termed by the workmen the *breaking-in machine*. This powerful apparatus consists of an elliptical-shaped trough, made generally of wood, lined with lead or copper; within it, a grooved roller revolves horizontally over the surface of a sharply-grooved plate, by which the rags are torn to shreds. The grooves on the roller, and those on the plate, act upon the pieces of rags much in the same manner as cutting with a pair of scissors. The trough is half filled with water, which comes in at one end, and escapes through holes at another part. The engineer puts the rags into the engine, spreads them with his hands, and by means of agitators at the bottom of the trough, no piece is allowed to escape the action of the roller. These troughs are about ten feet in length, four and a half in width, and two and a half in depth, being capable of holding from 112 to 120 pounds of rags. The operation of *grinding*, as it is called, occupies about an hour and a half; and when the rags are sufficiently reduced to a pulp, the stuff is passed down from the trough to the draining boxes, by means of a pipe six inches in diameter. This pipe is furnished with a valve at the bottom of the trough, which the engineer opens by means of an iron hook, and through this the pulpy matter flows freely. On reaching the draining boxes, the water is allowed to run off from the pulp previous to the bleaching process.

In the grinding operation a great improvement has lately been effected. It was found that the constant flow of water through the agitated trough of the engine carried off a considerable proportion of the finer particles of the stuff, and thus caused a serious loss. A plan has been invented to lift the waste water by a revolving sieve, which admits the water alone, and excludes the stuff, thereby effecting a most important saving to the manufacturer.

Bleaching is sometimes performed by subjecting the pulp to the action of chlorine, which is manufactured from sulphuric acid, sea salt, and the black oxide of manganese. The chamber in which this is performed must be close, so that the chlorine may not escape. A more common method of bleaching, however, is to steep the pulp in a solution of the chloride of lime, by which the fibres are not so much injured as when chlorine is used. In bleaching, great care should be taken that the solution is not too powerful, or the texture of the paper may be materially injured by the process.

The bleaching-house consists of a long apartment, furnished with stone chests about three feet deep, ranged on each side, and capable of containing about fifty-seven cubic feet. These chests have false bottoms, pierced with small holes, which can be opened at pleasure, to allow the solution to escape. When the water is drained off, the pulp is carried to the bleaching-chests, and about one hundredweight put into each, along with from six to eight pounds of Tennant's saturated chloride of lime, and about twelve gallons of water. The stuff is allowed to steep for twenty-four hours, being frequently stirred in the interval, so that every part may be equally bleached. After bleaching, the pulp is again put into a washing-machine, to free it thoroughly from the bleaching-liquor. This process is similar to that previously described, except that the roller is screwed down closer to the fluted plate, so as to reduce the pulp to a finer consistence. In making what is called machine-paper, the size is now added, the addition or the want of which constitutes the chief difference between paper for the reception of ink and the other sorts. The kinds of size principally used consist of either white soap, starch, glue, or dissolved resin, with the addition of a few pounds of alum. The size is strained through a sieve into the beating-engine, and there mixed with the pulp.

From the second washing, or beating-machine, the pulp is passed down to a large tun or vat, called the *stuff-chest*, which is merely a reservoir to keep the pulp till it is put into the machine which converts it into paper. This vat is furnished with agitators at the bottom, to keep the pulp of an equal thickness, which now bears a strong resemblance to curdled milk. Previous to being put into the vat, however, it is now almost universally the practice to strain the pulp through bars of brass. These are planed perfectly smooth at the edges, and placed so closely together, that the fibrous part of the matter must pass through longitudinally. By this means knots, &c. are kept out, which formerly cost considerable trouble to scrape from the surface of the finished paper.

Making by Hand.

This is the old method of making paper, which is now completely exploded, except for some kinds of writing and coarse packing-papers. The pulp is prepared without size, that being imparted afterwards to the sheets by dipping them in a tub. Properly prepared, the pulp runs into a vat, at one end of which stands the vatman, with two frames or moulds beside him, made of brass wires or wirecloth, fixed upon a wooden frame, of the size of the sheet to be made. The vatman holds in his hand a frame of wood called a *deckle*, which fits exactly all round the edge of the mould, for the purpose of giving a clean edge to the paper. For making what is called wove paper, a wirecloth is required. For laid or corded papers, however, the mould is made of brass wires lying longitudinally, crossed by wooden bars placed underneath, and interlaced by cross wires somewhat thicker than the longitudinal ones.

The vatman, laying the deckle upon the mould, dips it into the vat, and takes up a quantity of the pulp. If he considers there is too much in the mould, he throws off part of it, and then, holding the mould horizontally, he shakes it to and from him, which connects the fibres together, and renders the fabric of an equal thickness throughout. The water flows through between the wires, and as soon as the pulp has attained a degree of consistence, the vatman lifts off the deckle, and hands the mould to the coucher, who stands at the other corner of the vat. The coucher places the mould in an inclined position for a few seconds, so that as much water may flow from the pulp as possible. He then puts a piece of felt or blanketing upon a wooden board, and turning the mould over upon this, the pulp adheres, and the mould is handed back to the vatman. Another felt is placed upon the top of the pulp laid down, and the process is continued until what is termed a *post* is completed. A strong board is then placed upon this, and the whole is put under severe pressure, in order that the water may be thoroughly extracted. When the paper is taken out of this press, it may be handled, and the sheets are taken from between the felts, and placed by themselves. Another pressing is then given, slighter than at first; for if too severe, the sheets are apt to stick so closely together, that they cannot be afterwards parted without injury. After this pressing, the sheets are carefully separated from each other, and again pressed, previous to being sent to the drying loft. In making the finest writing-paper, this separation and pressing are performed twice, which considerably improves the texture of the paper.

The next process is drying, which is done in a loft containing a number of spaces filled with hair-ropes fixed into spars of wood, the ends of which slide up and down upright posts at the corners of each space. Five or six sheets of paper are hung together upon these ropes, and allowed to dry. The air is freely admitted by the sides of the loft, which are sparred with shutters, to close out the air entirely, in case of bad weather; and each loft is provided with pipes, which go round the room, and can be filled with steam, so that the drying process may go on at all times.

When the paper is quite dry, it is sent to the sizing-house, where it is made suitable for receiving ink. The size is made from the parings of skins, &c. which are boiled for about ten hours to reduce them to a gelatine. The gelatine is carefully strained; about a fourth of its weight of alum is then added, and the mixture is allowed to congeal. When used, it is diluted with water, and an additional supply of alum put in. The workman then takes about six quires of paper in his hand, and dips it into the tub containing the size, where it is allowed to remain for a few minutes, so that every sheet may be well soaked. The sheets are carefully lifted out one by one, and put into a press, which is slightly screwed down, that the surplus size may flow out. In order that the sheets may be easily separated, the edges are washed with hot water; and when taken out of the press, each sheet is laid between woollen cloths, in the same manner as when the paper was first taken from the mould. When strongly sized, the sheets are again separated carefully, and kept about forty-eight hours before being hung up to dry. In *blotting*-paper the usual sizing is omitted.

When sized and dried, the paper is taken to the finishing-house, where it undergoes several pressings to smooth the surface. It is then sorted, and put up in reams, consisting of twenty quires of twenty-four sheets each, or 480 sheets. *Hot-pressed* paper is rendered glossy by pressing it between hot plates of polished metal.

Making by Machine.

From the vat or stuff chest, the pulp, prepared as already described, is let out by a sluice into a pipe, which leads it to one end of the *making-machine*. The opening from this corresponds exactly with the breadth of the machine, and the quantity and thickness of the stuff admitted into the latter are regulated according to the kind of paper to be made.

The machine now in general use for the making of paper is the invention of Mr Louis Robert, and was brought to this country about forty years ago by a M. Didot, who, with the assistance of M. M. Fourdrinier, and Mr Dorken the engineer, greatly improved the invention, and obtained a patent for it.

The first part of the machinery upon which the pulp comes is a brass wirecloth, of so fine a texture that there are seventy wires in the inch, and which is woven in the same way as linen. This wirecloth may be described as a sort of belt without any break, which is kept continually revolving, but in such a way that the upper side, upon which the stuff is received, preserves a flat and horizontal surface. The wirecloth moves upon a number of small copper rollers, which have an agitating horizontal motion, and this distributes the stuff equally over the cloth, giving a uniform strength and thickness to the paper. After passing between a pair of rollers, where it delivers the stuff, it is led backwards again under the frame; and so goes on in a continuous revolution. Movable sides are attached to the upper surface of the wire, which regulate the breadth of the sheet to be manufactured.

The first pair of rollers through which the stuff passes are called the couching rollers. The under roller is simply cast-iron, while the upper one is covered with woollen cloth of a peculiar texture, manufactured for the purpose. It is upon this upper one that the stuff is delivered. The pressure from these rollers is slight; and the pulp is next led on to an endless felt, and passes between two cast-iron rollers. The machinery of this felt must be so regulated, that it will go with the same speed as the wirecloth and couching rollers, otherwise confusion would ensue. In passing through the first pair of rollers, only one side of the stuff is rendered smooth; but in the second pair it is reversed, and the rough side is now pressed. These rollers are closer than the first pair, and the pressure being greater, the sheet is now more dry and firm. It often happens that, in passing from these rollers to those that succeed them, the paper breaks, and adheres to the woollen cloth; in the event of which, should the broken parts be carried round on the surface of the roller, they would inevitably injure the part of the sheet which follows. To prevent this casualty, there is affixed lengthwise, along the upper surface of the roller, a large knife, called the *doctor*, the edge of which, being placed in a sloping manner, like the blades of a wright's plane, is brought so close to the roller, as effectually to shave off any substance that may chance to adhere to it.

The sheet next passes through two other pairs of rollers, which press out the water, and render the paper smooth and firm. It is then carried to the drying cylinders, which are hollow, and filled with steam, introduced by pipes placed at both ends of their axes. When these cylinders are too hot, the paper will be observed to shrivel; and by an ingenious contrivance, the extra steam can be let off, so as to reduce the temperature. The water which collects in the cylinder is carried off by means of an instrument shaped like a cork-screw, and which is wrought by the machinery. The paper is again passed through a pair of rollers, to smooth it after being dried, and is then wound upon a reel. As one reel is filled, it is taken off, and another put on in its place; and it is evident that the paper can be made of any length the reel is large enough to hold.

The whole machinery upon which the process we have described is performed, is about fourteen feet in length, and moves at the rate of from twenty-five to forty feet per minute. At one end is seen running in a stream of liquid resembling curdled milk, and at the other comes out a finished fabric, the time required for manufacturing thirty feet of which is little more than a minute. Near the extremity of the machine is usually placed an apparatus for receiving the reels of paper in web, and drawing out and cutting the web into sheets according to the regulated size. The sheets are then sorted and packed up in the usual manner.

By the operations now described, all the printing papers and also letter papers of an ordinary kind are now made, and that to an immense extent. 'Suppose,' says a writer on this subject in the Encyclopædia Britannica, 'that a machine makes ten yards lineal of a web per minute, or 600 in the hour, this is equal to a mile in three hours, or four miles per day of twelve hours. The paper is generally made about fifty-four inches wide. Reckoning that there are 300 machines in Great Britain, and that they work twelve hours a day on an average (many go both by day and night), the length of web would altogether be equal to 1200 miles, and the area of what was made would be about 3,000,000 yards daily.' The annual value of British-made papers is estimated at upwards of two millions.

CAOUTCHOUC—GUTTA PERCHA.

These two remarkable substances, to which we have briefly adverted in previous numbers, are now so largely used in connection with textile fabrics, that a more extended notice of their properties and applications may not be uninstructive to the reader.

Caoutchouc was first seen in Europe about the middle of the eighteenth century. It was then brought from Guiana, and other provinces on the eastern coast of South America, and, from its valuable power of cleaning paper, was called *India-rubber*. The striking elasticity and insolubility of caoutchouc, which we believe to be the aboriginal name for the juice, caused it speedily to become an object of attention to chemists and others, who imagined, not incorrectly, that the secret of dissolving it might be turned to some account. As the use of it increased in the civilised world, the substance became naturally an object of research to voyagers also, and varieties of it were found in many tropical climes, particularly in some parts of China, on the coast of Guinea, in Sumatra, and other East Indian isles and provinces. It was thus discovered to be the produce of several tropical trees, particularly *Ficus elastica*, *Jatropha elastica*, and *Urceola elastica*. It may also be obtained from the juices of others belonging to the same natural order; but our commercial supplies, which now amount to several hundred tons yearly, are mainly derived from the *Ficus elastica* in the old world, and from the *Jatropha* in the new. The mode of obtaining it is simple:—In the cooler seasons of the year, incisions are made around the tree, completely through the bark, and the milky juice which exudes is either immediately applied to moulds of unburnt clay, or collected in vessels. If applied to moulds, it is dried, layer by layer, over a wood fire, till of the desired thickness; if otherwise, it is allowed to coagulate and harden at leisure. In the former case, when the coating is judged to be sufficiently thick and dry, the clay mould, which, in the West Indies and South America, has usually the form of a pear, is broken, and the fragments are withdrawn through the neck; the caoutchouc thus comes to have the form of a flask, in which state it is exported. Besides bottles, shoes, tablets, toys, and the like, are formed on the spot by the native collectors. From the East Indies caoutchouc is exported in large junks and balls, lighter in colour than that brought from South America, these lumps being obtained by simple exposure of the juice to the sun. The juice itself, which is of a pale yellow colour, and about the consistence of cream, has of late years been imported into Europe in small quantities in closely-stoppered vessels; and if kept cool, and carefully excluded from the air, it may be preserved in this state for a considerable time. Caoutchouc in the solid state is highly elastic, is insoluble in any of the ordinary solvents, melts at 248° Fahrenheit, and remains viscid for a considerable time, is highly inflammable, burns with a white flame and much smoke, emitting at the same time a peculiar and offensive odour. When solid, it may be cut into threads and sheets of great tenuity and thinness; when melted, it may be used as a lute or cement; and when dissolved in naphtha, which is the most common solvent, it may be employed as a varnish, and applied to the surface of any textile fabric, rendering it quite impervious to air or moisture.

The applications of caoutchouc have of late years been very numerous. In the form of tapes and threads covered with silk, cotton, linen, &c. it is largely employed in the formation of elastic tissues. In solution, it has been applied for coating cordage and cables, to protect them from the destructive influence of salt water. An early application of the same liquid was in the preparation of waterproof cloth; of this a new variety has made its appearance within the last few months. Those valuable little articles known by the name of India-rubber *corks*, are formed of small stoppers of cotton, coated externally with a thin caoutchouc membrane. In the laboratory, sheet caoutchouc is quite indispensable; it supplies the place of a mass of expensive and easily-deranged mechanism of brass-joints and unions; it is easily made into a flexible tube, by taking a narrow ribbon of the membrane, slightly moistening the edges with turpentine, and laying them together over a glass tube; they immediately adhere with surprising tenacity, and in a few minutes the elastic tube is completed. Caoutchouc, in fact, may be said to have contributed in no small degree to the perfection of the experimental chemistry of the day. In mechanical surgery, caoutchouc is equally serviceable, forming elastic bandages, impermeable plasters, flexible tubes, and the recent elegant substitute for a poultice—a kind of half-sponge, with an India-rubber back to it; besides forming instruments of many kinds of great value but small cost. It has also been applied to bookbinding, which it effects without sewing or stitching. Among the most important applications of caoutchouc, is its use in the formation of marine glue, noticed in the preceding number.

Very recently, caoutchouc has been made to acquire new properties, by what has been termed *vulcanisation*. The process is thus described:—The caoutchouc is immersed in a bath of fused sulphur, heated to a proper temperature, until, by absorbing a portion of the sulphur, it assumes a carbonised appearance, and eventually acquires the consistency of horn. The same condition can, however, be produced by either kneading the India-rubber with sulphur, and then exposing it to a temperature of 190 degrees Fahrenheit, or by dissolving it in any of the common solvents, as turpentine, holding sulphur in solution or suspension. The *rationale* of this operation appears to be, that the India-rubber forms an actual chemical compound with the sulphur; becomes, in short, a sulphuret of caoutchouc, the properties of which are thus enumerated:—The new compound remains elastic at all temperatures, while ordinary caoutchouc becomes inelastic and rigid at a few degrees above the freezing-point: vulcanised caoutchouc is not reducible by the ordinary solvents, neither is it affected by heat within a considerable range of temperature. Finally, it acquires extraordinary powers of resisting compression, with a great increase of strength and elasticity. Most readers must be familiar with the construction of the powerful spiral spring in use for the 'buffers' of railway carriages, to moderate the effects of concussion; their ordinary strength is such as to demand a pressure equivalent to three tons and upwards, to compress the spiral close together. Mr Fuller has invented a spring, in which vulcanised caoutchouc takes the place of the steel, and the surprising result is, that the India-rubber springs are more than *three times* the strength of the metallic; that is, they resist, at the height of their tension, a pressure equal to from *five to ten tons*.

Gifted with these new powers, vulcanised caoutchouc has already been called into extensive employment for the most various and opposite purposes. It forms, in hydraulic engines of all kinds, one of the most valuable materials for 'washers,' applying itself so accurately to the surfaces between which it is placed, as to prevent the slightest leakage, other things being equal.

In this capacity, and from its power of resisting heat, it has also been proposed for the use of steam-pipe joints. It makes an admirable spring, more docile, and more equal in power, than those of steel: it has been for this purpose applied to locks and window-blinds. It is manufactured also into the most elaborate ornaments, being superior to leather in the sharp outline and bold relief of their detail. It is formed into a tubing of great strength and flexibility, well adapted, the consideration of expense excepted, for fire-hose, and for any apparatus required in conveying steam, water, or gas. This tube promises to become invaluable in the construction of life-boats, superseding those made of canvas, which were slowly destroyed by the influence of sea-water. A curious use to which it has been put is as a substitute for the iron tire or hoop of the carriage-wheel: the advantages it is said to afford are a much lighter draught, and an absence of noise. Its most important application is in its use in railways, and, as has been mentioned, in railway carriages. It is laid between the rail and the sleeper, and thus prevents the rails from indicating any traces of pressure. The useful little articles 'elastic bands' are made of this substance. Besides all these applications, it is proposed to apply it as a coating to protect the wires of the submarine telegraph from the influence of the sea water: it forms impervious bottles for ether, inkstands, trouser-straps, gloves, boots, surgical bandages, and a number of other articles, for which its nature almost seems to have been expressly designed.

Gutta percha is of recent introduction into England, having been first brought under the notice of the Society of Arts by Dr Montgomerie in 1843. The tree from which it is procured is said to belong to the natural order *Sapotaceæ*, and is found abundantly in Singapore, the Malayan Peninsula, Borneo, and in all probability throughout the entire Indian Archipelago. The tree is one of the largest in the forests, frequently attaining to the diameter of three, four, or even six feet. The timber is valueless for building purposes, on account of the loose and open character of its tissue; but the tree bears a fruit which yields a concrete oil, used for food by the natives. Gutta percha is contained in the sap, and is thus procured:—A magnificent tree of fifty, or perhaps one hundred years' growth, is felled; the bark is stripped off, and a milky juice, which exudes from the lacerated surfaces, is collected, and poured into a trough, formed by the hollow stem of the plantain leaf. On exposure to the air, the juice quickly coagulates. From twenty to thirty pounds is the average produce of one tree. This wasteful, sinful procedure, which might, and ought to be superseded by simply tapping or incising the bark, is adopted to a very large extent, as may be conceived from the amount of the gutta now imported reaching many hundreds of tons annually.

Gutta percha comes to us in two forms: in thin slips or scraps, or in rolls, which are formed by rolling the thin layers together in a soft state. When pure, the slips are transparent, and somewhat elastic, varying in colour from a whitish-yellow to a pink. In the mass it is seldom free from some impurities—such as saw-dust, pieces of leaves, &c. It is purified by a process called 'devilling,' or kneading, which is done in hot water: the water soon dissolves some of the foreign matters, and washes out others, until after a short time the gutta percha is left in a mass, ductile, soft, and plastic, of a whitish-gray colour. Thus prepared, gutta percha possesses very curious properties. Below the temperature of 50 degrees, it is as hard as wood, but it will receive an indentation from the finger nail. It is excessively tough, and only flexible in the condition of thin slips: in the mass, it has a good deal the appearance, and something of the feel, of horn; its texture is somewhat fibrous; and from the resistance it offers to anything rubbed across it, it appears that it was first used as a substitute for horn for the handles of knives and choppers. By an increase of heat, it is made more flexible, until, at a temperature considerably below the boiling-point of water, it becomes like so much softened bees'-wax. It is now easily cut and divided in any manner by a knife, and may be moulded into all varieties of form with the greatest ease; or may be cut, and united again so perfectly, as scarcely to exhibit even the appearance of a joint, and possessing all the strength of an undivided mass. Whatever be the shape into which the gutta percha is now formed, it will retain precisely the same form as it cools, hardening again to its previous state of rigidity. It is in a great measure devoid of elasticity, offering a striking contrast to caoutchouc, but its tenacity is little less than wonderful: a thin slip, an eighth of an inch substance, sustained a weight of forty-two pounds, and only broke with the pressure of fifty-six pounds. When in its hard state, it is cut with incredible difficulty by the knife or saw. Like caoutchouc, it burns brightly when lighted, disengaging the peculiar odour accompanying the combustion of that substance; like it also, it is soluble with difficulty in ether and other caoutchouc solvents, but very readily in oil of turpentine.

In solution, gutta percha appears to be as well adapted as that of India-rubber for the manufacture of waterproof cloth, and for the other purposes to which that liquid is now applied. In the solid state, it is in use among the Malays, as above-mentioned; and they prefer it to wood and horn, even where the latter is attainable. There are a number of cases also in which it appears likely to become an admirable substitute for leather, possessing, as it does, some properties in common with, and some vastly superior to, those of that material. Its value has been readily recognised by our inventors, as shown by the numerous patents taken out in reference to its applications. In these it is proposed to employ it as an ingredient in mastics and cements; for the manufacture of a thread which is used to form piece goods, ribbons, paper, and other articles; as a substitute for caoutchouc in binding books; for waterproofing boots, shoes, and other articles of apparel; for the manufacture of flexible hose, tubes, bottles, &c. But the most comprehensive is the patent of Mr Hancock, who has instituted a series of curious experiments upon this remarkable substance. He unites the gutta percha with caoutchouc, and another substance called *jintawan*, by which an elastic material results, which is impervious to, and insoluble in, water. The hardness or elasticity of the compound is easily determined by the alteration of the amount of gutta percha; the latter is added in larger quantity if firmness is requisite, and *vice versâ* if flexibility and elasticity are necessary. From this mixture a very curious substance, light, porous, and spongy, is prepared, suitable for stuffing or forming the seats of chairs, cushions, mattresses, &c.; it also forms springs for clocks, clasps, belts, garters, and string. By an alteration of the process, much hardness is acquired, and moulds and balls of the material are capable of being turned in a lathe, and otherwise treated like ivory. In this state it offers itself for a thousand other offices: thus it may be formed into excellent picture-frames, incredibly tough walking-sticks, door-handles, chess-men, sword and knife-handles, buttons, combs, and flutes. It has been proposed as a material for embossed alphabets and maps for the blind, on account of the clear sharp impression it is capable of receiving and retaining. It is also an excellent matrix for receiving the impression of medals and coins, and is valuable on account of its subsequent non-liability to break. By mixing a proper portion of sulphuric acid with it, or adding a portion of wax or tallow, it may be reduced to any degree of solubility, and furnishes a good varnish, quite impermeable to water. Mr Hancock proposes such a fluid as valuable for amalgamating with colours in printing: it appears probable that this will form an extensive application of the discovery, and that colours so printed will prove as lasting as the fabrics on which they are impressed. Time alone, however, can determine the extent to which gutta percha and its congener caoutchouc will be applied in the useful and ornamental arts.

MINING—MINERALS.

The term *Mineral* is somewhat varied and indefinite in its application. In the widest sense, it is made to embrace the whole of inorganic nature; and thus we speak of the mineral in contradistinction to the vegetable and animal kingdoms. Occasionally, it is restricted to those native products which appear in a crystallised or definite form; but more generally and properly it is extended to all the earths, rocks, salts, and ores which are obtained from the crust of the earth. Employing it in the latter signification, we intend, in the present sheet, to treat of the nature, origin, and uses of such substances as coal, limestone, sandstone, rock-salt, sulphur, gems—reserving consideration of the metallic ores and metals for a subsequent number. It is almost superfluous to observe, that the mining, digging, transport, and preparation of these materials for application to the purposes of civilised life, constitute departments of human industry of high scientific, as well as economic importance.

For the more accurate comprehension of the subject, it may be necessary to premise that we speak of the *crust* of the earth—meaning thereby that superficial rind or portion accessible to human investigation—in contradistinction to the interior masses, concerning the nature of which we can only form conjectures. In this crust the rocky substances are variously arranged: some are found in layers or strata—hence said to be *stratified;* others appear in vast irregular masses, presenting no trace of bed or layer, and are accordingly termed *unstratified*. The matter of the stratified has evidently been deposited from water, and from this view of their origin, they are generally known as *aqueous* or *sedimentary* rocks; while the unstratified, presenting no appearance of deposit, but everywhere an irregular configuration, and, moreover, often breaking through and contorting the stratified, are considered of *igneous* or *volcanic* origin. Both sedimentary and igneous rocks present various mineralogical and chemical characters: thus, of the former, we have roofing-slate, sandstone, coal, limestone, &c.; of the latter, granite, basalt, and lava—all very distinct in composition and appearance. Besides differences in mineral composition, the sedimentary rocks contain different kinds of fossils—that is, the petrified remains of animals and plants; and such distinctions have rendered it necessary to arrange the rocks constituting the crust of our globe into various *formations*—meaning by a formation any suite of rocks possessing some peculiar mineral or fossil character. Thus we speak of the 'coal formation,' meaning thereby not merely the beds or layers of coal, but the sandstones, shales, ironstones, and the like, which alternate with and accompany that mineral—seeing that the whole have been evidently deposited under similar conditions, and that similar organisms are found fossil within them. Further, both the stratified and unstratified rocks are frequently traversed by rents and fissures, some of which are entirely void, others partially filled or lined with crystallised products differing from the adjacent rocks, and many again wholly filled up with crystallised substances, metallic ores, and other ingredients, constituting what are termed *lodes* and *veins*. (See Geology.) Deviating in some degree from the usual technical arrangements, we shall describe the principal economic minerals under such heads as appear best calculated to aid the comprehension of the ordinary inquirer.

BITUMINOUS SUBSTANCES.

Bitumen—from a Greek word signifying the pitch-tree—may be regarded as embracing all those inflammable minerals which, like pitch, burn with flame and smoke in the open air. Naphtha, petroleum, and asphalte are familiar examples; but all substances impregnated with these bitumens are said to be *bituminous*. Hence under this head may be included coal in all its varieties, as well as bituminous slate, slaggy mineral pitch, and the asphaltes of commerce.

Coal.

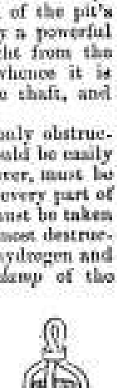
Coal, of which there are several distinct varieties, is one of the most important minerals with which man has yet become acquainted. By it he fuses the metals, produces steam which sets machinery in motion, prepares gas for light, heats his apartments, cooks his food, and, in short, renders all the resources of nature fit for civilised use. It is uncertain when coal first began to be used in Britain as fuel, but in all probability it was not earlier than the beginning of the twelfth century. In 1281, Newcastle is noticed as having some trade in that article; and a little later, we find it mentioned in the Chartulary of the Abbey of Dunfermline. In the reign of Edward I., its use in London was prohibited, in consequence of the supposed injurious influences of the smoke; and this prohibition we find renewed at several subsequent periods, but all to no purpose. The increasing scarcity of wood as fuel rendered some other substitute necessary; and, from its compact form and powerful heat, no known substance could for one moment be brought into competition with coal. The smoke nuisance was therefore submitted to; and despite of every obstacle, the 'obnoxious' mineral was soon in the ascendant. At the beginning of the sixteenth century, it seems to have been getting into use in the Lowlands of Scotland, where we find Bœthius taking notice of a 'black stone' found in Fife and the Lothians, the heat of which was sufficiently intense to fuse the most refractory metals. Since the time of Charles I. it has become almost the only description of fuel used in London, and in most other towns and districts throughout the kingdom—peat or turf being but occasionally employed, and that solely in remote localities. It is within the current century, however, that the great demand has been made upon our coal-fields; since the application of the steam-engine to the purposes of the mine, the factory, the railway, and river; since the introduction of gas, the extension of our foundries, and the general advancement of those economical processes which distinguish the present from every other period of our country's history. According to the most recent estimates, not less than thirty millions of tons of coal are raised from the different mines in the British islands, of which between three and four millions are exported to other countries.

The coal worked in Britain may be said to be exclusively obtained from the great coal-formation, where it alternates with strata of sandstone, bituminous shale, bands of ironstone, fire-clay, and impure limestone—the whole suite being usually termed the *coal-measures*. Attempts have been made to work the thin beds found in more recent formations, as the oolite and tertiary, but in every case without success. The principal districts, or 'fields,' as they are called, are those of Northumberland and Durham, Lancashire, Stafford, South Wales, and the Lowlands of Scotland—the latter extending from Fife to Ayrshire at an average breadth of about thirty miles. In these fields there may be as many as ten, twenty, or even forty seams or strata of coal, varying from a foot to thirty feet in thickness; but of these, in general, not more than five or six can be worked with profit. The mineral so obtained is of different varieties and qualities; so pure, as to leave after combustion the smallest per centage of ash; or so foul, as to be burned with difficulty. The principal varieties are—*caking* coal, a highly bituminous sort, like that of Newcastle, which emits much smoke and gas, and cakes together during combustion; *cubic*, which is also bituminous, but breaks into larger cubical masses, and does not cake while burning; *splint*, a hard slaty variety, which is still less bituminous, and does not cake, but burns with great heat, and leaves little ash; *cannel*, a compact shining variety, also bituminous, burns with a clear flame, does not cake, and leaves a whitish ash, principally used, where it can be obtained, for the manufacture of gas. All these varieties are less or more bituminous; but there is another variety, known by the name of *anthracite*, or 'blind coal,' which is non-bituminous. This anthracite has a glistening and semi-metallic aspect, does not soil the fingers when rubbed, and burns without smoke. It is, in fact, a natural coke, or charcoal, the original coal having been deprived of its bituminous products by heat or other causes. It is found in small patches in several coal-fields in contact with the igneous rocks, which have evidently produced the change, but abundantly in South Wales, where it occupies a considerable area. It is used exclusively in the reduction of the metallic ores, for which it has been employed only since the introduction of the hot-blast process. Several fields, both of bituminous and anthracite coal, occur in Ireland; but comparatively little is raised, and almost all the coal used in Dublin, Belfast, and other large towns is imported from England.

Besides the supply obtained in Britain, there are coal-fields, less or more extensive, in France, Spain, Belgium, and Germany; in India, China, the East India islands, Australia, and New Zealand; in Nova Scotia, and the states of North America; in the Isthmus of Panama, Chili, and Peru; and even in some of the islands of the Pacific and Arctic Oceans. Of these fields, the North American are by far the most extensive and important, presenting areas of bituminous and anthracite coal greater than the whole extent of our own island. That of Pennsylvania, Virginia, and Ohio, for example, extends continuously from north-east to south-west for a distance of 720 miles, its greatest breadth being 180 miles; its area thus amounting to 129,600 square miles. That situated in Illinois, Indiana, and Kentucky, embraces an area of 14,000 square miles; while several, many times larger than the largest coal-field in Britain, are found in Michigan, and other parts of the Union. Many of the coal-fields in the world are yet untouched; it being only after the wood of a new country has been used up, and civilisation made some progress, that man betakes himself to the difficult and often dangerous task of extracting mineral fuel. All the coal-fields now mentioned belong to the same great formation; but there are other patches of a more recent date which are occasionally worked, as the lignite, or brown coal of Germany, and of Bovey Hayfield, near Exeter. This, however, is a very different material in comparison, and is only had recourse to where the lower formation is absent, or at such a depth, as to preclude its easy working. Taking, therefore, an estimate of the whole amount of coal known to exist, there need be no dread of the supply being exhausted for thousands of years to come; for though the fields of one country should be exhausted, the fields of another lie patent to the same commercial influence which imports tea from China, cutlery and cloth from Britain, and cotton from America.

Coal being, in every instance, a true stratified rock, the modes of obtaining it are much the same in the different countries where it is sought after. In early times, our ancestors could avail themselves of little more than the mere outcrop—that is, that portion of a seam which approaches the surface; and this was excavated just as a stratum of limestone or sandstone is quarried at the present day. By and by they sank to greater depths, but still entering in a slanting direction, after the dip or inclination of the strata, and not descending by shafts or perpendicular pits, as is now the practice. To rid their workings of water, they hewed long tunnels or subterranean drains from some low level, and carrying this forward to the seam of coal, effected a drainage to that depth. Where the coal seams lay on high ground, and where there was any deep glen or ravine in the neighbourhood, such drainage often allowed them to work at a considerable depth; but these *day-levels* (so called from their discharging their contents to the open day, in contradistinction to other levels within the mine) were, upon the whole, but imperfect and expensive affairs. In some instances, where pits were sunk, windmills were erected for the purpose of pumping the water; but no certain effect could be calculated upon from an agency so unstable as the wind. The invention of the steam-engine soon set aside these rude and imperfect appliances; shafts, instead of slanting adits, are now everywhere sunk, and the water brought to the surface at once, no matter whether the depth be 20 or 300 fathoms. Of course the fittings of a coal mine depend, as do all other commercial speculations, upon the value of the material sought to be obtained. In some districts the shafts are of no great depth, the pumping engines small and rude, and the mineral brought to the surface simply by animal power; while in other localities the shafts are of enormous depth and finely executed, the engines of great magnitude and superior finish, and no animal power employed unless in the hewing of the coal. In Britain, a Newcastle colliery may be taken as the most perfect of its kind. Here the shafts, which are often sunk at vast expense, vary from 150 to 300 fathoms in depth, are lined with casings of stone, wood, or iron, and are divided into various compartments for the accommodation of the pumping gear, and the ascending and descending corves which contain the coal—these compartments also subserving an important end in the ventilation of the mine. Having reached the stratum of coal, which generally lies at a considerable inclination, main *drifts* or excavations are made in different directions for drainage, transit, and ventilation; and then the minor workings branch off from these, care being taken to leave pillars or masses of the stratum for the support of the superincumbent material. The water that oozes from the workings finds its way to the lower level, or *sump*, of the pit's bottom, from whence it is pumped up by a powerful engine; and the coal hewn out is brought from the various workings to the main drifts, whence it is dragged by ponies to the bottom of the shaft, and raised in corves, or baskets, to the surface.

Were the accumulation of water the only obstruction to the mining of coal, the difficulty could be easily surmounted. A supply of fresh air, however, must be regularly and unceasingly maintained in every part of the workings; and not only so, but care must be taken to prevent the accumulation of two gases most destructive to human life; namely, carburetted hydrogen and carbonic gas—the *fire-damp* and *choke-damp* of the miners. For this purpose the various underground workings are so arranged and boarded off, that while one set receives the descending current, another carries it forward again to the pit bottom, where, by means of rarefaction, produced by a huge fire, it is carried up the shaft to the atmosphere. By these means not only is fresh air supplied to the miners, but the deleterious gases are carried off, and the whole subterranean recesses rendered safe and healthy. The most ingenious of human inventions are, however, imperfect; and choke-damp and fire-damp will exude from the coal seam, and lurk in recesses, there either to suffocate the first comer, or to explode the instant that a lamp is brought in contact. To prevent these casualties as much as possible, various air-tight trap-doors and boardings are employed, and the miner is furnished with safety-lamps of various constructions,



which, while they afford sufficient light, prevent the carburetted hydrogen from coming in contact with the flame within (see fig.).* These remarks apply in particular to the Newcastle coal-field, where, in consequence of such difficulties, coal-mining is conducted with greater care and skill than in any other district; but it must be remembered that there are many fields where fire-damp is unknown, and where the most ordinary ventilation is sufficient to prevent the accumulation of carbonic acid or any obnoxious effluvia. Indeed we know of an excellent coal-field which returns its thousands annually, and where no precaution either as to lamps or ventilation is necessary—all that is requisite being occasional wooden props, to prevent falls of loose material from the roof of the compartment in which the miner may be working. In some of the largest Pennsylvanian mines even this precaution is unnecessary, the anthracite being of great thickness, and so exposed and level, that it is hewn out either in open quarry or in huge drifts, precisely after the fashion of our railway tunnels.

Important and varied as are the uses, and vast as must be the consumption, of this mineral in Britain, yet so abundant is it, that in many localities the best household coal never exceeds 7s. a ton, while in Edinburgh it averages about 12s.; and in London, to which it is all sea-borne, it ranges between 15s. and 23s. 'Notwithstanding the cheapness of the produce of this kind,' says Mr Ansted, 'the value of the coal actually brought to the surface in Britain amounts annually to nearly ten millions of pounds sterling, and almost the whole of this is derived, although in unequal proportions, from the Newcastle, the South Welsh, the Staffordshire, and Scotch coal-fields. With regard to the first of these—the Newcastle coal-field—it is said that upwards of six millions of tons are there annually raised up out of the bowels of the earth; that 60,000 persons are employed in the mining operations; that 1400 vessels are constantly engaged in conveying the coal (amounting to three millions of tons) required for the consumption of the Metropolis alone; and that the capital employed in simply conducting this trade amounts to several millions sterling.' From this single instance, some idea may be formed of the magnitude of the trade in coal, which is doubtless one of the most important props of our country's commerce, as it is of her manufacturing and mechanical superiority.

As to the origin of coal, no matter what the variety, there can be no doubt that it is essentially vegetable. Not only are fossil trunks, branches, leaves, and fruits found in the mass, but scarcely a portion of it, when submitted to the microscope, but shows the ducts and fibres of a true vegetable structure. We know, moreover, that vegetable matter, when subjected to moisture and pressure, and excluded from the action of the air, will in a short period pass into a bituminous or carbonaceous mass, which time and greater pressure and heat would by and by convert into true mineral coal. Peat, were it excluded from atmospheric influence, would soon pass into a species of coal: brown coal and lignite, in which the trunks and branches of the trees are still perceptible, are only varieties less perfect than the true coal; and even in the old coal formation itself, various beds present various degrees of perfection, according as the vegetable mass seems to have been more quickly and perfectly removed from the action of the atmosphere. How the masses of vegetable matter were accumulated, is still a subject of speculation with geologists—some contending that the trees, grasses, ferns, &c. which compose it, must have grown and accumulated just as peat-mosses do at the present day, and that the land was then submerged, and the mass covered over by layers of sand and mud, which, hardening, formed strata of stone and shale; others reject this theory as untenable, and consider the whole strata (sandstone, shale, &c.) of the coal-measures to have been deposited in estuaries liable to periodic inundations, like those of the Niger and Ganges, but only on a more gigantic scale. According to this notion, which is more in accordance with the phenomena presented, coal is partly composed of vegetables which grew *in situ* in the form of jungle, and partly of masses drifted down from the interior by the waters of the river.

* Very few persons are unacquainted with the nature of the safety-lamp, invented by Sir Humphry Davy, and introduced to the miners in 1816. As shown in the text, it consists of an oil-lamp enclosed in a wire-gauze cylinder, of which the apertures are extremely minute—a square inch of the surface containing 625 openings. Through apertures so small, flame will not pass, and the lamp may therefore be carried into the most explosive atmospheres without risk. When the fire-damp is to the air in the proportion of 1 to 5, 6, or 7, the cylinder is filled with the flame; but even though the wire-gauze should become red hot, the exterior air is not kindled. It is perhaps possible, by certain chemical arrangements, to force the flame through the gauze, if a strong current be employed, but no instance of such an event ever having occurred naturally in a mine is, we believe, recorded; and therefore the Davy-lamp in its original form is esteemed perfectly safe, notwithstanding the numerous *improvements* proposed on it. If the miners would always employ this safeguard instead of candles, there can be little doubt that fewer explosions would occur; but the feeble light which it affords renders it unacceptable, and men will actually, and without dispute, frequently risk their lives for the sake of a little more light and the avoidance of a little trouble. Many mines have been conducted since the introduction of this lamp, which, without it, must have been closed; and some have been re-opened that could not be worked in safety with the old *steel-mill*—a machine of revolving steel and flint, employed before the Davy lamp in dangerous pits. This is especially the case in what are termed the 'pillar-workings' of the pit, where the ventilation becomes more difficult; and in almost all pillar-workings the *Davy*, as the pitmen call it, is in requisition. In many pits a *locked* Davy is delivered to the pitmen, who return it to the overseers before leaving the pit.

Jet—Amber.

Though the chief use of coal be doubtless that of producing heat and light, there are certain minor purposes to which some of the varieties are applied. Thus we have occasionally seen very pretty vases, and other ornaments, made from cannel coal when it is sufficiently compact and lustrous. It is easily turned on the lathe, and takes a polish which is not readily tarnished; the only objection to its use being brittleness, and liability to be injured by fire.

Jet, of which necklaces, ear-rings, and other ornaments are made, is but a variety of coal, as common in its origin and nature as that which we pile on our fires. It is occasionally found in the lignite beds of England, but principally in Germany and Prussia, where it occurs associated with amber, which is regarded as a fossil gum, while jet seems to be the trunk and branches of trees more completely bituminised, and freer from earthy impurities than cannel or other coals. It is easily turned on the lathe, or cut with the chisel, and is susceptible of a fine polish. Imitations of jet are extensively manufactured by the glass-maker; but these may be readily detected by their greater hardness and weight.

Amber, a well-known yellow resin-like substance, is believed, as stated, to be a fossil gum or resin; and its connection with deposits of lignite seems to confirm that opinion. It is solid, brittle, commonly transparent, and when rubbed, becomes electrical. It is found in various countries, more particularly on the Adriatic and Sicilian shores; on the Baltic, between Memel and Dantzic, where there are regular mines of it; and in Japan, Madagascar, and the Philippine Islands. It is used chiefly in the manufacture of beads, necklaces, trinkets, and various ornaments, for which purpose it is easily cut, and takes a beautiful polish. Dissolved by drying linseed oil, it forms amber-varnish. The largest known specimen of amber was found near the surface of the ground in Lithuania, about twelve miles from the Baltic: it weighs 18 lbs., and is in the royal cabinet at Berlin. Other curious specimens have been detected enclosing insects, and even drops of water—

these apparently having been enclosed when the gum was exuding in a fluid state from the living tree.

Naphtha—Petroleum—Asphalte.

Naphtha, petroleum, mineral pitch, and asphalte, may in a great measure be regarded as one and the same substance in different degrees of concentration and purity. Thus naphtha, on exposure to the air, soon loses its limpid appearance, and passes into petroleum; and petroleum, under similar treatment, dries and shrinks into a viscous sluggy state, undistinguishable from native mineral pitch.

Natural naphtha is a limpid, or but slightly-coloured bitumen, highly inflammable, and of a strong bituminous, but not disagreeable odour. It is found at Baku on the Caspian, at Hit on the Euphrates, and at other places in Mesopotamia; it occurs abundantly in the lower districts of the Birman empire; exists at various places in the north of Italy, as Piacenza, Modena, &c.; and in some districts of North America. It generally exudes from fissures in the rocky strata, or is collected in shallow wells, dug in the clays and shales where it occurs. A similar liquid can be obtained by distilling petroleum, coal-tar, and other bitumens; but the artificial product has a more penetrating and unpleasant odour. Naphtha has the property of dissolving most of the essential oils and resins, and is at present largely used as a solvent of caoutchouc. It is also used for lamps; and the cities of Parma and Genoa are said to be lighted with the produce of the wells in the duchies of Modena and Parma. A very fine black pigment may be prepared from the soot of naphtha lamps.

Petroleum, or rock-oil, is another liquid bitumen, of a brownish colour and variable consistency, and yielding a strong disagreeable odour. It is found exuding from various secondary strata, but chiefly in coal districts, where it is evidently a product of that formation. It occurs in small quantities in various localities of Britain, but abundantly in other countries of Europe, in Persia, the Birman empire, in Texas, and in the islands of Trinidad and Barbadoes. On exposure to the air, petroleum thickens, and assumes a darker hue, in which state it is generally known by the name of mineral pitch, or Barbadoes tar. On further exposure, and especially when mingled with earthy impurities, it passes into a solid state, then becoming the common asphalte or bitumen of commerce. In its ordinary liquid state it is burned for light; worked into balls with earth and gravel, it is used in eastern countries as fuel; and mingled with grease, it is occasionally employed as a substitute for tar in coating vessels.

Asphalte, so called from its adhesive nature, differs from mineral pitch in being solid and brittle at the ordinary state of the atmosphere. It melts easily, and is highly inflammable, leaving, when pure, little or no ash after combustion. It is found in most of the localities where petroleum springs occur, being nothing more than their accumulated produce. The chief supplies are obtained from the shores of the Dead Sea, from Barbadoes, from Trinidad, where it occupies a basin or lake about three miles in circumference, and from Clermont, Seyssel, and Bourg in France, where it occurs in limestone and calcareous shales. Asphalte was employed by the ancients in some of their cements, and also in the process of embalming. It is now extensively used in the formation of pavement, roofing, and other economical purposes. Melted and mingled with properly-sifted gravel, or iron slag, it forms a very durable and unexpensive pavement—being liable to be softened, however, during intense heats. See p. 336.

CALCAREOUS SUBSTANCES.

Under this head we include such economic minerals as contain a notable proportion of *calx* or lime in their composition. Common limestone, magnesian and lithographic limestones, marble, chalk, marl, gypsum, and alabaster, are familiar examples. Some of these have evidently been deposited from calcareous waters; others are as evidently the production of animalcules, like the coral polype; and some are almost wholly composed of the shells of molluscs, and of other calcareous exuviæ. Whatever may have been their several origins, they have all undergone certain chemical and structural changes since their formation—thus rendering them less or more compact and crystalline, producing a dull massive rock or a brilliant marble, an opaque gypsum or a translucent alabaster. Chemically, they have one common basis; namely, *calcium*—a substance obtained with difficulty in the laboratory, and never found as a natural product. It is one of the metallic elements discovered by Davy, and so extremely oxidable, that on exposure to the air it is almost instantaneously converted into lime (oxide of calcium); and this lime, if further exposed, becomes a limestone or carbonate of lime, by absorption of moisture and carbonic acid.

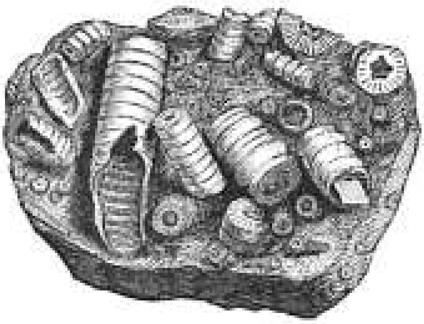
Common Limestone.

Limestones fit for building and agricultural purposes are found in every formation, from the oldest to those of the most recent origin—being crystalline and concretionary in the primitive and transition series, but gradually losing this structure, and becoming more earthy in the secondary and tertiary strata. In all of them there is a certain amount of impurities, consisting for the most part of clay and sand, with traces of iron and other ingredients. The economic value of any limestone, as well as its fitness for any particular purpose, must depend therefore upon its actual composition, and not upon its absolute purity as a carbonate. The rock is generally dug from open quarries, but occasionally, when it dips rapidly, and is worth the expense, it is followed downward by mining—the greater part of the stratum being excavated, and only portions left at intervals to support the superincumbent material. It is then broken into fragments of moderate size, and conveyed to a kiln, where, being placed in alternate layers with coal or turf, it is roasted, thereby expelling its water and carbonic acid. In the best-contrived kilns the process is carried on continuously; broken limestone and fuel being constantly thrown in at the top, and the burned lime raked out at intervals from beneath. In this state it is known as *shell*, or unslaked lime, and requires to be moistened with water to convert it into powdery quicklime. Occasionally, when the limestones contain a considerable per centage of silica (sand), and the heat been very high, the lime refuses to slake, and is said to be *over-burned*; in other words, a portion of silicate has been formed. Quicklime is a soft bulky powder soluble in water; and what is remarkable, the colder the water the larger quantity of lime is taken up. Thus a pint of water at 60 degrees will dissolve eleven grains; while at 212 degrees, or the boiling point, only seven grains are retained in solution. As stated under 'Fictile Manufactures,' and 'Applied Chemistry,' quicklime is largely employed in the formation of mortar and cements, in glassmaking, leather-dressing, dyeing and bleaching; and, as will hereafter be seen, its uses are not less important in agriculture, in the purification of gas, in medicine, and other industrial processes. Applied to land, it promotes the decay of vegetable fibre, neutralises the effects of certain hurtful compounds of iron, and probably serves to liberate potash from the insoluble silicates of that base contained in the soil. Lime-water for chemical and pharmaceutical purposes, is always prepared by agitating cold water with excess of quicklime in a closely-stoppered vessel, and then after subsidence pouring off the clear liquid. Besides the above applications, a large quantity of limestone is used as a flux in metallurgy, such strata being sought for this purpose as contain but a small per centage of impurities.

Limestone is one of the most abundant of rocks, there being no district of any extent in which it does not appear as a member of one or other of the geological formations. In Great Britain and Ireland the supply is inexhaustible; it is worked in beds from a few feet to one hundred in thickness; the mountain or carboniferous limestone, which underlies the coal-formation, often exceeding that thickness, and ranging unbroken for many miles in extent.

Marble.

Marble is but a technical term for any species of limestone sufficiently pure and compact to be susceptible of a fine polished surface. No matter what the colour, whether white or black, whether studded with the strange forms of fossils or streaked with the most fantastic veinings, marble is but a carbonate of lime, containing only a few subordinate impurities, which do no more than affect its colours and markings. The best varieties are obtained from the primary and transition formations, in which they occur granular, crystalline, and not unfrequently replete with party-coloured veinings. Pretty enough marbles for slabs and other architectural purposes are sometimes obtained from the secondary formations, these being, in general, curiously marked with the shells, encrinites, and other corals



Fragment of Encrinital Marble.

which are imbedded in the mass. None of these, however, are susceptible of the same degree of polish as the primary marbles, some of which, like that of Carrara, seem almost translucent. Most countries of any extent have varieties of native marbles, which, though inferior to those of Italy and the Archipelago, might still be more extensively used than they are, were it not for the expense in cutting and polishing, and, above all, for the rapidity with which many of them become weathered and tarnished.

Sculptors and architects generally arrange the marbles of a country into some such divisions as the following: — *Uni-coloured*, as the black and white; *variegated*, when marked with irregular spots and veins; *madrepore*, when studded with encrinal or coral markings; *shell*, when only a few shells are interspersed through the mass; *lumachelli*, entirely composed of shells; *cipolin*, containing veins of greenish talc; *breccia*, marbles formed of angular fragments of different composition and colour; and *puddingstone*, when the fragments are round instead of angular. The celebrated marbles of Greece and Rome, such as the Parian, the Pentelic, the Carrara, &c. were of one uniform colour, and only occasionally marked with grayish or greenish veins. Besides these, which were chiefly employed in sculpture, and in the decoration of their public edifices, the ancients indulged in a variety of fancy marbles for minor ornamental purposes—such as black, red, green, yellow, spotted, and veined. The localities of some of these ancient marbles are lost, but inexhaustible supplies of first-rate statuary and architectural marbles can still be obtained from the Archipelago, from Carrara, Genoa, Corsica, Sicily, and other parts of Italy. At Carrara alone, about 1200 men are employed at the different quarries, and at the mills for sawing the marble. The annual rental is calculated at about £28,000, and the value of the yearly exportations of the raw material is not less than half a million. So accessible are these quarries, and so free from flaws is the rock in some portions, that blocks of more than 200 cubic feet can be detached by means rude and primitive compared with quarrying in Britain. The value of the material differs according to the quality and size of the block; large blocks ranging from £2 to £3 per cubic foot.

Many marbles of excellent quality are found in France; in England they are abundant in the counties of Derby, Devon, and Anglesea, the last being of a green colour; in Scotland, at Assynt, Ballachulish, and in the islands of Tyree, Skye, and Jura; and in Ireland, at Kilkenny and other places. The Kilkenny marble is black, and encloses shells of a whitish colour, which, when cut across and polished, present various circular markings, which add to the beauty of the slab. The United States also furnishes some excellent architectural marbles, principally of primary formation. One range, which passes unbroken through several of the states, is perhaps one of the most extensive and valuable primary limestones in the world. It is of a pure white colour, and of a highly crystalline texture, affording blocks of more than fifty feet long and eight feet thick. It is employed in several of the states' public buildings—as, for example, the City Hall of New York, and Girard College, Philadelphia.

The applications of marble are so numerous and common, that we need here merely indicate its use in building, statuary, and monumental erections; in internal decoration, as mosaic-work, mantel-pieces, vases, table-slabs, and other articles of furniture. Party-coloured stones susceptible of a high polish, as porphyries, serpentines, and the like, are commonly but erroneously termed and classed with 'marble'—a term which is applicable alone to rocks essentially composed of carbonate of lime, and susceptible of polish as above described. As limestones, all marbles are consequently corroded and acted upon by acids; while porphyries and serpentines being essentially siliceous, are not so affected. Even alabaster, though having a calcareous base, is not in the above sense a marble; but is, as will shortly be seen, a sulphate of lime incorrodible by acids. The preparation of marble as an ornamental material is simple but laborious. The blocks are generally detached from the quarry by sets of iron wedges—blasting by gunpowder being apt to produce rents and flaws where least wanted. They are next reduced by hammer and pick, and finally chiselled into the desired form. Slabs are obtained by cutting the blocks asunder with a thin plate of soft iron, under which sand or grit, liberally supplied with water, acts as the cutting agent. Pieces of moderate size are generally cut by hand; but where the blocks are large, machines of various constructions are employed. Marble cutting, indeed, is the subject of several patents, in which machinery, moved by steam or water, effects not only plain cutting and polishing, but even mouldings and ornaments of an intricate kind. In polishing, sharp sand, emery, tripoli, and tin-putty are the substances employed—the workman graduating his material with the increasing smoothness of the surface. The body with which the sand is rubbed upon the marble is usually a plate of iron; but for the subsequent process a plate of lead is used, with fine sand and emery. The polishing rubbers are coarse linen cloths, wedged tight into an iron planing-tool. Throughout the whole operation, a constant supply of water is indispensable.

Magnesian Limestone—Magnesia.

Magnesian limestone, which appears extensively in England, Germany, and other continental countries, occurs often in beds of great thickness, immediately above the coal-measures, just as the mountain or carboniferous limestone lies immediately beneath. It is usually of a cream-yellow colour, and of very variable consistency, some layers being soft and powdery, others irregularly crystalline and concretionary, and some compact and homogeneous. The compact granular variety is generally known by the name of *dolomite*, after Dolomieu, a French geologist. Magnesian limestone is, for the most part, used as the ordinary carbonates of lime—that is, for agricultural and building purposes—some of the English quarries furnishing an exceedingly durable material. The new houses of parliament, for example, are built of a magnesian limestone; that of Bolsover Moor in Derbyshire having been selected after the most rigid scientific tests of a commission of inquiry. Besides these uses, some of the more compact and homogeneous schists are employed for lithographic blocks, the chief supply for that purpose being derived from Germany, though lithographic schists are also obtained from the white lias limestone in England. (See LITHOGRAPHY.)

Magnesian limestone is so called from its containing a notable per centage of magnesia—a well-known medicinal earth, commonly obtained by burning the carbonate of magnesia. Magnesium is the metallic basis of magnesia, just as calcium is the base of lime; it is strictly a product of the laboratory, and does not occur in nature. The *calcined magnesia* of the druggist is procured either from this source, or from the bittern of sea-salt, or from the waters of certain springs impregnated with the sulphate of magnesia. The hydrated carbonate of magnesia, the *magnesia alba* of the shops, is also obtained by a chemical process from the sulphate. Natural carbonate of magnesia is found in Piedmont, in Moravia, in the United States, and in the East Indies. It exists as a component part of many mineral substances, making them feel soft and soapy to the touch. *Sulphate of magnesia* (Epsom salts) is obtained by a simple process from bittern, by treating magnesian limestone with dilute sulphuric acid, or from certain mineral springs, as, for example, those of Epsom in Surrey, which give to the salt its most familiar name. This salt, which consists of 20 parts magnesia, 40 sulphuric acid, and 63 of water, is one of the most common and useful in medicine, and is, moreover, the chief source of the other forms in which magnesia is administered.

Meerschaum (German, *foam of the sea*), a substance in great repute among tobacco-pipe fanciers, is an earthy carbonate of magnesia, extremely light, and of a yellowish-brown colour. It is found in various parts of southern Europe, particularly in Greece and Turkey, where, besides being fashioned into pipe-bowls, it serves also the purposes of a fulling-earth. Germany, however, is the great seat of the meerschaum pipe manufacture, whence France and England obtain their supplies. The substance is first soaked in tallow, then in wax, fashioned into the desired form, and finally polished with shave grass. The rage for this species of pipe has led to clever imitations, which the most practised connoisseur cannot detect till he has used the article for some time; the spurious material assuming a dry and calcined appearance, or cracking and splintering, while the genuine meerschaum becomes of a beautiful brown, and remains quite uninjured by fire.

Chalk.

Chalk, another well-known mineral, is a carbonate of lime of a white or whitish-gray colour, having a soft meagre feel and earthy fracture. It is the last or youngest of the secondary rocks, and constitutes an important geological feature of England—the chalk-hills which form the white cliffs of our southern shores having conferred the ancient name of *Albion* (*alba*, white) upon our island. Calcined like common lime, it is used for manure and cement, in polishing metals and glass, as a marking material, in painting and whitewashing, and in various other processes. For the last purpose it is purified by trituration and elutriation, and sold under the name of *whiting*, or *Spanish white*. The chalk-formation yields also the flint of commerce; but this more properly falls to be considered under the class *siliceous substances*. What are called *Drawing chalks* have no relation to this substance. *Red* chalk, for example, is a clay, coloured with peroxide of iron, found in several localities; and the *French* chalk used by artists is a soft magnesian mineral, allied to steatite. *Crayons* are usually made of fine pipe-clay coloured with metallic pigments.

Marl—Calc Sand.

Marl is one of the most recent calcareous deposits, being in many places still in the course of formation. Though essentially a mixture of carbonate of lime and clay, it occurs in various states of purity, from a marly clay, which will scarcely effervesce under acids, to shell-marl, containing from 80 to 90 per cent. of lime. *Marl-clay*, for instance, occurs as a whitish friable clay, with an admixture of lime, and sometimes also of magnesian earth; the term *clay-marl* is used when the calcareous matter prevails over the clay. *Shell-marl* is almost wholly composed of lime and fresh-water shells, with a trace of clay and other earthy matter, and where solidified by chemical aggregation, is known as *rock-marl*. Marl uniformly occurs in valleys formerly the sites of lakes, or in existing lakes, and seems to be partly derived from the waters of calcareous springs which enter such lakes, and partly from the shells and secretions of the fresh-water molluscs which inhabit them. It is dug from open excavations, and applied to certain soils as a manure, or as a top-dressing for pasture.

Calcareous sand, which consists almost entirely of comminuted shells, is another recent product occasionally employed as a fertiliser. It is found in layers in ancient or raised beaches, and in masses by the sea-shore, where, thrown up by the waves, it often consolidates into beds of considerable thickness. As an instance of its value, Sir H. de la Beche mentions that between five and six millions of cubic feet are annually conveyed from the Cornish coasts, to be spread over the land in the interior as a mineral manure. As shells consist almost wholly of carbonate of lime, with a little animal matter, it would be more advantageous in most cases to reduce them to quicklime, which must be much more energetic in its action as a fertiliser.

Gypsum—Alabaster.

Gypsum, also known as sulphate of lime and plaster of Paris, is found in England, and in many other countries. It occurs in various states of crystallisation and purity: thus the ordinary gypsum of commerce is soft, and imperfectly crystalline; *selenite* is a transparent, highly crystalline mass; *satin gypsum* is fibrous and crystalline; and *alabaster* is pure white, and translucent. Gypsum occurs both in old and new formations, but principally in the new red sandstone, and in the tertiary beds, or those above the chalk. It is mined in various localities in England, and extensively quarried at Montmartre near Paris, whence it has derived its ordinary name of plaster of Paris. Calcined, pulverised, and mixed with water, it is run into moulds, forming stucco images, mouldings, and ornamental fronts for buildings. It is also used for stereotype and pottery moulds, and for medals and casts of various kinds. Mingled with a certain per centage of quicklime, it makes an excellent mortar; its virtues as a fertiliser have been also greatly extolled.

Some of the English gypseous alabasters, such as those of Derbyshire and Staffordshire, stand the turning-lathe well, and are accordingly formed into jars, vases, and other mantel-piece ornaments. The finest specimens, however, are found near Volterra in Tuscany. These are of a pure white colour, and granular texture, and when cut and polished, outrival the finest Carrara marble, from which they are, however, readily distinguished by their softness and liability to tarnish. A large trade in alabaster work is carried on in Florence, Leghorn, and Milan, where the material is fashioned, partly by the chisel, and partly by the turning-lathe, into statues, vases, lamps, boxes, stands for time-pieces, and other ornamental objects. All sculptures of alabaster should invariably be kept under a glass-shade, as a few months' exposure destroys at once their purity of colour and marble translucency.

Coral.

Coral, or coral-stone, is another calcareous material of commerce, which deserves to be noticed. Being entirely the secretion of certain marine animalcules, it is pretty nearly a pure carbonate of lime, and occurs in the warmer latitudes of the Pacific in vast barriers and reefs, often from fifty to one hundred feet in thickness, and from a few miles to hundreds of leagues in linear extent. Selecting for their residence some submarine ledge of rock, the animalcules begin to ply their vocation, increase, and spread, ever adding to their calcareous secretions, which by and by come to the surface, when they stop and carry on their operations laterally—thus in time elaborating masses which may well compete with any of the ancient rock formations. [See Zoology]. There are numerous varieties of the coral animalcule, each variety forming a coral of different shape, but still of the same substance; and ultimately, when indurated by ages, of the same solid and rocky-like consistence. Coral-rock is occasionally employed in the settlements of the South Sea islands as a building stone, volcanic forces having thrown beds of it several hundred feet above the present sea-level.

The recent branching corals are solely in request for ornamental purposes—their value depending upon the size, solidity, and colour of the specimen. Black and red varieties are the most highly prized—portions of Sicilian coral having been known to bring as much as eight or ten guineas per ounce. The price, however, is extremely variable, other portions of the same mass selling for less than a shilling a pound. Regular coral fisheries are established in the Straits of Messina, on the shores of Majorca and Ivica, the coast of Provence, and in other parts of the Mediterranean. Abundant supplies are also obtained from the Red Sea, the Persian Gulf, the coast of Sumatra, &c. The mode of fishing coral, as practised in the Mediterranean, is extremely primitive, but curious:—Seven or eight men go in a boat commanded by the proprietor; the caster throws the net or dredge used to tear up the coral from the bottom of the sea, the rest of the hands work the boat and help to draw the net. This is composed of two beams of wood tied crosswise, with leads fastened to them to sink them: to these beams is fastened a quantity of hemp twisted loosely round, and intermingled with some loose netting. In this condition the machine is let down into the sea, and when the coral is pretty strongly entwined in the hemp and nets, they draw it up with a rope, which they unwind according to the depth, and which it sometimes requires half-a-dozen boats to draw. Coral is worked up like precious stones, and must be kept from the action of acids.

ARGILLACEOUS SUBSTANCES.

Under this section we include all those substances in which clay (*argilla*) is a prevailing ingredient—as the common clay of the brick and tile-maker, the prepared clay of the potter, fullers' earth, and the slate now so generally used for roofing. Argillaceous compounds occur in every formation, from the lowest slate, through the shales and fire-clays of the coal-measures, up to the plastic clays of the tertiary and superficial deposits. In the earlier formations they are compact, slaty, and somewhat crystalline; as we ascend, they become dull and merely laminated; while in the more recent deposits lamination disappears, and we are presented with mere tenacious masses, void of anything like structural arrangement. As discovered by Davy, *aluminium* is the metallic basis of pure clay or alumina (oxide of aluminium); but neither the metal nor its oxide is ever found in nature in a state of absolute purity. Sand, lime, magnesia, metallic oxides, and other ingredients, are less or more incorporated with all natural clays; and according to the characters so derived, do they acquire their peculiar values.

Clay.

The common superficial clay, which is so liberally spread over our island, must be familiar to every one. It is of various colours—yellow, red, or bluish; more or less mixed up with sand and fragments of rock; and when softened with water, becomes plastic and tenacious. It is this variety that is ordinarily used for the manufacture of bricks, roofing and drain-tiles, chimney-tops, water-tubes, and the coarser sorts of earthenware. For these purposes it is broken down, partly by exposure to the weather, and partly by the pug-mill, kneaded with water, and freed from the grosser impurities, after which it is beat up into the desired consistency, passed through moulds, dried so far in the atmosphere, and then burned in clamps or in kilns. For bricks, slabs, crucibles, &c. which have to resist the action of fire, some of the coal-measure clays are generally had recourse to; these, from their greater purity, and a certain per centage of silica, being susceptible of a more thorough burning. In this case the raw material requires to be mixed, but generally in connection with the working of coal or ironstone. In England, the Windsor, Stourbridge, and Welsh fire-clays are esteemed the best—the latter yielding those large square slabs employed in the construction of drying-kilns, brewers' coppers, sugar-boilers, furnaces, &c. In the preparation of fire-clays, greater labour and care are necessary—the crude material being generally ground under heavy stone or cast-iron wheels, and in most instances requiring artificial admixture.

Pipe-clay, potters'-clay, and porcelain-clay, are but technical names for pure varieties of well-prepared specimens of the same substance. We have seen that common brown ware can be made from ordinary clay; but when the finer varieties of white ware or china are attempted, not only finer clays must be sought, but even these must be mixed with a certain proportion of calcined flint or silex. One of the finest varieties of aluminous earth is the China-clay of Devon and Cornwall, or the *kaolin* of the Chinese. This is a decomposed felspar—one of the constituent minerals of granite—which has accumulated in vast quantities in certain localities, having been no doubt washed down by rains from the weathered and exposed surface of granitic rocks. At one time the use of this substance was unknown in England, but now about 38,000 tons, worth about £50,000, are annually exported from the south of England for the Staffordshire potteries, and for the manufacture of mosaic tesseræ, buttons, artificial gems, and the like. The best pipe-clay is obtained from Poole in Dorsetshire, and the isle of Purbeck; it is employed in the manufacture of tobacco-pipes and fine pottery, and also sometimes used for the fulling or scouring of woollens.

Fullers' Earth.

Fullers' earth is a soft, dull, unctuous kind of clay, usually of a greenish-brown colour. It is dug in various parts of England, particularly in Buckingham, Surrey, Hampshire, and Bedfordshire, the lighter-coloured beds being the most esteemed. It is used in the fulling of cloth, from its property—a property common to all soft aluminous minerals—of absorbing oil and grease. At one time it was deemed of so much importance to the national trade in woollen, that its exportation was prohibited; but now soap is chiefly used instead, and fullers' clay has fallen in importance. What the present consumption may be, it is impossible to say; but about forty years ago not less than 7000 tons were annually made use of. Although denominated a clay, it is essentially composed of siliceous earth, only about a fourth part being pure alumina; and if the proportion of clay were much greater, it would become too tenacious to be worked by the fuller. Every clay that is of an unctuous or saponaceous quality, will answer in some degree the purposes of fulling; but not so well as proper fullers' earth, which is distinguished from common clay by its falling to pieces in water with a slight crackling noise, instead of making a paste with it as clay does.

Ochre.

This is a painter's term for a native earthy mixture of alumina, silica, and oxide of iron. It is found of various hues, but chiefly of a yellow or reddish-brown, and is employed as an ingredient in painters' colours, and in the polishing of metal articles. It is obtained from various places, particularly from Shotover Hill, near Oxford; from the coal-measures of the east of Fife; and from Italy. The quantity raised in Britain is unknown, but about 5000 hundredweights are said to be annually imported. In general, ochre is obtained by a rude sort of mining; and requires to be prepared for use by trituration and elutriation.

Clay-Slate.

Clay-slate, of which roofing and writing-slate are the most familiar examples, is very extensively diffused, and as extensively made use of, in the British islands. It belongs to one of the lowest or oldest formations, is essentially composed of alumina and silex, has a peculiarly fissile structure, and is usually of a dark lustrous blue, bluish-green, or purplish colour. Like all mixed rocks, the chemical composition of clay-slate varies considerably. The following is given as the analysis of a common Scotch variety:—Silex, 50; alumina, 27; oxide and sulphate of iron, 11; potash, 4; magnesia, 1; carbon, a trace; and water, 7. The principal quarries are in Wales, where they give employment to nearly five thousand hands; in the north of England and west of Scotland; the most extensive being in Caernarthen near Bangor, in Borrowdale in Cumberland, and at Easdale and Ballachulish in Argyleshire. The beds of clay-slate are often of great thickness, but only certain portions are sufficiently compact to be of commercial importance. The chief consumer of this material is the slater, though considerable quantities are also used as pavement in cellars and warehouses, for shelves in dairies, for the construction of cisterns, and the like. The finer-grained varieties are polished for school-slates and slate-pencil; and those of attractive colours are now manufactured into flower-pots, vases, fancy-tables, and other ornamental objects.

Clay-slate is invariably quarried; and here it must be observed that the splitting of the rock does not take place in the direction of the bed, but at a considerable angle to the plane of stratification. This peculiar structure is known as *cleavage* (see GEOLOGY), and seems to have been superinduced long after the deposition of the strata. It is totally different from *lamination*, which allows certain sandstones and shales to be split into thin slaty bands, and which is a natural structure of deposition, always parallel to the plane of stratification. A piece of slate being split to the desired thickness, it is next squared by a knife or cutting edge of steel, the slate being held over a similar cutting edge or anvil. Polishing is performed by sand, emery-powder, and water; and some varieties of slate stand to be sawn, planed, and turned by tools differing little from those of the joiner. The following is generally given as a test of the fitness of slates for roofing and other external purposes:—Lay one in an oven till perfectly dry; weigh it, and then immerse it in water for some time. When taken out, wipe it carefully with a dry cloth, and weigh it again. Those slates which have acquired the least additional weight, and consequently have absorbed least water from being the least porous, are the fittest for roofing. Good slates should be thin, dense, and of a smooth surface. Balance one on the finger, and strike it with a hammer; if the sound is clear, the slate may be considered as firm; if dull, the slate is less dense, and should be rejected. *Whet, polishing*, and other varieties of slate, are treated under the following section.

SILICEOUS SUBSTANCES.

Silex or silica is one of the most important and most generally diffused of the mineral ingredients that enter into the composition of the rocky crust of the globe. Rock-crystal, quartz, chalcedony, and flint, may be regarded as nearly pure silica; and all the varieties of sandstone, quartz-rock, and granite, are in a great measure composed of it—many sandstones, for example, being pure granular quartz or silica, with a slight argillaceous cement. As in the case of the alkaline earths, it has been shown that silica is an oxide, the basis of which is *silicium* or *silicon*—a substance more closely allied to boron than any other substance, but probably not metallic.

Quartz—Rock-Crystal.

Quartz and quartz-rock, though of importance as forming the bases of other rocks, are of themselves of no great commercial value. Pounded quartz, as stated under 'Fictile Manufactures,' enters largely into the composition of Chinese porcelain, performing the same part as calcined flint in the wares of England. The purer varieties of rock-crystal are occasionally cut as ornamental stones; and of late the transparent and colourless varieties have been pretty generally adopted by opticians as spectacle lenses. Their extreme hardness renders them more durable than glass, and less liable to be scratched, while they are altogether cooler and more agreeable. The so-called Brazilian pebble, used for this purpose, is of pure silica, and is sometimes found in crystals as large as a cocoa-nut. Quartz, in its distinctly crystalline forms, constitutes several of the 'Precious Stones,' or gems, and will be further treated under that head.

Flint.

The common nodular flints found in the chalk-formation are nearly pure silica, exhibiting but a trace of alumina, oxide of iron, and lime. The formation of flint within a mass so different in composition as chalk, is still, in some respects, an unsolved problem in geology. It occurs in nodular masses of very irregular forms and of variable magnitude, some of these not exceeding an inch, others more than a yard in circumference. Although thickly distributed in horizontal layers, they are never in contact with each other, each nodule being completely enveloped by the chalk. Externally, they are composed of a white cherty crust; internally, they are of gray or black silex, and often contain cavities lined with chalcedony and crystallised quartz. When taken from the quarry, they are brittle, and full of moisture, but soon dry, and assume their well-known hard and refractory qualities. Flints, almost without exception, enclose remains of sponges, alcyonia, echinida, and other marine organisms, the structures of which are often preserved in the most delicate and beautiful manner. From these facts, it would seem that flints are simply aggregations of silex around some organic nucleus, the same as iron-stone nodules or *septaria* are aggregations of clay and carbonate of iron.

The uses of flint are various: calcined and ground to a powder, it is used in the manufacture of the finer sorts of pottery and porcelain; it also enters into the composition of flint-glass; is employed in the preparation of certain kinds of soap; and before the invention of the percussion-cap, gun-flints were in universal use. Flints also form excellent building materials, because they give a firm hold to the mortar by their irregularly rough surfaces, and resist, by their hardness, every vicissitude of weather. The counties of Kent, Essex, Suffolk, and Norfolk, according to Dr Ure, contain many substantial specimens of this sort of masonry. The reduction of flint to economical uses is extremely simple. We have stated how it is prepared for the potter and glass-blower (p. 321); the formation of gun-flints is a process strictly mechanical, and depends wholly on dexterous manipulation. Having made choice of a good nodule, weighing from 2 lbs. to 20 lbs.—that is, one of a fine uniform grain, compact, and possessed of a certain translucency—the workman, furnished with an assortment of iron mallets, proceeds, first, to break the block in moderate-sized fragments; secondly, to cleave these fragments into chips, which scale off with a conchoidal fracture; thirdly, to fashion them into gun-flints; and lastly, to trim the edge which is intended to strike against the lock. A clever workman will cleave and fashion about 2000 gun-flints a-week without any assistance, if the balls be of good quality.

Sandstones.

Sandstone, or freestone, as it is sometimes called, occurs in innumerable varieties, differing in colour, in composition, fineness of grain, and compactness. Thus we have some red, from the presence of iron oxide; some silvery and glistening, from the presence of minute scales of mica; others white, yellow, and mottled; and some almost jet-black, from the presence of bituminous or carbonaceous matter. As to mineral composition, there is no other class of rocks so varied; for though quartz grains give to them their family character, clay, lime, mica, carbon, iron, and the like, mingle with them so capriciously, that it is impossible to find any two strata of sandstone exactly of the same composition. Again, their texture is equally if not still more varied; in some the grains being as large as peas, in others quite impalpable; some being so soft and friable as to be rubbed down by the hand, and others so hard and compact that nothing but the chisel of the stone-cutter can touch them. The principal use of sandstone is in building, and for this purpose good durable strata are found in almost every formation, from the greywacke up to the recent tertiaries.

In England, where bricks form the more available material for the construction of houses, there are comparatively few freestone quarries of much importance. Those of Portland Isle, which have furnished the stone for St Paul's and other public buildings in London, those of Bath, and of Gateshead Fell, near Newcastle, are the most extensive and valuable. In Scotland, freestone of excellent quality is to be found in most localities, and consequently it is the prevailing architectural material. The best strata are those underlying the coal-formation—such as are quarried in the neighbourhood of Glasgow, near Linlithgow, in the neighbourhood of Edinburgh, and in several parts of Fifeshire. The blocks from the quarries of Craigleith, Granton, Cullelo, &c. which all belong to the same suite of strata, almost rival marble in their whiteness, compactness, and durability, and even surpass it in fitness for certain kinds of architectural sculpture. The principal buildings of the New Town of Edinburgh are constructed of this material, and certainly no city in the world can boast of similar erections. Good building sandstone is also obtained from the old red formation, such as is quarried at Kingoodie, and other places near Dundee, the rock being at once exceedingly durable, and producing blocks of any dimensions.

Many sandstones are likewise used as pavement, those being sought for that purpose which are at once compact and thin—bedded or schistose. By far the most valuable of this kind are the Forfarshire gray micaceous flagstones, now so generally employed as foot-pavement in all our large towns. A very extensive trade in these is carried on at Arbroath and Montrose, the flagstones being now dressed and hewn by machinery at the quarries. Another excellent material, still more durable, but exceedingly hard and refractory, is also obtained from Caithness, which, when well laid down, appears to the unpractised eye more like plates of cast-iron than slabs of stone. Pavement of average quality is likewise obtained from the coal-measures; but being of a softer and more absorbent texture, is not so well adapted for out-door purposes. All these beds are highly fissile or schistose, occurring in laminæ or layers of from one to fourteen inches in thickness; and thus accounts for the fact, that at one time the thinner sorts were used for roofing, under the name of *tile-stones* or gray-slate.

Besides building and paving, several sorts of sandstone are employed for grindstones, millstones, whetstones, and the like. Thus the quarries of Gateshead Fell, situated on the *millstone grit*, or quartzose sandstones of the lower coal-measures, furnish the grindstones known in all parts of the world as 'Newcastle grindstones.' Good millstone and whetstone beds are found in various other places, as are also varieties fit for the wheels of glass-cutters and cutlers. The stones chiefly used in Sheffield are procured at Wickersley in Yorkshire. The celebrated *burr* millstones of France are obtained from the upper fresh-water siliceous limestones of the Paris basin, and are not strictly sandstones, in the usual acceptation of that term. A close grit, containing a certain amount of talc, is quarried at Coxgreen, in the neighbourhood of Newcastle, and highly prized as a firestone in the erection of glass-furnaces.

Sand.

On narrowly inspecting the immense masses of sand borne down by our rivers, piled up along our shores, or scattered in dunes and strata over the surface of the country, it will be found that the great bulk of it is composed of siliceous particles, evidently derived from decomposed quartz-rock, granite, sandstone, and the like. As might be expected, most sands are mingled with clay, lime, and other earthy impurities; and it is according to their siliceous character, and degree of purity from earthy ingredients, that they become of value in the arts. Thus sharp, well-sifted sand is an indispensable ingredient in well-prepared mortar, without which the builder, the plasterer, and fresco-painter could not proceed a single step: the commoner sorts are widely used in paving, in the construction of ovens, kilns, annealing furnaces, and the like, where heat is wished to be retained; and some peculiar varieties are much used in the preparation of moulds for the casting of iron, brass, and other metals. Good siliceous sand is an indispensable ingredient in all sorts of glass, now one of the most important manufactures in the civilised world. The most valuable sands for this purpose are those of Aumont, near Senlis, in France, and those of the Isle of Wight, and of Lynn in Norfolk, in England; though of course each glassmaking country possesses sands more or less fitted for the same uses, if properly washed and sifted.

Granitic Rocks.

This term may be considered as embracing not only the true igneous granite, but the gneissose and mica-slate rocks, which, though stratified, partake of the same mineral character, and are usually associated with it. In all of them, silica is a predominant ingredient, imparting those hard and durable qualities which render them of economical importance. Ordinary granite is a crystalline compound of quartz, felspar, and mica; but other minerals, such as hornblende, hyperstheme, &c. occasionally mingle with it, thus producing a number of varieties. The small-grained grayish granite of Aberdeen is essentially a compound of quartz, felspar, and mica; that of Peterhead is the same compound, rendered red by the oxide of iron contained in the felspar crystals. Granitic compounds are very widely distributed, forming the fundamental rock of our principal mountain chains. The Grampians in Scotland, the Cumberland and Cornish hills in England, the Wicklow mountains in Ireland, the Pyrenees in Spain, the Dovrefelds in Norway, the Ural in Russia, the Abyssinian and other African ranges, and the Andes in South America, are all less or more composed of rocks partaking of a granitic character.

The economical uses to which granitic rocks are applied are by no means unimportant. Compact granite, from its extreme hardness, is largely employed in the construction of docks, piers, lighthouse foundations, bridges, and other structures where durability is the main object in view. Waterloo Bridge in London, the Liverpool and other English docks, are built of granite. It is the ordinary building stone in Aberdeen, and is largely used in the metropolis for paving. The Pyramids, though internally constructed of limestone, are externally coated with granite. Pompey's Pillar, and other ancient Egyptian structures, are composed of it; the column of Alexander, and the pedestal of the colossal statue of Peter the Great, in the Russian capital, as well as several monumental monoliths in other countries, are also of granite. Within these few years, the granite of Aberdeenshire has been brought into use as an ornamental stone; and machinery has been erected, we believe, both at Aberdeen and Peterhead for the purpose of polishing it like marble, to which many prefer it, for chimney slabs, vases, pedestals, pillars, &c. When uniform and compact in grain, it is susceptible of a very high polish; and has this advantage over marble, that it is not easily stained or scratched, nor at all acted upon by acids.

Serpentine, or the magnesian rock generally so called, is one of very varied composition and quality. The noble serpentine of the mineralogist is a green translucent rock, rather soft, but susceptible of a good polish; and if found in sufficiently large blocks, would make not a bad substitute for marble. We have before us a specimen of a beautiful leek-green variety from New Zealand, where it is said to occur eight or ten feet thick, and capable of being raised in blocks of any size. Should this be the case, the houses of our brethren who have made these islands their adopted home, need be in no lack of interior decorations. Potstone, the *lapis ollaris* of the ancients, is another granitic product, easily worked into form, and formerly used for culinary vessels; whence its common designation. *Jade*, sometimes called *nephrite*, from its supposed medicinal virtues, is another dark leek-green mineral of the same family. It contains a larger amount of silica than the true serpentine, which it greatly resembles. In New Zealand and the Indian Archipelago, it is fashioned into hatchets, edge-tools, and other implements.

Mica—Talc—Asbestos.

Mica, talc, asbestos, and other kindred minerals which are the products of the granitic and primary rocks, may be appropriately considered in this place. The silvery-looking, scaly substance which occurs in ordinary granite is mica, so called from its glistening aspect. It is sometimes found in crystals more than a foot square; and when of this size, is split into thin plates, and from its transparency, used in certain cases as a substitute for glass. It stands a higher degree of heat, without splintering, than glass, and is well adapted for ship-lights, not being liable to fracture during the firing of cannon. The large sheets exposed for sale by the mineral dealers are generally brought from Siberia; hence the term, *Siberian glass*.

Talc, when crystallised, has much the same appearance, but on trial, will be found to be less transparent, softer, and non-elastic. The larger crystals are sometimes applied to the same purposes as mica, but the principal use of the mineral is in porcelain paste, and in polishing alabaster figures. It is also said to be an ingredient in rouge for the toilet, having the property of communicating softness to the skin. Talc-slate, the other form in which this mineral occurs, is a massive mineral, breaking up in tabular fragments; it has a white streak, and greasy or soapy feel. It is employed in the porcelain and crayon manufactures, and is used as a marking material by carpenters, tailors, and others. Talc occurs in the primary and transition districts of Scotland, in various parts of the continent, and largely in India and Ceylon.

Asbestos, or amianthus, is a soft mineral, occurring in separate filaments of a silky lustre, and consisting essentially of silica, magnesia, and lime. When steeped in oil, it may be woven into cloth, which is incombustible, and may therefore be purified by fire; hence the terms amianthus (*amianthus*, undefiled) and asbestos (*asbestos*, unconsumable). Cloth of this kind was used by the ancients to wrap the bodies of the dead about to be burned, to prevent their ashes being mixed with those of the funeral pile. In the United States of America, asbestos is sometimes used as a lamp-wick.

Whetslate, or whetstone, also with some degree of scientific pedantry termed novaculite, from *novacula*, a razor, is an allied substance, essentially composed of silica in impalpable grains, with a small per centage of magnesian earth. Very fine varieties are brought from Turkey, under the name of *hones*, and largely used for sharpening steel instruments.

Basaltic Rock.

Under this head we include all the basalts, greenstones, whinstones, and traps, which make up the sum of the igneous rocks of the secondary formations. They are essentially siliceous—quartz, hornblende, hypersthene, augite, and so forth, entering largely into their composition. Some of the basalts and greenstones dress well under the hammer, and though of a dingy colour, make an excellent building stone, their durability being equal to that of granite itself. Ordinary greenstone, or whinstone, is a very valuable rock in many districts of Scotland, where it furnishes material at once for houses, fences, drains, and roads. Indeed no rock is better adapted, or more extensively used, for causewaying, and for macadamised roads it is unrivalled. Large quantities are, or at least used to be, shipped from the Firth of Forth for the kerbstones and causeways of the streets of London. We have seen some ornamental pedestals in basalt which took on a pretty fair polish; and an elaborately-carved Bhuddist idol, of considerable size, now in the museum at St Andrews, is of the same material. Some of the trap-rocks stand fire to perfection, and this has suggested their use as oven-soles, where such varieties can be procured. An attempt has also been made to employ certain varieties of trap in the manufacture of a coarse bottle-glass.

Volcanic Products.

The mineral products ejected from volcanoes are chiefly lava, obsidian, pumice, scoriæ, and a light impalpable dust, in all of which silica and alumina are the main ingredients. Some of the compacter sorts of *lava* are hardly to be distinguished from the trap-rocks of the secondary formations, and may consequently be employed for the same economical purposes. *Obsidian*—so named, according to Pliny, from one Obsidius, who first brought it from Ethiopia—is a true volcanic glass, of various colours, but usually black, and nearly opaque. In Mexico and Peru, it is occasionally fashioned into adzes, hatchets, and other cutting instruments, or into ring-stones. So closely does it resemble the slag of our glass furnaces, that in hand specimens it is almost impossible to distinguish the natural from the artificial product. It consists chemically of silica and alumina, with a little potash and oxide of iron. *Pumice*, a well-known volcanic product, is extremely light and porous, and of a fibrous texture; it is harsh to the touch, is usually of a grayish colour, and has a shining pearly lustre. Like obsidian, it is principally composed of silica and alumina, with traces of potash, soda, and oxide of iron. Pumice is quarried and exported in large quantities from the Lipari and Ponza islands, off the coast of Sicily. It is used for polishing metals, glass, marble, wood, ivory, and also in the smoothing of parchment and vellum. *Pozzolana*, already described under 'Fictile Manufactures,' is another volcanic product, which has been long and largely used in the preparation of hydraulic cements.

Tripoli, &c.

We include under this head several siliceous earths and slates extensively employed in the polishing of metallic surfaces. The most familiar of these are tripoli (so called from Tripoli in Barbary, where it was originally procured), polishing-slate, semi-opal, and some of the porcelain earths. The uses of these substances are well known: it is their peculiar origin that confers on them an especial scientific value and interest. It has been established by Ehrenberg that these and several other rocky masses are not the results of ordinary deposition, but an aggregation of the siliceous shells of the minutest animalcules. This is a curious fact: the remains of creatures individually invisible to the naked eye, forming rocks which, in the course of time, were to figure in the economical applications of the human race!

On analysis, a hundred parts of tripoli are found to contain upwards of eighty of silica, the remainder consisting of alumina, oxide of iron, and water. The *polirschiefer*, or polishing-slate of the Germans, found at Billin in Bohemia; and the *berg-mehl*, or mountain-meal of the Swedes, said to be mixed with bread in times of scarcity, are substances of similar origin and use. Another species of infusorial earth is said to be occasionally eaten by the North American Indians; it is probably the same as the European mountain-meal. The well-known *rotten-stone* of Derbyshire and other localities is more argillaceous than siliceous; it is largely used for giving the final polish to metals, glass, marble, and precious stones.

SALINE SUBSTANCES.

Under this section we comprehend such products as rock-salt, alum, saltpetre, borax, and the like, which are found either as native salts, or are procured by artificial processes from certain mineral substances with which they are combined in nature. Some of these salts are of vast economical importance, and appear to be as indispensable to the progress of civilised life as either coal or iron.

Rock-Salt.

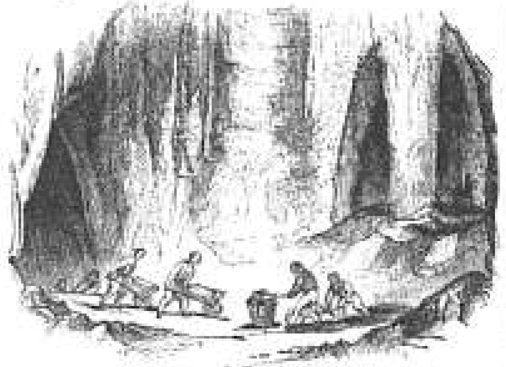
The common culinary salt of every-day use is chemically a muriate of soda, or, more strictly, a chloride of sodium, every hundred parts of which are composed of sixty chlorine and forty soda. It exists abundantly in sea-water, constituting more than a thirtieth part of its weight; it is discharged by salt or brine-springs—which arise from different geological formations, and are situated in different countries—to the extent of from 20 to 30 per cent.; and it is found in various degrees of purity in beds and irregular masses, from 20 or 30 to more than 120 feet in thickness. Native chloride of sodium is never found in a state of absolute purity, but is always less or more combined with certain salts of lime, magnesia, soda, iron, and alumina; to free it from these impurities, and render it fit for culinary purposes, is the duty of the salt-boiler and refiner.

At one time salt was largely, and is still to some extent, derived by evaporation from sea-water, by the following simple process:—A reservoir is erected near the sea, into which, at high water, supplies are taken by means of a pipe extending a good way down the beach. The pipe is generally placed near the low-water mark, in order to get the water from a point as far from the surface as possible, so that it may be the more impregnated with salt, and require less boiling. The pans are built on a range on both sides of the reservoir, from which the water is pumped into them after the impurities have settled. The pans are shallow vessels, made of sheet iron, about twenty feet long, and twelve broad, with a furnace below. These are contained in a small low-roofed house, the covering of which is of deals, with an opening at the meeting of the roof and the wall, to allow the vapour to escape. When the water is boiling, a little bullock's blood is put into the pan, which brings the impurities to the surface, and allows of their being skimmed off. As the water boils down, more is pumped in; and this process is repeated before the salt is finally drawn. From a pan of 1300 gallons, fifteen or twenty bushels, of fifty-six pounds each, are obtained in this manner, the process requiring about twenty-four hours. The salt is at first very light and floury in proportion to its bulk, and in this state is most appreciated. A still finer article resolving into large crystals—bay-salt—is made with a low fire, and when a longer time is allowed in the evaporation. For use at table, the salt is refined, and usually run into large lumps.

The water which remains after the salt is crystallised, called the *mother-water*, contains a considerable quantity of the chloride of magnesium or bitterns, chloride of sodium, and sulphate of magnesia. If the mother-water is exposed in tanks during winter, it will afford three successive crystalline deposits, the last of which is sulphate of soda nearly in a pure state. The chloride of magnesium deteriorates the salt very much, but may be removed by the following simple expedient, mentioned by Dr Ure:—'Let quicklime be introduced in equivalent quantity to the magnesia present, and it will precipitate this earth, and form chloride of calcium, which will immediately react upon the sulphate of soda in the mother-water, producing sulphate of lime and chloride of sodium. The former being nearly insoluble, is easily separated. Lime, moreover, decomposes directly the chloride of magnesium, but with the effect of merely substituting chloride of calcium in its stead. But in general there is abundance of sulphate of soda in brine-springs to decompose the chloride of calcium. A still better mode of proceeding with sea-water would be to add to it in the settling tank the quantity of lime equivalent to the magnesia, whereby an available deposit of this earth would be obtained. Brine thus purified may at once be safely crystallised by rapid evaporation.'

The process of procuring salt from sea-water is now all but abandoned in Britain, and is only had recourse to in some southern and tropical countries, where the arts of life are still in a rude and primitive condition. The supply is mainly obtained from brine-springs, such as those of Droitwich in Worcestershire; and from the mineral rock-salt, which abounds in the new red sandstone and upper secondary formations. This important mineral product occurs in Cheshire and Worcester in England, at Altemonte in Calabria, Halle in the Tyrol, Cardona in the Pyrenees, Wieliczka in Poland, and in several districts of North America. As brine-springs always issue from saliferous deposits, and are doubtlessly derived from the solution of the solid masses by subterranean waters, we shall restrict our description to the solid rock-salt, taking the mines of Cheshire as a sufficiently illustrative example. These mines, together with the brine-pits of Worcester, not only supply sufficient salt for the consumption of almost the whole of Britain, but furnish an article of export to the extent perhaps of half a million tons annually.

It has been stated that the chief deposits of English rock-salt are confined to the new red sandstone formation, where it alternates with its argillaceous and gypseous marls. 'In Cheshire,' says Professor Ansted, 'the rock occurs in large quantities in the condition of an impure muriate of soda, and associated with a peculiar marl; it is sometimes massive, and sometimes existing in large cubical crystals; and the beds containing it usually alternate with considerable quantities of gypsum, although this latter mineral is not worked to profit. The appearance of the rock-salt is by no means of that brilliant character, nor has it the delicate transparency and bright reflecting surface which the reader may perhaps suppose characteristic of it. It is usually of a dull red tint, and associated with red and palish-green marl; but it is still not without many features of great interest; and when lighted up with numerous candles, the vast subterranean halls that have been excavated present an appearance richly repaying any trouble that may have been incurred in visiting them. At Nantwich, and the other places in Cheshire where the salt is worked, the beds containing it are reached at a depth of from fifty to a hundred and fifty yards below the surface. The number of saliferous beds in the district is five; the thinnest of them being only six inches, but the thickest nearly forty feet; and a considerable quantity of salt is also mixed with the marls associated with the purer beds. The method of working the thick beds is not much unlike that of mining the thicker seams of coal. The roof, however, being more tough, and not so liable to fall, and the noxious gases—with the exception of carbonic acid gas—totally absent, the works are more simple, and are far more pleasant to visit. Large pillars of various dimensions are left to support the roof at irregular intervals, but these bear only a small ratio to the portion of the bed excavated, and rather add to the picturesque effect in relieving the deep shadows, and giving the eye an object on which to rest. The intervening portions are loosened from the rock by blasting; and it may be readily understood that the effect of the explosions heard from time to time, and re-echoing through the wide spaces, and from the distant walls of rock, give a grandeur and impressiveness to the scene not often surpassed. The great charm, indeed, on the occasion of a visit to these mines, even when they are illuminated by thousands of lights, is chiefly owing to the gloomy and cavernous appearance, the dim endless perspective, broken by the numerous pillars, and the lights, half-disclosing and half-concealing the deep recesses which are formed and terminated by these monstrous and solid projections.



The descent to the mines is by a shaft, used for the general purposes of drainage, ventilation, and lifting the miners and produce of the mine. The shafts are of large size in the more important works, and the excavations very considerable, the part of the bed excavated being in some cases as much as several acres. Over this great space, the roof, which is twenty feet above the floor, is supported by pillars, which are not less than fifteen feet thick. The Wilton mine, one of the largest of them, is worked 330 feet below the surface; and from it, and one or two of the adjacent mines, upwards of 60,000 tons of rock-salt are annually obtained, two-thirds of which are immediately exported, and the rest is dissolved in water, and afterwards reduced to a crystalline state by evaporating the solution.' The modes of working rock-salt are much the same in all countries; while the fineness and purity of the manufactured material depend upon the rapidity with which the brine is evaporated, and the nature of the clarifying agents employed. The uses of salt, whether obtained from sea-water or from mineral products, are so numerous and so well known, that it would be almost superfluous to attempt their enumeration. From its use as a simple condiment, through all its applications in the arts, up to the manufacture of soda from its substance, salt is one of the most important of natural products.

The formation of rock-salt is a subject which has much engaged the attention of speculative geologists. The sandstones and marls with which it is associated are evidently derived from deposition in water; but the irregularity of the salt beds, the fact of their occurring in masses of vast thickness, and the soluble nature of the compound, all point to a somewhat different origin. At present, salt lakes and superficial accumulations of salt occur in various parts of the world, and these have furnished data for reasoning as to the saliferous deposits of earlier eras. Salt lakes are chiefly derived from salt springs; and being subjected to the vapourising influence of the sun, which carries off only fresh vapour, their waters become in time saturated with saline matter. But water can hold only a fixed amount of salt in solution; and so soon as this amount is attained, the salt begins to fall to the bottom by its own gravity. In the course of ages these layers will form a thick bed, interstratified, it may be, with mud, or other earthy sediment; and should the lake be ultimately dried up, the salt will constitute a deposit something analogous to the rock-salt of the new red sandstone. Such is the process which some geologists have advanced to account for the formation of rock-salt—supposing that portions of the seas of deposit were occasionally cut off by igneous disturbances from connection with the main ocean, and subjected to a rapid evaporating power, without receiving fresh accessions of water.

Alum.

This is a well-known earthy salt, found native only in small quantities, but very largely manufactured from certain argillaceous strata, generally distinguished as alum-clays and shales. It is composed of alumina, sulphuric acid, potash, and has a sweet and astringent taste, and is a powerful styptic. It is much used in dyeing and in calico-printing, in consequence of the attraction its base has for colouring matter; it is also used in lake colours, in leather-dressing, in the preparation of paper pastes, in clarifying liquors, and by candlemakers to harden and whiten the tallow.

Native alum being too scanty a product to be used for any of these purposes, it has become the duty of the chemist to prepare it artificially—either from mineral substances which contain the elements of alum, or by mixing these elements together, so as to lead to their chemical combination. Thus at Hurlett and Campsie, near Glasgow, it is manufactured from certain of the coal shales, and at Whitby in Yorkshire from strata of alum-slate belonging to the lias formation; while at Newcastle and in France it is artificially prepared by mixing clay, sulphuric acid, and potash—soda or ammonia being sometimes substituted for potash. In the former case, if the crude ore is hard and slaty, it requires to be calcined, and exposed to the air, in order to facilitate its solution in water; if soft, crumbling, and efflorescent, calcination is dispensed with. This being effected, it is next steeped till the ore is spent; the liquid is then pumped off, boiled, and ultimately crystallised by adding the potash, without which, or some other alkali, sulphate of alumina does not crystallise. When alum-shale contains sulphate of iron (copperas or green vitriol), which is the case at Campsie, this salt is removed from the concentrated solution before adding the potash to obtain the alum. In the second or chemical mode of manufacture, calcined Cornish clay and sulphuric acid are combined to form the sulphate of alumina, to a solution of which the sulphate of potash is added to induce crystallisation. These different ingredients are allowed to remain at rest in circular vessels, where the alum gradually crystallises round the sides, shooting forth large crystals towards the centre, where the mother-liquor (or uncrystallisable portion) remains. The alum thus produced requires to be further fined or *roched*; that is, dissolved by the action of steam, and again crystallised for the market.

In both of the methods above described, an alkali is used to induce crystallisation; but as the sulphate of alumina is the sole efficient agent in the arts, a process has been invented to produce a 'patent alum' having all the properties of common alum, but without containing potash. 'In making this alum,' says Mr Dodd, 'sulphuric acid and Cornish clay are used as in the other case; but the clay is used in greater proportion, so as to form a thick paste. This paste is placed in a heated trough, where the moisture is so far evaporated as to convert the mass to the form of a dry earth. From the trough it is removed to tanks, where water is employed to dissolve it; and while in the liquid state, the composition is acted upon by an agent intended to remove any iron that may be in the clay—this being the only contained ingredient which is injurious to the alum. The agent employed combines with the iron existing in the clay, and forms with it Prussian blue. This pigment is allowed to subside, and the remaining liquor, being a solution of sulphate of alumina, is boiled till all the water is driven off. The solid residue is formed into cakes an inch or two in thickness, and in this form it comes into the market. Instead of being a crystal, it is an opaque earthy solid, differing from common alum in containing no potash, but possessing in common with it the properties which render it valuable in the arts. As the Prussian blue is procured in far too large a quantity to be allowed to remain in that state, it is restored again, by chemical means, to the form which it before presented, ready to be again used in making more alum.

Of the alums manufactured in other countries, the *roch* (so called from Roccha in Syria) is imported from Smyrna, and the *Rowan* prepared at La Tolfa, near Rome—either of which brings fully double the price of the British manufacture, the annual value of which is estimated at £22,000. Alum is also largely prepared in China, whence India obtains her main supply.

Nitrate of Potash.

This is the *saltpetre* of ordinary language—a salt composed of nitric acid and potash. It is of very varied utility, being used in the manufacture of gunpowder, signal-lights, nitric and sulphuric acids, and in dyeing, metallurgy, curing of meat, and in medicine. The sal-prunella of the shops is the ordinary saltpetre purified and moulded into cakes and little balls. Our main supply of saltpetre is derived from Bengal, where it exists in the soil, and from which the rough nitre or crude saltpetre of commerce is obtained by washing, evaporation, and crystallisation. From 10,000 to 15,000 tons of this salt are annually imported into Britain. In France, Germany, and other continental countries, the salt is produced artificially on what are called *nitriaries*, or nitre-beds.

Nitrate of Soda.

This salt, sometimes known by the name of cubic nitre, possesses properties similar to those of saltpetre, differing chiefly in being more pungent in taste, more soluble in cold water, and more inclined to attract moisture from the atmosphere. It differs also in the form of its crystals—these being of a rhomboid form, while those of saltpetre are six-sided prisms. It is obtained almost wholly from South America, where it occurs in immense deposits in the high districts of Atacama and Tarapaca in Peru. Indeed, according to Darwin, a great proportion of the surface of the southern regions of South America consists of *salinas*, or salt plains, from which common salt, and the sulphates and nitrates of soda, might be procured in any quantities—these occurring sometimes as an efflorescence, sometimes in crystallised strata, but oftener mingled with clay, sand, and other earthy impurities. One deposit which he visited in 1835, was full 3300 feet above the Pacific, and consisted of a hard stratum, between two and three feet thick, of the nitrate mingled with the sulphate of soda, and a good deal of common salt. It lay close beneath the surface, and followed, for a length of 150 miles, the margin of a grand basin or plain, which, from its outline, must once have been a lake, or more probably an inland arm of the sea, as iodic salts were abundant in the stratum. This salt was first imported from Iquique in 1830, and so rapidly has its commercial value increased, that, ten years after, about 150,000 hundredweights were shipped for Great Britain alone. In 1835, Mr Darwin found the selling price at Iquique 14s. per 100 pounds—the main part of the expense being its transport from the mountains on mules and asses. It is principally used as a manure, and as a top-dressing for pasture, its advantages being very perceptible on all but wet plashy soils; it is also used in the preparation of nitric acid, and for many of the purposes to which saltpetre is applied; but, owing to its deliquescent properties, it is not adapted for the manufacture of gunpowder.

Natron.

Natron is a native sesquicarbonate of soda, found as an efflorescence or as deposit in sandy soils in Egypt, Mexico, Hungary, and other countries; hence sometimes called *mineral soda*. At the lakes of Sukena in Africa, this salt is said to form a striated crystalline stratum just below the surface. From these lakes several hundred tons are collected annually in the dry season, chiefly for consumption in Africa, but sometimes exported to Europe under the name of *trona*. Natron has many of the properties of the two preceding salts, and according to Herodotus, was employed by the Egyptians in the process of embalming.

Borax.

This compound salt is found native as an efflorescence on the soil, or dissolved in the waters of certain lakes, in Persia and Thibet, in China, Ceylon, and South America. It occurs also in combination with several minerals, and, as might be expected, is given off in solution by hot and thermal springs. It is a compound of soda with a peculiar acid, first isolated by Homberg about the beginning of last century. The acid is now known to be an oxide of an elementary substance, to which the name of *boron* is given (see CHEMISTRY); the acid itself is known by the term *boracic acid*. 'Until the recent discovery of a more advantageous mode of obtaining borax, it was brought to Europe,' says Parnell, 'in considerable quantities from the East Indies. It was imported in small dirty crystalline masses called *tincal*, which contain scarcely more than half their weight of pure borax—the remainder consisting chiefly of a peculiar saponaceous combination of soda with a fatty acid. The salt was never termed borax till purified by some such process as the following:—The crude salt, being placed in proper pans, is covered with cold water to a height of two or three inches above its surface, and allowed to stand for some hours. Recently-slaked lime is then added to the amount of one part to four hundred parts of tincal; the mixture is thoroughly stirred, allowed to stand for twelve hours, again strongly agitated, and the troubled supernatant liquid decanted. The liquor is not thrown away, but preserved to wash the impure borax; the solid matters held in suspension being first separated by subsidence and decantation. The washing is continued with the same liquid, clarified by subsidence as often as applied, until it is no longer rendered turbid. In this way a great portion of the fatty matter may be washed away as an insoluble soap of lime. The salt thus purified is dissolved in two and a half parts of boiling water, and mixed with a solution of chloride of calcium, containing two parts of that salt to one hundred parts of tincal. A precipitate is thereby produced, consisting chiefly of the insoluble soap of lime; the liquor is separated from the precipitate by filtration, and evaporated down to a density of 1·14 or 1·16. It is then run off into crystallising vessels, and cooled very gradually to obtain large crystals.' Such, with some slight variations, was the mode of preparing borax from tincal.

Tincal, however, is now no longer the European source of the salt, which is largely and economically obtained from the boracic lagoons of Tuscany. These lagoons may be ranked among the wonders of the age, and are unique in Europe, if not in the world. They are situated on the sides of hills, and are supplied with water by the condensation in them of volcanic vapours or soffioni, highly charged with free boracic acid, together with borate and sulphate of ammonia, and other saline substances. The soil surrounding these beds of hot water is covered with a saline efflorescence, consisting chiefly of boracic acid, but likewise containing in smaller proportion salts of ammonia, borate, and sulphate of alumina, and persulphate of iron. The presence of free boracic acid in these and other volcanic vapours was ascertained towards the end of last century; but it was not till 1816 that an effectual mode of procuring the crystallised product was discovered. The lagoons are now artificially constructed over the soffioni, the continuous discharge from which more largely impregnates the water with boracic acid, and this solution is still further concentrated by ingeniously applying the superabundant heat of the soffioni to evaporate the water. Passing in this manner from reservoir to reservoir, and from evaporating pan to pan, the solution is ultimately allowed to crystallise; and the acid so obtained packed in barrels for exportation. For the conversion of this crude acid into borax there are several processes in use, the chief objects of which are to get rid of the ammonia and other natural impurities, and ultimately to obtain the pure salt in large and hard crystals.

The applications of borax in the industrial arts are already numerous, and constantly on the increase: about 800 tons boracic acid, at an average of £45 per ton, being annually imported into Britain, besides perhaps 200 or 250 tons of tincal, at £2 or thereby per ton. After refinement, a large proportion, perhaps one-half, is re-exported. Borax is largely employed by braziers, silversmiths, and other workers in metals, as a flux; by potters in the formation of a glaze for earthenware and porcelain; by chemists as a reagent in blowpipe analyses; in the preparation of certain kinds of glass, and generally if its price permitted; in the fabrication of artificial gems; in medicine; and in other minor arts.

Baryta—Strontia.

These are two alkaline earths (see CHEMISTRY) very similar to each other, and indeed, till recently, considered identical. The former is an oxide of barium, the latter of strontium; neither the metalloids nor their oxides are found in nature. The only two abundant natural compounds of baryta are the sulphate, which occurs crystalline, and the carbonate. Sulphate of baryta, or *heavy spar*, is found in various districts, particularly in Cumberland and Westmoreland; a variety from Derbyshire is provincially called *cawk*. Heavy spar, according to Dr Ure, is used to adulterate white lead by the English dealers to a shameful extent; sulphuret of barium is employed as a chemical reagent; and all the salts of baryta, with the exception of the sulphate, are highly poisonous. The native forms of strontia are the carbonate and sulphate, both found in a crystalline state. The former occurs abundantly in the lead mines at Strontian, in Argyleshire; hence the name; the latter is found near Bristol, and associated with native sulphur in Sicily. The only preparation of strontia used in the arts, is the nitrate employed in combination with chlorate of potash and charcoal, to produce the brilliant red colour in fireworks and theatrical conflagrations.

Sulphur.

Though sulphur or brimstone be an elementary substance, *sui generis*, and, strictly speaking, does not come under the head of saline substances, yet it may, without much impropriety, be considered in this place, as often occurring in efflorescent salts or crystals. It is a yellow brittle mineral product, found in most parts of the world, but most abundantly in volcanic regions, and in the immediate neighbourhood of burning mountains, such as Ætna, Hecla, &c. It occurs either as an efflorescence on the surface, or in masses mingled with clay, ashes, and other volcanic products. Our chief supply is obtained from Sicily, where it occurs in beds of a blue-clay formation; and whence it is imported, as dug from the mines, in square masses or blocks, called rough brimstone. Sulphur is also obtained artificially from the sulphurets of copper, iron, and other metals; but the facility with which native material can be secured, prevents its artificial production from being followed to any great extent.

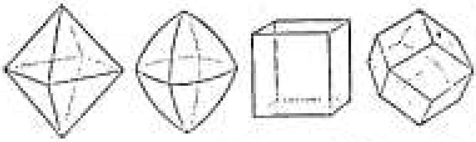
Unlike most other materials of commerce, the formation of sulphur is still going forward wherever volcanic agency is in a state of activity. It appears to be sublimed by the subterranean heat through the crevices and fumeroles of the mountains; and this collects either as a slight efflorescent crust on the surface, or in crystals and in masses throughout the material of the ejected clays, ashes, &c. Speaking of the sulphur mountains of Iceland, Sir George Mackenzie says—'At the foot of an elevation, in a hollow formed by a bank of clay and sulphur, steam rushed with great force and noise from among the loose fragments of rock. Ascending still higher, we came to a ridge composed entirely of sulphur and clay, joining two summits of the mountain. Here we found a much greater quantity of sulphur than on any other part of the surface we had gone over. It formed a smooth crust, from a quarter of an inch to several inches in thickness: the crust was beautifully crystallised. Immediately beneath it we found a quantity of loose granular sulphur, which appeared to be collecting and crystallising as it was sublimed along with the steam. Sometimes we met with clay of different colours—white, red, and blue—under the crust; but we could not examine this place to any depth, as the moment the crust was removed, steam came forth, and proved extremely annoying. We found several pieces of wood, which were probably the remains of planks that had been formerly used in collecting the sulphur, small crystals of which partially covered them. There appears to be a constant sublimation of this substance, and were artificial chambers constructed for the reception and condensation of the vapours, much of it might probably be collected. As it is, there is a large quantity on the surface, and by digging, there is little doubt that great stores may be found.' Such is the usual origin of native sulphur—a substance of greater commercial value to a country like Britain than the most of our readers may imagine. It is employed for making gunpowder, sulphuric acid—which is indispensable to so many manufacturing processes—cinnabar, and for a variety of other purposes in the arts, as well as being used medicinally—requiring altogether an annual supply little short of 20,000 tons. For a further account of the nature and properties of sulphur, and of the manufacture of sulphuric acid, see 'Chemistry,' pp. 298-9. Orpiment and realgar, the one a yellow, and the other a red sulphuret of arsenic, though found in a mineral state, and as such used in the arts, will be more systematically treated under 'Metals and Metallurgy.'

PRECIOUS STONES.

All our so-called 'precious stones'—the diamond, ruby, emerald, amethyst, &c.—are but compounds of carbon, alumina, silica, lime, &c. and might therefore, so far as their mineralogical character is concerned, have been considered under the sections already presented. As none of them, however, occur in rocky masses, but rather as crystals, geodes, and concretions within other rocks, and as fashion has generally set a price upon them wholly disproportioned to their utility, it may be as well to treat them as an independent class. Our limits will only permit us to mention a few of the more esteemed; seeing that lapidaries, jewellers, and others, have vastly increased the nomenclature of precious stones by giving individual names to specimens which are, in reality, but varieties of the same substance. For an account of *pastes*, or *artificial gems*, see 'Fictile Manufactures,' p. 333; and for *pearls*, native and artificial, which are often erroneously classed with gems, see 'Zoology,' p. 183, and 'Fisheries,' pp. 703-4.

Diamond.

The most highly-prized of precious stones is the diamond, a crystalline mineral of unsurpassed lustre and hardness. It is the hardest known substance, and can be polished or cut only by its own dust or powder; hence the common saying of 'diamond cut diamond.' When perfectly pure, it is as transparent as a drop of the purest water, in which state it is known as a diamond of the first water; and in proportion as it falls short of this perfection, it is said to be of the second, third, or fourth water, till it becomes a coloured one. Coloured diamonds are generally yellow, blue, green, or red, and the higher the colour, the more valuable they are, though still inferior to those absolutely transparent. Diamond, as has been demonstrated by numerous experiments, consists solely of carbon, being, in fact, a crystallised charcoal, generally appearing in one or other of the subjoined forms:—



Diamonds were originally discovered in Bengal, but they have since been found in other parts of India, in the East India islands, in the Brazils, and recently in the Ural mountains. They occur chiefly in alluvial deposits of gravel and sand, lying in detached octohedral crystals, sometimes with plain, but more frequently with rounded surfaces. The finest are cut for ornamental purposes into *brilliants*, having curvilineal faces both at top and bottom; or into *rose diamonds*—that is, those having their tops or upper surfaces cut into a number of triangular facets, but quite flat beneath. The black, dirty, and flawy ones, and those unfit for being cut (technically called *boats*), are pulverised for the purpose of polishing others, besides being applied to various uses in the arts. Fractured portions, with good cutting edges, are usually set for glaziers' cutting pencils, in which state they are worth from twelve to twenty shillings; and also as *drills* for piercing other precious stones. It is the ornamental diamonds that bring the exorbitant prices so frequently mentioned in modern history, their value depending upon shape, colour, and purity, and being fixed at so much per carat of 3⅕ troy grains. 'The largest diamond ever known was brought to the king of Portugal from Brazil. It is uncut, weighs 1680 grains, and its value is often quoted at £5,644,800. Similar extravagant valuations are applied to the famous Russian one weighing 195 carats; to that in the possession of the Great Mogul, weighing, cut, 280 carats; and to others; but it does not appear that any sum exceeding £150,000 has ever been given. The last great sale of jewels was in London in 1837, for the distribution of the Deccan booty, obtained by the army under the Marquis of Hastings. On that occasion, the magnificent Nassau diamond, weighing 357⅛ grains, of the purest water, brought only £7200.' The Russian diamond, says another authority, is of the size of a pigeon's egg, and was purloined from a Brahminical idol by a French soldier; it passed through several hands, and was ultimately purchased by the Empress Catharine for the sum of £90,000, an annuity of £4000, and a title of nobility. Perhaps the most perfect and beautiful diamond hitherto found is a brilliant brought from Malacca by a gentleman of the name of Pitt, who, after getting it cut in London, sold it to the Regent, Duke of Orleans, for the sum of £100,000; its weight 136¾ carats. It is now, or rather we should say was lately, in the crown jewels of France; its further history is a problem yet to be solved.

The art of cutting diamonds—which is distinct from that of the lapidary or polisher of inferior gems—is thus described by Webster:—The gem may be split by a steel tool if a blow be applied; but to effect this it is necessary to have a perfect knowledge of its crystallised structure; and the workman cannot form facets at pleasure by splitting. To produce the faces which are required for exhibiting the gem in all its beauty, the process called *cutting* is resorted to, but which is, in fact, abrasion rather than cutting. For this purpose the diamond is fixed on the end of a stick or handle, in a small ball of cement; that part which is to be reduced being left to project. Another diamond is also fixed in a similar manner, and the two stones are rubbed against each other with considerable force, until they are ground away as much as is necessary to produce a facet. Other facets are formed in a similar way by shifting the position of the diamonds in the cement. When the faces are thus completed, they are next to receive an exquisite polish. For this purpose the stones are imbedded in soft solder, contained in a small copper cup, the faces to be polished being left to protrude. A flat circular plate of cast-iron is then charged with diamond-powder, and the stone is held against this plate, while it is made to revolve till the polish is complete.

Sapphire—Ruby—Topaz—Garnet, &c.

These may be conveniently grouped together as consisting essentially of crystallised alumina—traces of magnesia, silica, fluoric acid, chromic acid, &c. constituting the specific distinctions. The sapphire is of various colours—the *blue* being generally known among jewellers and lapidaries as the sapphire; the *red*, the Oriental ruby, and, next to the diamond, the most valuable of gems; and the *yellow*, the Oriental topaz. Sapphires are sometimes substituted for diamonds, by exposing them to a strong heat, which destroys their colour, but improves their hardness and transparency; and this kind of fraud would be difficult to detect by any one who was not a good judge of those gems.

Corundum, or adamantine spar, is nearly allied to the sapphire, and, with the exception of the diamond, is the hardest substance known. It is almost a pure crystallised alumina, consisting of more than ninety per cent. of that substance, with a little silica and iron. It is found in India, China, and some parts of Europe; and is used in the East for the same purposes to which diamond powder is applied in England. Emery, so called from Cape *Emeri*, in the island of Naxos, is but a variety of corundum, with an admixture of iron, which gives to it a bluish-gray colour. From its extreme hardness, its powder is largely employed in the polishing of glass and metals, and in the cutting of gems and other minerals—all of which are abraded by it, with the exception of the diamond. Emery-powder is prepared by grinding the mineral in steel mills; it is afterwards assorted into parcels of different degrees of fineness, by agitating it with water, and separating the particles which deposit themselves at different stages—the finest being the last which subside. Emery paper and emery cloth are prepared like common sand paper—namely, by coating the fabrics with a strong size of glue, gum, flour, and alum, upon which the powder is sifted while the size is sufficiently soft to retain it.

The ruby, found chiefly in the sand of rivers in Ceylon, Pegu, and Mysore, is also of various colours—the scarlet-coloured being distinguished as *spinelle ruby*; the pale or rose-red, *balass ruby*; and the yellowish-red, *rubicelle*. Rubies from two to six carats are rare, and when of this size, and of the fine deep cochineal red so much prized, fall little short of the diamond in value. The topaz likewise presents various shades between yellow and wine-colour; but, from its large per centage of silica, is harder than either of the preceding. The best varieties are known as the Brazilian, the Saxon, Siberian, and Scotch.

The garnet, another well-known mineral, belongs to the same section, the varieties being essentially of alumina, with silica, magnesia, iron, &c. The most valuable is the *precious garnet*, almandine, or carbuncle, which is commonly a transparent, red, and beautiful mineral, either crystallised, or in roundish grains. It is found in Ceylon, Pegu, and Greenland. The *pyrope*, a blood-red variety, found in Germany and Ceylon, is perfectly transparent, and, in roundish or angular grains, is perhaps next in value. The common garnet is not transparent like the preceding, and is most frequently of a dull-red or blackish-brown. It is found plentifully in Scotland, Sweden, and other countries, where the primitive rocks abound; but comparatively few specimens are fit for the jeweller. The black garnet, or, more properly, *melanite*, is a mineral found in volcanic rocks, and worked into necklaces at Naples.

Emerald—Beryl—Amethyst—Carnelian, &c.

In these the predominant ingredient is silica; they may be called siliceous gems, just as the ruby and sapphire might be styled aluminous, or the diamond carbonaceous. The emerald is one of the most esteemed, being of a beautiful green colour, and occurring in prismatic crystals. It consists essentially of silica, with a small per centage of alumina and glucina, the colouring matter being oxide of chromium. The finest emeralds are brought from Peru and Brazil; the mines from which the ancients obtained their supply are said to have been in Upper Egypt. Fine emeralds are extremely rare; and one of four carats, of approved hue, and well cut, is worth about £160. Beryl differs little from emerald except in colour—the latter name embracing the green varieties, the former all those that are tinged less or more with yellow or blue, or are altogether colourless. Beryls are found in Siberia, France, the United States, and in Brazil, the latter country furnishing the brilliant variety known as the precious beryl, or aqua-marine. Heliotrope, or *bloodstone*, is another common deep-green siliceous mineral, somewhat translucent, and often variegated with blood-red spots—whence its common appellation. It is found in Siberia, in Iceland, and the Hebrides, but chiefly in India, which furnishes the finest specimens. It is in request among the Chinese as an ornament to their girdle-clasps.

Amethyst is a pure rock-crystal, of a purplish-violet colour, and of great brilliancy. It is found in India, in Germany, Sweden, and Spain, but chiefly in Brazil, and is in great request for cutting into seals, bracelets, and brooches. 'Some of the ancient vases and cups,' says Brande, 'are composed of this mineral, and it was an opinion among the Persians that wine drunk out of such cups would not intoxicate; hence its name from the Greek *amethystos*.' The cairngorm of the lapidary is another crystallised quartz, of various hues, and nearly transparent. It derives its name from the mountain Cairngorm in Inverness-shire, and is much used as an ornamental stone in this country.

Agate, chalcedony, opal, carnelian, sardonyx, jasper, and some kindred substances, may be, without much impropriety, regarded as merely varieties of the same mineral, having different colours and degrees of transparency. They are found in most countries, and are used for seals, brooches, cameos,* and other ornamental purposes—the larger geodes or mass being often fashioned into cups and vases. Carnelians and opals are perhaps the most valuable, some specimens of the Oriental opal being worth double the price of a sapphire of the same size. This variety is sometimes known as the Nonnius opal, from the senator Nonnius, the possessor of the famous opal of Rome, worth 20,000 sesterces, who preferred banishment to parting with it to Antony. The *cat's-eye* opal, so called from its presenting an effulgent pearly light, like the changeable reflections of the eye of a cat, is another siliceous mineral or quartz, interspersed with filaments of asbestos. It is found chiefly in Ceylon and the Indian peninsula, and is held in great estimation among gem fanciers. When the late king of Candy's jewels were brought to the hammer in London, in 1820, a specimen, which measured about two inches in diameter, brought upwards of £400. *Mocha-stone*, also in some repute, is a semi-transparent chalcedony, enclosing various ramified forms produced by oxide of iron, or other metallic substances, but sometimes also by the presence of vegetable bodies, such as mosses. The finest are found in Guzerat, but receive their name from being brought from Mocha. The *onyx*, so much admired by the ancients, is a species of agate, in which the siliceous particles are arranged in alternating horizontal layers of opaque white and translucent blue, gray, or brown. It is employed for cameos, the figure being cut out of the opaque white, and the dark part forming the ground, or *vice versâ*. It is most valuable when the colours are in strong contrast, and when the layer is thick enough to give a high relief to the object engraved.

The district of Cambay in India, yields agates, chalcedonies, carnelians, and jaspers of every variety, and of enormous size; and these, now so common in the market, are known by the general name of *Cambay Stones*. Great numbers of people find constant employment in quarrying these. When first taken from the rock, their colours are faint and tracings imperfect. They are first exposed for some time to the air, and afterwards heated nearly to redness by a slow fire of wood or cow-dung. Under this process the colours come out in the greatest brilliancy. They are now cut up by the common lapidaries' wheel, and polished in the usual way with emery or ground corundum. Cutting is but rarely resorted to: in general the stones are chipped as nearly to the required form as possible, and then ground with emery and polished. They form a considerable article of sale in the Bombay market, and are imported in immense quantities by the London lapidaries, who improve their polish, and alter their forms into such as may be considered most saleable. The Bombay brooch and necklace pieces, paper-folders, finger-rings, shirt-buttons, earring-drops, &c. are those most frequently found on sale.

Lapis-lazuli, or azure-stone, at one time held in the highest estimation, is another precious mineral, whose chief constituents are silica and alumina. Its principal localities are China, Persia, and Siberia, where it occurs in massive, but rarely in regular crystals. The finer specimens are prized by the lapidary; but by far the most important application of the substance is to the production of ultramarine—a pigment which, till of late, was more precious than gold. Within these few years, however, the chemist has succeeded in producing an artificial ultramarine, possessing all the properties of the native pigment, and at such a rate that several pounds weight can be procured for what, a dozen years ago, would scarcely have purchased a single ounce.

Calcareous Spars.

Several of the calcareous spars are of great beauty and transparency, but in general their softness and frangibility prevent them from being employed for ornamental purposes. *Iceland spar*, so called from the largest and most transparent specimens being found there, is a rhomboidal carbonate of lime, much used for experiments on the double refraction and polarisation of light. *Fluor spar* is a common mineral product, found in many places, but in great beauty and abundance in Derbyshire. It is a fluoride of calcium, occurring in crystals and in nodules of various colours, and often very prettily banded. The nodular specimens are occasionally worked into beads, brooches, and other ornamental purposes; but chiefly manufactured into vases, toilet-boxes, jars, and such-like articles. The acid of fluor spar, when disengaged, is used in etching on glass (p. 331); and the spar itself is occasionally employed, under the blowpipe, as a flux for promoting the fusion of other minerals.

* *Cameo* (a word of Oriental origin) is the term applied to gems of various colours sculptured in relief. 'The art of engraving on gems,' says Brande, 'boasts of high antiquity, having been practised with various degrees of success by the Egyptians, Greeks, and Romans. It was again revived in Italy in the fifteenth century, and is even at the present day cultivated with great avidity and considerable success. The cameos of the ancients were usually confined to the agate, onyx, and sard, which, on account of the variety of their strata, were better accommodated to a display of the artist's talents; but they are also occasionally found executed on opal, beryl, or emerald, and even on a sort of factitious stone, the *Vitrum obsidianum* of Pliny, distinguished by the moderns as the antique paste. One of the most famous cameos is the onyx at present in Paris, called the *apotheosis of Augustus*. It is one foot in height and ten inches in width.' To this we may add, that a cheap kind of cameo has recently been prepared from large shells found on the coasts of Africa and Brazil. These shells have two layers, the ground being either of a pale coffee colour, or of a reddish orange, and the figure of a nacreous white. Cheap imitation cameos are also extensively manufactured in glass enamel.

The peculiar lustre of the metals, arising out of their opacity and reflective power with regard to light, their conduction of heat and electricity, their density, fusibility, ductility, malleability, and the like, are features which, though differing in each, yet readily distinguish them as a class from all other substances. It is this density and hardness in some, this ductility and malleability in others, and the facility with which many of them can be amalgamated, that have rendered them such valuable aids to human progress, and made them available for almost every purpose of utility or ornament. Without them, indeed, any high degree of civilisation were impossible; they are essential to every process in agriculture, architecture, machinery, navigation—to every art, in fine, which marks the advancement of mankind from the lowest stages of barbarism. As elementary substances, their scientific distinctions have been detailed under CHEMISTRY; we would now direct attention to their history, the localities where found, the modes of obtaining and preparing them, the purposes to which they are applied, their relative values, and other particulars of economic importance.

GEOLOGICAL CONDITIONS.

The metals, as found in nature, are seldom or never in a state of purity. It is true that the miner occasionally detects a fragment of native gold, native silver, and the like; that is, specimens of gold and silver, pure and ductile as from the crucible of the chemist; but such fragments are rare, and bear no appreciable proportion to the quantity which occurs in the crude state of ores. These ores are sulphurets, carbonates, oxides, &c. mingled with earthy impurities, generally situated in veins, sometimes disseminated through rocky masses, rarely in beds or strata, and distributed through the formations of all eras, but more especially through those of the primary and transition series. Thus iron, the most familiar and useful of all the metals, occurs in more than twenty different mineral states, being combined with carbon, oxygen, sulphur, phosphorus, &c.; is found in veins traversing different formations; is disseminated through various rocks, so as to give to them a ferruginous aspect; and, as clay-ironstone, is interstratified with the clays and shales of the coal-measures. To arrange and classify the ores is the study of the mineralogist; to determine their value, or the amount of metal they contain, is the art of the chemist; to raise them from their various positions, is the labour of the miner; to separate the metal from the earthy impurities with which it is associated, is the work of the metallurgist; and to fashion it into implements, utensils, and machines, is the calling of the founder, blacksmith, machinist, cutler, and others. As with the ores of iron, so with those of the other metals, only that few of them can be said to occur stratified like the clay or carbonaceous ironstone. It must not be supposed, however, that the respective metals always lie in separate veins—that copper, for example, is always the only metal found in a copper vein; or lead in a so-called vein of lead. The fact is, that though some one metal generally predominates, three, four, or even more metals, may be strangely combined and intermixed with the same veinstone. In our own island, the vein which contains lead as the principal metal, often embodies silver, zinc, and cobalt: platina is generally associated with gold; manganese not unfrequently with iron.

Respecting the origin of the metals, geology and chemistry afford us no certain knowledge. We cannot tell why, or in what manner, the Creator has formed gold, or silver, or iron, any more than we can tell why he has created oxygen, hydrogen, or any other so-called *elementary* substance. Investigation has, no doubt, collected a vast amount of accurate data as to the nature of veins, and the ores which fill them; and we can speculate with some degree of certainty as to the causes which have contributed to these results. We see that subterraneous and igneous forces have at various epochs upheaved and rent asunder the stony crust of the globe; that the fissures so produced have been subsequently filled with mineral matter, differing widely in kind from the rock in which it is enclosed; and that, incorporated with this mineral *matrix* or veinstone, occur various metallic ores in films, strings, crystals, or amorphous masses. But whether this veinstone, with its associated metals, has been the result of infiltration from above when that portion of the globe was under water, of sublimation from igneous sources beneath, or of long-continued chemical and electrical agencies, science has not been, nor may ever be, able to determine; and even if it could determine, still the question would remain—Whence the substances we designate metallic? Are they further developments of previously existing bodies? Are any or all of them transmutable one into another under the operation of certain natural agencies? Or are they, in reality, elementary substances, each after its own kind? These are questions which have engaged the attention of the scientific in all ages; years and lives have been spent in attempting a solution; and yet, except in the acquirement of more correct data whereupon to pursue the inquiry, man is no nearer to a satisfactory answer. It would be a strange revelation indeed, if we could detect nature elaborating substances having so many different aspects and properties from the same source; and more wonderful still, if the chemist, imitating her processes, could accomplish the like results. Laying aside, however, these high aspirations, we observe in the present day many waters containing iron, copper, lead, and the like, in solution, which waters, gathering these ores from existing sources, transport them to new localities, where they combine with other substances, and form new deposits, as bog-iron ore, cupriferous marls, or auriferous sand. In time these sands, marls, and bog-silts become true rocky strata, either to present phenomena analogous to the clay-ironstone of the coal-measures, or if subjected to igneous and other forces, to contribute, it may be, to the formation of new metallic veins. The operations of nature are ever in progress; each stage presenting new phases, which gradually merge into those that follow, and never exhibiting any appearance which can suggest to the mind the idea of an ultimate completion.

Beds—Veins.

It has already been mentioned that the chief forms in which the metalliferous ores occur are *veins*, *beds*, or *fragmentary deposits*. In the last of these the ore is associated with sand, gravel, and other superficial debris, which has evidently been transported by alluvial agency from mountain metalliferous districts. In this case there is no geological complexity; the matrix in which the ore originally lay has been disintegrated by atmospheric forces, and its fragments borne down by rains and streams to the valleys in which they now occur. The origin of metalliferous beds or strata, whether in the older or more recent formations, is almost as apparent. The stratum, for the most part composed of earthy matter, is a true sedimentary rock, and has evidently been deposited in waters holding in solution a notable amount of the metal in question, which, uniting with the earthy matter, determined the quality of the matrix. Every stratified rock, indeed, is less or more impregnated with one or other of the metals, but it is only those in which the metallic ingredient is peculiarly abundant that demand the attention of the miner. Veins, however, are the principal forms in which metallic ores are distributed throughout the crust of the globe. A description of those of Cornwall will almost suffice for those of every other country, as the differences are comparatively unimportant to the general observer.

A vein may be said to resemble a deep cleft or rent in a clayey field, which has been subjected for some time to the desiccating influences of the sun. This cleft, whatever may be its depth, must of course have a direction under ground, either slanting or perpendicular; and if we suppose it filled with metallic ore, we form the idea of a vein, or, as it is termed in Cornwall, a *lode*; if we suppose the cleft filled with any other stony substance, we can imagine what is called a non-metalliferous vein, of which there are many, sometimes pursuing their own exclusive courses, and at others intersecting the metalliferous veins. The direction of the lodes is by no means accidental, but nearly determinate. They usually *strike* east and west, and *dip* or underlie either towards the north or south; while the non-metalliferous veins, which run north and south, dip either towards the east or west. The cases in which metalliferous veins assume a north and south direction are few, and chiefly foreign. It frequently happens that the metalliferous lodes, as we have said, cross each other; and, as a leading fact, the intersection of two lodes at a small angle is productive of good ore. Should, however, a copper lode pass through a tin lode, the copper lode invariably divides the tin one, and generally heaves it out of its course, to the frequent perplexity and loss of the miner. All mining experience of a general character is, nevertheless, sometimes set at defiance; for, in the small space of one little hill, instances may be found in which veins of almost every description dip or underlie in numerous directions, traversing each other in such a manner as completely to baffle the miners; but it is an ascertained fact, that there are seldom or never, *in the same district*, two *series* of metalliferous veins running at right angles to each other. On an average, the direction of the Cornish lodes are about 4 degrees south of true west, and their dip or inclination about 60 or 70 degrees from the horizon.

The length of no one lode has as yet been satisfactorily traced, though some of them have been followed for two or three, or even four or five miles; nor has the miner ever yet seen the bottom of one, although there are several mines in Cornwall upwards of 1000 feet in depth from the surface, and two or three about 1300 feet deep. The lodes differ exceedingly in respect of width, in which, indeed, they vary from a mere line to forty or fifty feet. On the average, they may be assumed to be three and a-half feet wide. Lodes of from one to three feet in width are usually less intermixed with foreign and troublesome substances than those which are wider. A vein of tin in a mine called Whealan Coates was only three inches wide, and yet proved so rich as to be worth working. Some of the veins containing copper in Herland mine did not exceed six inches in width; and after continuing this thickness for a few fathoms, eventually passed away east and west in mere strings; but they yielded ore of a very rich character. In the next hill there was also a very productive vein from twelve to twenty-four feet in width.

The compositions of the lodes or veins are as variable as the nature of the rocks through which they pass. By far the greater number consist of matter similar to that of the contiguous or intersected rock; but many also contain large intermixtures of quartz. These ingredients occasionally occur in separate streaks or striæ, but for the most part they are mingled without regularity or order, and throughout them are dispersed the metallic ores. Sometimes these are aggregated very thickly, and very generally occur in large irregular lumps or patches, called *bunches*, connected with each other by small films or *threads* of ore. At other times the ore is very sparingly sprinkled through the whole of the earthy matter of the vein, and in some rare instances it forms the larger part of its contents. The sides of metalliferous veins are usually very determinate, being covered by a hard dark-coloured crust, called by the miner the *walls* of the vein.

We have noticed that there is a second series of veins, called non-metalliferous veins, which run north and south; that is, nearly at right angles to the metalliferous lodes. When these veins are chiefly composed of quartz, they are locally denominated *cross-courses*; and when consisting mostly of clay, they are named *flucans*. Their general direction, when accurately traced, is about south-east and north-west. Their dimensions are variable, being perhaps on an average about two feet; their dip, too, fluctuates, but, as a general rule, it is greater from the horizon than that of the lodes. The clay with which the flucans are filled invariably partakes of the same character as the contiguous rock. Tin and copper ores are occasionally found in small quantities in the cross veins, and in two or three instances silver and its ores have also occurred to some amount. The chief metallic produce, however, of this class of veins is lead ore; but this they seldom yield in the neighbourhood of lodes which have been productive of other metals. Indeed it is, as has been stated above, a general law in Cornwall, that two series of productive metalliferous veins, at right angles to each other, are very seldom or never found in the same district. Both the lodes and the cross veins ramify and divide; and whilst the part which in one place is large will sometimes, within a short distance, dwindle and die away, the portion which is small, where the other is rich, will often, within a small space, enlarge and become productive.

As these two series of veins—the lodes and the cross veins—run at right angles to each other, they of course frequently meet and intersect. In a few instances the lodes traverse the cross veins, but in far the greater number of cases the cross veins cut through the lodes. Occasionally, the cross vein simply intersects the lode; but more generally displacements, provincially termed *heaves*, attend their contact. If, for example, a cross vein, in its north or south course, meets with a lode containing copper or tin, the last seems to have been split, as it were, into numerous little branches by the first, which generally pursues its uninterrupted course straight forwards. Another effect, too, of a much more extraordinary kind, is produced by this intrusive cross vein. In searching for the tin or copper lode on the other side of this north and south vein, a lengthened period frequently elapses before the fugitive can be discovered. Notwithstanding the experience of the miners, forty years have sometimes passed over before the search, though carried on with vigour and great expense and labour, has proved successful. It is by no means a simple task for the mining engineer to lay down a law for the recovery of the lode. Instances have been known in which it has been again found 120 or even 450 feet north or south of its original course. The cross vein will not perhaps generally intersect the lode exactly at right angles, but its inclination to the course of the lode will usually be such as to produce at the intersection an obtuse angle at one side of the lode and an acute at the other side; and it is thought, by the most experienced observers, as well in Saxony as in Cornwall, that the second portion of the lode will more frequently be discovered on the side of the obtuse angle, formed by it with the cross course, than on the side of the acute angle. In other words, on whichever portion of the lode we approach the cross vein, the other portion will be found towards the same hand—namely, to the right. There are other kinds of interruption to which metalliferous veins are subject, though far less extensive in their agency than the cross veins. These are denominated *slides*, and generally consist of clay or argillaceous matter. (See GEOLOGY.) Their direction is nearly parallel to that of the contiguous lodes; but their dip or underlie being either greater than, or opposed to, that of the latter, they intersect them either in a horizontal, or more or less inclined direction.

It is a well-known but remarkable fact, that some of the metallic ores lie much nearer to the surface than others. Gold, in the small veins of it which are sparingly distributed through some of the rocks in Brazil and elsewhere, is worked by open cuttings from the surface. Silver is found in some foreign mines at a depth of from two to three hundred feet, while the silver mines of Mexico are of a much more considerable depth. Tin is also found at shallow depths, of which the great lode of the Charleston mines in Cornwall furnishes a good example. Lead is usually met with at a trifling depth, and slightly spotted veins of it are sometimes to be observed in the sides of brooks, and in the rocky channels of rivers. Copper, on the contrary, generally lies deep, and the enormous deposits of this metal found in Cornwall are generally situated two or three hundred feet below the surface. Where tin and copper are found together in the same vein, the tin commonly occupies the upper part, and disappears at the depth at which the copper is discovered. Sometimes, however, the ores of both metals occupy the vein together to a great depth, as at the Poldice mine near Redruth. On referring to the *known* depths to which different metals extend, it will be found that those which commonly lie near the surface, as lead, zinc, gold, and occasionally tin, do not generally penetrate to any great depth; while those which lie deeper, as copper and silver, are worked in the bottoms of our deepest mines. This coincidence may be the result of a natural law, or it may be apparent, and consequent only upon the limit of our experience and knowledge.

MINING OPERATIONS.

When the mineral contents of a district are entirely unknown, the operations instituted for the discovery of lodes must be founded upon the general presumptions furnished by geological science in connection with mining experience, as metallic veins usually present no precise traces of their existence at the surface. The first objects of pursuit, in such circumstances, to the Cornish miner, for example, are what he denominates *shode* or *shoad-stones*. These stones are partially rounded and apparently water-worn, and are found on the surface, or at very small depths below it. Their mineralogical characters nearly resemble those of the contents of the lodes in the vicinity, of which they are presumed to be portions removed by alluvial action. As, however, the shoad-stones contain tin ore, a careful search for them has been constantly kept up, and their increasing scarcity will probably render this mode of discovery impracticable. When they were uncollected, the examiner might commence marking their presence at any given spot, and then trace them to where they appeared in the greatest abundance, which situation was probably the nearest position of the lode itself. Upon arriving at this place, he would cut trenches, or dig small shafts, or trial-pits, to ascertain how far his suspicions were well founded.

Should the precise situation of the vein, whose existence has been ascertained by tracing the shoad-stones, or by any other mode, be unobservable, it may be ascertained by opening trenches in the alluvial soil, deep enough to expose the solid rock; their direction being at right angles to that in which analogy, or the position of other veins in the neighbourhood, would render it probable that those in question should lie. Supposing the direction or strike of the vein, and its dip or underlie, to be ascertained either by the shoding, and by sinking a few shallow pits upon it, or by previous experience in some adjoining mine, the further exploration may be continued, either by sinking upon its course from the surface, or by forming a horizontal passage to intersect it, which is commenced from a valley, or the lowest point in the neighbourhood, and is called an *adit*. This last plan, however, being both tedious and costly, is seldom adopted, unless there is a tolerable certainty of its results being highly favourable.

The lode and its directions being discovered by the means above detailed, the next point is to determine the site of the shaft, upon some convenient spot of ground. If the shaft is to be sunk in an inclined direction upon the course of the vein, which is frequently desirable, the site is not so circumscribed as when it is to be sunk perpendicularly upon it. In the latter case, the shaft is necessarily commenced on that side towards which the vein inclines or underlies, and at such a distance from its appearance at the surface (or outcrop) as to cut the vein at a premeditated depth, which may be from ten to thirty fathoms, in accordance with the means of the adventurers, and with their knowledge of the quality and conditions of the lode, the upper portions of which are seldom productive.

The vein being cut, the shaft may be continued either perpendicularly, and through the vein, or obliquely, and in the course of the vein. Should the lode be expected to turn out profitably, the former plan will be adopted, as it will be ultimately the most advantageous, and will enable a large mine to be carried out. But if the lode is questionable, and the means of the miner the same, the latter course will be proceeded upon, as it is far the cheaper one, as well as the speedier.

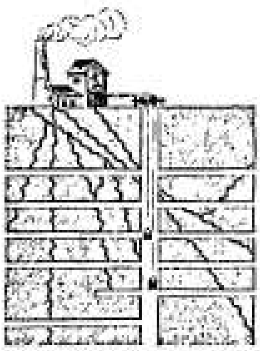
In driving the second and the succeeding levels, it is clear that the further we proceed from the shaft in each direction, the greater will be the closeness of the air, and the more essential will ventilation become. It is then that small shafts, called *winzes*, are sunk. Thus a communication is opened between all the levels, each one of them possessing winzes opening upwards from itself to the next superior level, and also others opening downwards from itself to the next inferior level, by which means a double communication with the atmosphere and every level is effected, and an ascending and descending current of air produced. In other respects, the system of ventilation very closely resembles that adopted in coal-mines. (See MINING AND MINERALS.)

In addition to their utility for the purposes of ventilation, winzes are equally necessary to the working out of the ore from the lode, and, indeed, are advantageous in trying its value. Unless little or no ore has been discovered upon the opening of the first level, winzes will be commenced at a very early stage of the mining operations; and when the ore is found to be tolerably good, they will be opened at intervals of twenty or thirty fathoms in each level. Their position will be especially determined, so as to prove the richest and most promising parts of the vein, and to avoid those hard and unproductive portions which may be supposed to be unworthy of exploration. As far, too, as it can be effected in accordance with these views, the position of the winzes will be such as that each of them may come about midway between the nearest two above it. The system of works, therefore, by which the lode is explored and the mine established, is not unlike a system of masonry, if the horizontal beddings of the stonework be supposed to represent the levels, and the vertical joints the winzes.

When, by these arrangements, the lode has become divided into a number of solid rectangular masses, as just described, the mine will have been brought into an effective state of working, and parties of men will be set to raise ores from all the most productive points. Where the vein is not very hard and stubborn, the ore may be broken down with the pick and wedge only; but it is generally necessary to blast the rock with gunpowder or gun-cotton, by which mode large quantities of ore are detached at every 'shot.' In working the ores either by the pick or the blast, the men usually work upwards, from the upper part of one level towards the bottom of the one above it; and the excavations are so arranged that the ore may readily fall down to the level below them, whence it is carried in tram-wagons to the nearest point of the shaft, and is thence raised to the surface, either by a horse *whim* or by a steam-engine.

Simultaneously with the working of the ore, provision must be made for carrying off the water which issues from the rocky sides and bottom of the mines. This is generally effected by pumping apparatus, moved either by water or steam-power. In the early periods of mining industry wooden pumps alone were employed; but they have been for many years entirely superseded by iron pumps, which admit of the *lifts* or columns being carried to a great height without the danger of leaking or bursting. None of the pumps used in mines act at all by atmospheric pressure, as in the case of the common household pump; for they are invariably arranged in lifts of considerable height, such as from twenty to thirty fathoms, and the water itself is discharged into cisterns placed at the foot of each lift, whence it is raised again by mechanical means. The whole column of pumps is usually worked by a single pump-rod, which traverses the middle of it, and communicates with each column by a rod attached to its side. The efficiency of a steam-engine for mining purposes is estimated by a standard which is termed *duty*, and which conveniently and accurately defines the work performed, with reference to the consumption of a given quantity of coal. By the duty of an engine is meant the number of pounds (always expressed in millions) of water which have been raised through the height of one foot by the consumption of a bushel of coal; the data for this calculation being the quantity of water discharged from the pumps in a given time, and the quantity of coal consumed by the engine in the same time. In 1813, a system for the registration of the duty, and other peculiarities of the performances of the engines working in Cornwall, was organised, and the results, ascertained monthly, have since been published in the shape of monthly reports. In considering that some of the most powerful engines in Cornwall consume from three to four thousand bushels of coal per month, that some mines employ several such engines, and that the mere expense of drainage is not unfrequently £12,000 or £13,000 per annum, the immense importance of the improvements, the results of which are just noticed, will be at once understood. The Messrs Lean estimate the saving to the county effected since 1813, upon the whole number of engines reported, to amount to a hundred thousand tons of coal in the year, equivalent in value to £80,000 sterling per annum.

A mine in a complete working condition exhibits a most extensive series of operations, in connection with the shaft, the lifting and descending by ropes and pulleys, the drainage, the excavation, the ventilation, &c. At the bottom of the shaft, and in the various stages in which the excavations are going on by the miners, in their attempts to follow the lodes, the operations are on a scale which seldom fails to surprise the stranger. When the levels have been carried to a considerable distance from the shaft, the ventilation will again be found defective, notwithstanding the frequent communications by winzes; for the greater the distance the current of air is carried, the more feeble it plainly becomes. This deficiency is still further augmented by the increasing number of the men now employed in the works, the presence of a great number of candles, and the smoke resulting from the larger employment of gunpowder in the process of blasting. The expense, too, of the transport of ore and masses of rubbish or *deads* to the shaft, is, on account of its greater distance, much more considerable. To add to these, we have the greater expenditure necessary for the drainage of the water from the mine, and for the support of its passages and roofs by timber, or by rude masonry. In addition to the circumstances just named, the irregular distribution of the metalliferous portions of the lode will cause inequality in the workings, and will, with the other matters, render the sinking of one or more shafts indispensable. Again, when the depth becomes very considerable, many of the first shafts are rendered in a great measure useless, either from their being inclined, and thus inconveniently circumstanced for machinery, or from having cut the lode at a shallow depth, and thus requiring cross-cuts progressively, longer in proportion to the increase of the depth and inclination or distance of the lode from the shaft. Hence, in very deep mines, a double line of shafts will often be found to range along the course of the principal veins; and sometimes even three shafts will be found placed opposite each other, and intersecting the same lode successively at increased depths. In such cases, while the most recent shafts are used for drainage and the extraction of the ore and masses of rock, the older and more shallow shafts are often fitted up as footways, and serve for the partial ascent and descent of the miners. In some of the large Cornish mines, it is customary to sink two new shafts within a few fathoms of each other—one being of large dimensions, and intended as a drainage or *engine-shaft*; and the other being smaller, and adapted to the drawing only of ore and *stuff*. Both shafts are united at convenient distances by cross-cuts.



When circumstances permit, mines are entered, as has been stated, by an adit in a hill-side, instead of by shafts. Of this character are the openings into the lead-mines of the north of England, of Derbyshire, and of North Wales, all of which are situated in the carboniferous limestone, and the grits and shales resting upon it. In some valley, where the edges of the strata are exposed to view, a spot is selected from which it may be practicable to drive a level upon the vein itself, and in one of the beds known to be favourable to its productiveness. The progress of such a level explores the vein most efficiently, and opens a convenient passage for the extraction of the ore. In the case of fragmentary deposits, all that is necessary is to turn the debris over with pick and shovel, and make selection of the more promising fragments. The mining of stratified ores, as the clay or carbonaceous ironstone, is conducted precisely in the same manner as coal; but being in thinner layers, the workings are not upon such a costly and extensive scale.

METALLURGY.

Metallurgy—from the Greek *metallon*, and *ergon*, a work—is the art of separating metals from their ores; and as this separation is undertaken only with a view to some economic purpose, the term may be regarded as embracing the whole art of working in metals, from the reduction of the ore, to the ultimate application of the metallic product. With respect to the primary reduction, though heat be the grand agent, yet so different is the treatment of the different ores as to dressing, roasting, smelting with fluxes, the application of amalgams, and the use of even more complicated chemical processes, that what is peculiar in each, will be best adverted to under our notices of the respective metals, which are here tabulated in the order of their specific gravities, taken at 60° Fahrenheit:—

Name.	*Specific Grav.*	*Melting Point.*	*Discoverer.*	*Date.*
Platinum,	20·98	ox. bl.*	Wood,	1741
Gold,	19·26	2016°	Known to the Ancients.	
Tungsten,	17·60	ox. bl.	D'Elhuiart,	1781
Mercury,	13·57	−39°	Known to the Ancients.	
Palladium,	11·35	...	Wollaston,	1803
Lead,	11·35	612°	Known to the Ancients.	
Silver,	10·47	1873°	Known to the Ancients.	
Bismuth,	9·82	497°	Agricola,	1530
Uranium,	9·10	ox. bl.	Klaproth,	1789
Copper,	8·89	1996°	Known to the Ancients.	
Cadmium,	8·60	442°	Stromeyer,	1818
Cobalt,	8·54	2810°	Brandt,	1733
Nickel,	8·98	2810°	Cronstedt,	1751
Iron,	7·79	3480°	Known to the Ancients.	
Molybdenum,	7·40	ox. bl.	Hielm,	1782

* Ox. bl.—Fusible only by the oxy-hydrogen blowpipe.

Tin,	7·29	442°	Known to the Ancients.	
Zinc,	7·92	773°	Paracelsus,	1520
Manganese,	8·05	2960°	Gahn and Scheele,	1774

Gold.

As the most valuable and longest known of the metals, gold deserves to rank first in our catalogue. When pure, it is of a deep and peculiar-yellow colour, rather soft, and extremely heavy, having a specific gravity of 19·3; that is, nineteen times heavier, bulk for bulk, than pure water. It exceeds all the other metals in ductility and malleability; it may be beaten into leaves 1-282,000th of an inch in thickness, and a single grain may be drawn out into 500 feet of wire. Though soft, its fusing-point is as high as 2016° of Fahrenheit; it is unchanged by fire with access of air—the hottest furnace producing no other effect upon it than to keep it in fusion, when it appears of a brilliant greenish colour. It expands during fusion, and contracts in cooling, more than any other metal. It is not acted upon by any of the common acids; but chlorine and nitro-muriatic acid (*aqua regia*) corrode and dissolve it, forming a chloride of gold, which is soluble in water. The metal occurs in greater or less abundance in almost every quarter of the globe, and is obtained either in the native state, from alluvial sands and gravels, or in mineral veins in combination with silver, and often mixed with metallic sulphurets and arseniurets. In the native state it occurs in small crystals, in threads or granular fragments, which, when of a certain magnitude, are called by the name of *pepitas*. The largest known pepita is said to have been found in Peru, its weight being about 20¼ lbs. avoirdupois; but masses have been reported from the province of Quito weighing 50 and 60 lbs.!

The geological formations in which gold occurs are the crystalline primitive rocks, the compact transition strata, the trachytic and trap rocks, and alluvial grounds of the current era. In the three former sources, the ores of the metal are *in situ*; in the latter, it is a travelled or transported product, being carried thither, from the rocks in which it was originally formed, by streams and rivers. In the former case, it is obtained by the difficult and dangerous process of mining; in the latter, the soil or gravel is merely turned over, and the metallic portions (the *gold-dust* of commerce) separated by hand-picking, washings, and siftings. It is thus obtained from *mines* in Brazil, Peru, Mexico, Carolina, Hungary, Transylvania, and the Uralian Mountains; and from *sands* from the Peruvian, Mexican, and Brazilian rivers, the coast of California, several of the rivers of Africa, from the Rhine, Rhone, and Danube, in continental Europe, and in small quantities from Wicklow in Ireland, from Cornwall, and from the Leadhill district in Scotland. With the exception of iron, perhaps there is no metal more generally disseminated than gold; but in comparatively few localities is it sufficiently abundant to repay the cost of mining and collecting. The deposits, for example, in our own country are quite insignificant; that of Wicklow, to be sure, yielded some years ago a few thousand ounces, but is now, we believe, abandoned like all the other localities. It is the new world which yields the great commercial supplies of the precious metals, and which, under more skilful modes of procedure, could readily supply double the amount, and that at little more than the present cost. Of late years, several English companies have attempted improved modes; but the systems of mining, the apparatus, the methods of reduction, are still exceedingly rude and wasteful.

Mr Gardner, who recently travelled in Brazil, describes the gold field of that region, whether in veins or in alluvial deposits, as inexhaustible, but extremely irregular in the amount of production; a vein which, for weeks, had yielded only a few ounces, all on a sudden producing more than 100 lbs. in a single day. The following is the treatment of the ore as practised at one of the most extensive mines he visited. 'The ore is first removed from its bed by blasting, and is afterwards broken by female slaves into small pieces, about the size of the stones put upon macadamised roads, after which it is conveyed to the stamping machine, to be reduced to powder. This machine consists of a number of perpendicular shafts placed in a row, and heavily loaded below with large blocks of iron; these, being alternately lifted up to a certain height by a toothed cylinder, turned by a large water-wheel, fall down upon and crush the stones to powder. A small stream of water, constantly made to run through them, carries away the pulverised matter to what is called the strakes, a wooden platform, slightly inclined, and divided into a number of very shallow compartments, of 14 inches in width, the length being about 26 feet. The floor of each of these compartments is covered with pieces of tanned hide, about 3 feet long and 16 inches wide, which have the hair on; the particles of gold are deposited among the hairs, while the earthy matter, being lighter, is washed away. The greater part of the gold dust is collected on the three upper skins, which are changed every four hours, while the lower skins are changed every six or eight hours, according to the richness of the ore. The sand which is washed from the head skins is collected and amalgamated with quicksilver in barrels, while that from the lower skins is conveyed to the washing-house, and concentrated over strakes of similar construction to those of the stamping mill, till it be rich enough to be amalgamated with that from the head skins. The barrels into which this rich sand is put together with the quicksilver are turned by water, and the process of amalgamation is generally completed in the course of forty-eight hours. When taken out, the amalgam is separated from the earthy sand by washing; it is then pressed in chamois skins, and the quicksilver is separated from the gold by sublimation. In the whole process, the loss of mercury amounts to about 35 lbs. a-month; but up to two months before my visit, it was nearly double that quantity. For a long time the gold dust was extracted from the sand by hand-washing in Bateias, after the Brazilian manner; but the process of amalgamation is found to be superior, requiring less labour, and extracting a larger proportion of gold. The *sillerthal*, or running amalgamation process, similar to that used in the Tyrol, has also been tried here, but was not found to answer, owing to the great loss of quicksilver. The roasting process has also been attempted; but although by this means the ore yields a much larger per centage of gold, the fumes arising from the arsenic were found to be so injurious to the health of the workmen, that it was abandoned.' In different countries different metallurgic processes are adopted; but on the whole, that of stamping and amalgamating seems to be the readiest and most successful. The metallic grains found in the sands of rivers do not require to be subjected to any metallurgic process, in the strict acceptation of that term.

The applications of gold are numerous and important; but in most cases it is used in an alloyed, and not in a pure state. This arises from its softness, and consequent liability to be worn down; the common alloys of copper or silver conferring the necessary hardness, without impairing in any appreciable degree the beauty and lustre of the more precious metal. In this condition it is employed for coin, plate, and a variety of articles of luxury and ornament, for which purposes it has ever been in the highest repute. It is also extensively used in the arts for gilding, conferring on materials often the most worthless the semblance of its own unrivalled beauty. The gold coin of the realm, commonly called *standard gold*, consists of 11 parts pure gold and 1 of copper; it is extremely ductile and malleable, but harder than pure gold, and therefore better calculated to resist the wear and tear of circulation. The colour of this alloy is deeper yellow than that of pure gold, and verges upon orange; 20 lbs. troy of it are coined into 934½ sovereigns; 1 lb. troy, therefore, produces 46 29/40 sovereigns. It sometimes happens that a part of the alloy of gold coin is silver; hence the pale colour of some sovereigns as compared with others. The gold employed by jewellers, &c. is all less or more alloyed; and from the great skill now attained in putting rich surfaces on such alloys, it requires very considerable skill on the part of the purchaser to prevent deception. The art of *gilding* consists in covering other substances with a thin coat of gold, which may be done either by mechanical or chemical means. The mechanical mode is the application of gold-leaf or gold-powder, which is made to adhere by size or varnish; the chemical, by plunging the substances in solutions of gold, or by the electrotype process. The production of *gold-leaf* and *gold-wire* of such extreme fineness as we have mentioned, requires considerable ingenuity; and is all the more readily accomplished the finer the standard of the metal. The former is made by rolling out plates of pure gold as thin as possible, and then beating them between folds of fine vellum (gold-beaters' skin) by a heavy hammer, until the requisite degree of tenuity has been reached; the latter is formed by drawing a cylindrical rod of the pure metal through a series of gradually-decreasing holes punched in a steel plate.

The probable supply and consumption of gold are generally estimated in conjunction with those of silver, the two conjointly forming the 'precious metals' of the economist and statistician. (See p. 375.)

Silver.

This is another of the metals which have been longest known and esteemed, having been extensively employed from the earliest times in the fabrication of articles both of utility and ornament. Every one must be familiar with its peculiar white colour and great lustre; the epithet *silvery* conveying an idea not to be confounded with any other. In malleability and ductility it ranks next to gold, being frequently hammered into leaves 1-10,000th part of an inch in thickness, and drawn into wires finer than the human hair. Its specific gravity is only 10·5, and its fusing point 1873° of Fahrenheit. Silver is a widely-disseminated product of nature, occurring in the metallic or native state in fine threads or strings in various rocks, but chiefly in veins in primitive and secondary mountains. It is found also in combination with other metallic ores, as those of lead, and as a native sulphuret.

Silver, we have said, is very generally distributed; but the great sources of supply are Mexico and Peru in the new world. A considerable supply is also obtained from other parts of South America, from the Uralian Mountains, Austria, and Norway. In Britain it is found in small quantities, associated with lead—as in Derbyshire, at Alston Moor, Leadhills, &c.; and also in veins in the island of Anglesey. Most of the silver mines are situated in high, bleak, desolate tracts, which would never be inhabited by man, unless for the sake of the treasures in the rocks beneath. Those of Peru, for example, are found at an elevation of from 12,000 to 14,000 feet above the sea, in a wild barren region, to which every necessary of life has to be brought from a toilsome and expensive distance; and yet towns like Cerro de Pasco, of 18,000 inhabitants, have there risen into life and activity. The silver veins of Pasco are extremely rich. 'One of them,' says a recent traveller, 'runs nearly in a straight line from north to south, and has already been traced to the length of 9600 feet, and the breadth of 412 feet; another, which takes a direction from east-south-east to west-north-west, and which intersects the former, is known to the extent of 6400 feet long, and 390 feet in breadth. From these large veins numberless smaller ones branch off in various directions, so that a network of silver may be supposed to spread beneath the surface of the earth. Some thousand openings, or *mouths*, are the entrances to these mines. Most of these entrances are within the city itself, in small houses; and some are in the dwellings of the mine owners. Many of them are exceedingly shallow, and not more than five hundred deserve the name of shafts. All are worked in a very disorderly and careless way, the grand object of their owners being to avoid expense. The dangerous parts in the shafts are never walled up, and the excavations proceed without the adoption of any measures of security. The consequence is, that accidents, caused by the falling in of the galleries, are of frequent occurrence; and every year the lives of numbers of the Indian miners are sacrificed.' All the other operations, it would appear, are as rude as the mining: the raising of the ore, the breaking and stamping, the separating of the silver from the dross, are all executed in a very clumsy, imperfect, and at the same time a very expensive manner. 'The amalgamation of the quicksilver with the metal is effected by the tramping of horses! The animals employed in this way are a small ill-looking race, brought from Ayacucho and Cuzco, where they are found in numerous herds. The quicksilver speedily has a fatal effect on their hoofs, and after a few years the animals become unfit for work. The separation of the metals is managed with as little judgment as the amalgamation, and the waste of quicksilver is enormous. It is computed that on each mark of silver half a pound of quicksilver is expended. The quicksilver, with the exception of some little brought from Idria and Huancavelica, comes from Spain in iron jars, each containing about 75 lbs. weight of metal. In Lima, the price of these jars is from 60 to 100 dollars each, but they are occasionally sold as high as 135 or 140 dollars. Considering the vast losses which the Peruvian mine owners sustain by the waste of quicksilver, and the defective mode of refining, it may fairly be inferred that their profits are about one-third less than they would be under a better system of management.' Within the last few years, however, a number of English companies have been drawn to South America, and, in consequence, mining has received a new impetus, and attention has been directed to the adoption of a more speedy and less expensive system of amalgamation. The different modes of refining and working the metal are too numerous, and, in general, too complicated, to be here alluded to.

The numerous uses and applications of silver are well known. In its pure state it is too soft for coin, plate, and most ornamental purposes; but alloyed with copper in proper proportions, it becomes hard, without being materially impaired in colour. The *standard silver* of British coin is an alloy of 11 oz. 2 dwt. of pure silver, and 18 dwt. of copper, to the pound troy; and this weight is coined into 66 shillings. In the arts, silver is extensively used, particularly for silvering or plating other metals; and for this purpose, silver-leaf and solutions of silver are applied much in the same way as in gilding. The oxide of silver is used for colouring porcelain; and the iodides and nitrates are the ingredients upon which the new processes of Daguerreotype and Calotype mainly depend. The only pure acids which act upon silver are the nitric and sulphuric, producing respectively nitrates and sulphates of considerable importance. The nitrate, for example, is the strongest and most manageable caustic known in surgery, being applied as a common black wash, or as *lunar caustic*, which is merely the nitrate melted, and run into moulds after evaporation. A solution of two drachms of the nitrate of silver in an ounce of water, coloured by a little sap green or Indian ink, forms the marking ink of the laundress; and when a nitric solution of silver is mixed with alcohol, a violent effervescence ensues, and *fulminating powder* is produced. This powder is one of the most dangerous compounds known, exploding with violence upon the slightest friction of hard bodies, or when struck, rubbed, or heated. It is used in the preparation of lucifers, percussion-caps, Congreves, and the like.

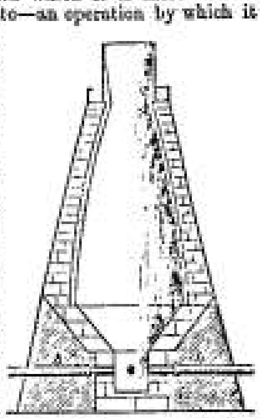
Respecting the supply of the precious metals—gold and silver—Mr M'Culloch reckons the total available annual produce of the South American and Mexican mines at £5,600,000; of the United States, £100,000; the European, £750,000; and the Russo-Asiatic, £2,600,000—making in all £9,050,000. The total annual consumption he sets down at £6,050,000—namely, for the United Kingdom, £2,500,000; France, £1,000,000; Switzerland, £450,000; the rest of Europe, £1,600,000; and North America, £500,000. Commenting on the future supply of these metals, the same authority remarks, 'that there are not merely probable, but good grounds, on which to anticipate a large future increase of the annual produce of the mines and washings in most parts of the world. The late increase of the latter in Russia has been quite extraordinary; and if it should go on for any considerable period, it would have a powerful influence over the value of gold, and would not only sink it as compared with silver, but as compared with all other things not produced with the same increased facilities. It is reasonable, also, to suppose that the produce of the South American mines should be gradually increased. The anarchy which has so long disgraced and desolated the country cannot continue for ever; and means have lately been taken for reducing the price of quicksilver, the high cost of which has latterly contributed more than anything else to paralyse the efforts of the miners.'

Iron.

Every person knows, or ought to know, says a high authority; the manifold uses of this truly precious metal. It is capable of being cast into moulds of any form; of being drawn out into wires of any desired strength or fineness; of being extended into plates or sheets; of being bent in every direction; of being sharpened, hardened, and softened at pleasure. Iron accommodates itself to all our wants, our desires, and even caprices; it is equally serviceable to the arts, the sciences, to agriculture, and war; the same ore furnishes the sword, the ploughshare, the scythe, the pruning-hook, the needle, the graver, the spring of a watch or of a carriage, the chisel, the chain, the anchor, the compass, the cannon, and the bomb. It is a medicine of much virtue, and the only metal friendly to the human frame. The ores of iron are scattered over the crust of the globe with a beneficent profusion, proportioned to the utility of the metal; they are found under every latitude and every zone, in every geological formation, and are disseminated in every soil. It has also been well remarked by another authority, that he who first made known the use of iron may be truly styled the Father of Arts and Author of Plenty.

The metal thus eulogised is of a peculiar gray colour, and strong metallic lustre, which is capable of being heightened by polishing. In ductility and malleability it is inferior to several of the metals, but exceeds them all in strength and tenacity. At common temperatures it is hard and unyielding; it is, too, one of the most infusible of metals, its fusing point being 3480° of Fahrenheit; but this disadvantage is counterbalanced, for all practical purposes, by its possessing the property of *welding* in high perfection. Iron is not a dense metal, its specific gravity being only 7·78. When exposed to air or water, it absorbs oxygen with rapidity, and becomes an oxide, or rusts. It is attracted by the magnet, and may itself be rendered permanently magnetic. It is found *native* in very small quantities; but, as already stated, its ores, amounting to about twenty in number, are all but universally diffused. Of these ores, about ten are worked by the miner either for the sake of the metal they contain, for use in their native state, or for some principle (as sulphur, arsenic, chromic acid, and the like) which they contain. The chief metal-yielding ores are—the red oxides of iron, included under the name of red hæmatite; the brown hæmatite of the mineralogist; the black oxide, or magnetic iron ore; and protocarbonate of iron, either pure, or in the form of clay iron ore. The three former occur in veins or nests in primary formations, and supply the finest kinds of iron, as those of Sweden and Hindoostan; while clay ironstone, from which most of the British iron is extracted, occurs chiefly in the coal formation, imbedded in the clays and shales, either in bands or nodules.

The forms in which the metal commonly appears in the arts are cast iron, malleable iron, and steel; substances of such immense and varied importance, that a short outline of their nature and mode of production cannot fail to interest the intelligent reader. The ore being brought from the mine, and broken into fragments, the first process is that of roasting or calcining it in the open kilns, in order to drive off the water, sulphur, and arsenic, with which it is more or less combined in its native state—an operation by which it loses one-sixth of its weight. The roasted ore is then transferred to the blast-furnace, which is usually a large pyramidal building, with arched openings at each side for the insertion of the blast pipes. Of late years, blast-furnaces have been built of a round shape, called the cupola furnace, which form is by many preferred. The inside is either cylindrical or square, widening from the top to near the bottom, when it is suddenly contracted, and terminates in the hearth or crucible in which the metal is received.



The blowing pipes, *b b*, as shown in the accompanying sectional drawing, are situated a little above the hearth on each side, and the air is forced into the furnace by means of an engine adjoining the furnace. Into this furnace the ore, or *mine*, as it is called, is put, along with coke as the combustible agent, and lime to act as a flux. By the combustion of the coke an intense heat is raised, which softens the ore; the limestone combines with the earthy ingredients of the ore, and the metallic particles fall down into the hearth or crucible. When it is properly fused, a tap-hole is opened in the crucible, and the metal is allowed to run out from time to time, and conducted into moulds formed of sand, for the various articles made of cast iron; or it is conveyed into channels for the *pigs*—the form in which cast iron is sold as a raw material, and the produce of which averages in Britain about 60 per cent. The term *pig iron* was given by the workmen: the metal being run off from the furnace in a main channel, which they call the *sow*, and the bars at right angles to it, like *pigs* attached to the teats of their mother. The quality of pig iron depends upon the nature of the ore and fuel employed; but it is common to divide it into foundry iron and forge iron—the former being adapted for castings, the latter for malleable purposes.

To convert pig into *bar* or malleable iron, it is first refined, an operation chiefly conducted in the 'puddling-furnace,' by exposure to a strong heat, while the melted metal is diligently stirred, and a current of air plays upon its surface. By this means any undecomposed ore is reduced, earthy impurities rise to the surface as slag, and carbonaceous matter is consumed; and the more thorough the separation of these, the better the iron. As the purity of the metal increases, its fusibility diminishes, until at length, though the temperature remain the same, the iron becomes solid. It is then, while still hot, beaten under the 'forge hammer,' or subjected to the operation of rolling, by which its particles are compacted, and its tenacity greatly increased. By these several processes the metal is converted from a fusible, hard, and brittle substance, to a tough and elastic bar, which is hardly fusible; and which, from its property of yielding and altering its form under the hammer, has acquired the name of *malleable* iron. There are various qualities of malleable iron, according to the processes followed; and what is strange, the most perfect processes will not bring the iron of one district up to the same standard as another, nor will the forging of one season be equal, even from the same furnace, with the forgings of another season.

Bar iron is converted into *steel* by being exposed to the action of heat, in contact with carbonaceous matter. Steel is thus a peculiar stage of iron, depending on the quantity of carbon which it contains, though we are unable to give a criterion for that quantity. Pig iron contains more carbon than steel, and steel about 1 per cent. more than wrought iron. Steel is therefore an intermediate step in the transition of pig to wrought iron. It has consequently been produced by melting these substances together; by which means the pig iron has imparted to the wrought iron so much of its carbon, as would serve to reduce it to a kind of steel. There are three kinds of steel—blistered steel, shear steel, and cast steel. *Blistered steel* is made by placing alternate layers of wrought iron and carbon in a furnace exposed to considerable heat. The steel thus made is found to contain small bubbles or blisters, and the process is termed 'conversion' or 'cementation.' *Shear steel* is made by choosing proper pieces of blistered steel, about three feet long, and 1½ inch square. Half-a-dozen of these are heated in a box with a flux, such as sand or clay, to the required pitch. These being hammered under a tilt, are welded into what is called single shear; the process performed over again gives double shear steel. This article, properly prepared, and cast into ingots, becomes *cast steel*. Before the introduction of Heath's process (which consists in smelting shear steel with an admixture of carburet of manganese), all which was to be worked into a fine edge, was made of iron procured from one mine only—that of Dannemara in Sweden. It was consigned to one house at Hull, at a cost of £38 per ton, and in quantities not exceeding 1100 tons per annum. Since the adoption of Heath's process, steel having all the beauty of cast steel, and all the welding advantages of shear steel, can be manufactured from any sort of iron, at a rate not exceeding £15 per ton.

The most remarkable, as well as the most useful of the properties of steel, is the power which it has of changing permanently its degree of hardness and elasticity by being *tempered*—that is, by undergoing certain changes of temperature. No other metal, says Thenard, is known to possess this property, and iron itself acquires it only when it is combined with a minute portion of carbon. If steel is heated to redness, and suddenly plunged in cold water, it is found to become extremely hard, but at the same time it is too brittle for use. On the other hand, if it be suffered to cool very gradually, it becomes more soft and ductile, but is deficient in strength. The process of tempering is intended to give to steel instruments a quality intermediate between brittleness and ductility, which shall insure them the proper degree of strength under the uses to which they are exposed. For this purpose, after the steel has been sufficiently hardened, it is partially softened, or let down to the proper temper, by heating it again in a less degree, or to a particular temperature, suited to the degree of hardness required, after which it is again plunged in cold water. Different methods have been pursued for determining the temperature proper for giving the requisite temper to different instruments. One method, which answers sufficiently well in practice, is to observe the shades of colour which appear on the surface of the steel, and succeed each other as the temperature increases. Thus at 430° of Fahrenheit, the colour is pale, and but slightly inclining to yellow: this is the temperature at which lancets are tempered; at 450°, a pale straw colour appears, which is found suitable for the best razors and surgical instruments; at 470°, a full yellow is produced, suitable for penknives, common razors, &c.; at 490°, a brown colour appears, which is used to temper shears, scissors, garden hoes, and chisels intended for cutting cold iron; at 510°, the brown becomes dappled with purple spots, which show the proper heat for tempering axes, common chisels, plane irons, &c.; at 530°, a purple colour is established, and at this degree the temper is given to table-knives and large shears; at 550°, a bright blue appears, used for swords and watch-springs; at 560°, the colour is a full blue, and is used for fine saws, augers, &c.; at 600°, a dark blue, approaching to black, has become settled, and is attended with the softest of all the grades of temper, used only for the larger kinds of saws.

The uses of these three substances—cast iron, malleable iron, and steel—are so numerous and varied, that it would be impossible, even within the limits of our sheet, to give anything like a satisfactory detail. In one or other of its forms, iron is now employed for almost every purpose to which wood, or any of the other metals, can be applied in the arts of civilised life. In agriculture, architecture, ship-building, the fabrication of machinery, railways, the construction of implements and utensils either for the objects of war or peace, and in the formation of all those articles which come under the designation of *hardwares*, its importance is pre-eminent—conferring upon Britain a wealth, power, and pre-eminence which, but for the presence of her coal and iron, she could never have attained. But though iron is thus important, abundant, and common, it is by far the most difficult of the metals to bring into a state fit for use; and the discovery of the methods of working it seems to have been long posterior to the use of gold, silver, and copper. At what time it began to be made in this country, there is no means of ascertaining: iron-works are said to have been established by the Romans in the Forest of Dean in Gloucestershire; but be this as it may, it is not till a comparatively recent period that the manufacture began to assume anything like a national importance. 'Down to the seventeenth century,' we quote the Cyclopædia of Commerce, 'the ore was entirely smelted with charcoal; and there was a considerable number of furnaces in those districts where wood and iron were plentiful, particularly the Weald of Kent, Surrey, and Sussex; but in course of time, wood-fuel becoming scarce, the trade was threatened with decay. Many attempts were made during the seventeenth and early part of the eighteenth century, to retard the decline by the use of pit-coal, but without effect; the simple hand-worked bellows, or the more powerful water-movement, which produced a sufficiency of blast for charcoal, having little effect upon coal; and the number of furnaces, which in 1619 was estimated by Lord Dudley (who in that year obtained a patent for smelting with coal) at 300, fell off towards the middle of the eighteenth century to 59. Science, however, came to the rescue of one of our greatest staple manufactures. In 1760, Smeaton erected a cylinder blasting-machine for the Carron Company, which, after some improvements, enabled the same furnace that formerly yielded 10 or 12 tons weekly, to produce 40. Shortly after this, Watt's improvement of the steam-engine, and its application to iron-works, not only revived the trade, but enabled it to distance all foreign competition. Ores that formerly could not be worked with profit, either from their inherent intractableness, or from the small proportion of metal they contained, were now advantageously submitted to the furnace, and more metal was extracted from the richest ores. Various improvements also took place in the manufacture of bar iron, particularly by the substitution of hammering machinery for hand labour; by Mr Cort's invention of "puddling" (1783)—the great distinction of coal-made iron—and also by that gentleman's patent (1784) for the rolling of iron; while at the same time the extent of the iron-works was greatly enlarged, and improvements made in the form of the furnaces. Of recent inventions, by far the most important is the substitution of the *hot* for the cold blast, by artificially heating the currents of air impelled into the furnace. This discovery of Mr Neilson of the Clyde Iron-Works, operates by obtaining a larger quantity of metal with a less degree of fuel. In 1829, with cold air, 1 ton of iron consumed 8 tons 1 cwt. of coal; in 1833, with hot air, the same quantity of iron was procured with only 2 tons 5 cwts. of coal.'

The result of these successive improvements and inventions presents the statistician with some of the most astonishing facts in the history of British manufactures. In 1740, the quantity of iron made in the United Kingdom did not exceed perhaps 25,000 tons; after the cylinder invention, it rose in 1796 to 124,879; in 1802 it was estimated at 170,000; in 1823 it rose to 702,584; in 1839 to 1,512,000; and at the present time it cannot fall much short of 2,000,000 tons! It is true that the trade is subject to rapid and extensive fluctuations, the production rising and falling to the amount of several thousand tons, and the price ranging from £6 to £14, or even higher, a ton; but the immense demand now made by railways both at home and abroad—by ship-building, bridge-building, and the like—is not likely to suffer any considerable decline for several years to come. The other countries producing iron to any extent are—France, Belgium, Sweden, Saxony, Austria, Spain, and the United States; the whole furnishing an aggregate supply somewhat less than that of Great Britain, though in the last-mentioned country the trade has increased prodigiously since the application of the hot-blast to American anthracite has proved successful. At home, the chief seats of the iron trade are—Staffordshire, Shropshire, South Wales, Yorkshire, Derbyshire, and Lancashire in England; Lanarkshire and Stirlingshire in Scotland; in Ireland there are no iron-works of importance. The manufacture of hardwares, machines, engines, iron-steamers, locomotives, &c. is now more generally diffused throughout the country, though Birmingham and the towns around it still maintain their supremacy in general hardwares; Sheffield in cutlery;* Manchester, Glasgow, and Dundee, in machinery; Glasgow and Liverpool in ship-building; and Carron in cannon and other heavy castings. At present (1847), the annual value of this metal, including under that term every form of cast and malleable iron, may be safely estimated between nine and ten millions; while the annual value of hardware, manufactured partly from iron and other metals, is not less than eighteen millions. This last estimate is exclusive of watches, plate, jewellery, &c. which are valued by Mr Jacobs at somewhere about three millions.

Copper.

This was one of the earliest known of the metals, and not less extensively used than known by the nations of antiquity; its tenacity and durability rendering it the best substitute for iron, ere man had learned to reduce that valuable but more refractory metal. It derives its name from the island of Cyprus, where it was extensively mined and smelted by the Greeks, who employed it, either pure, or in an alloyed state, in the fabrication of their domestic utensils and implements of war. It is a metal of a beautiful red colour, and considerable lustre, very malleable and ductile, but more capable of being hammered into leaves than drawn into wire. In tenacity it yields to iron, but surpasses gold, silver, and platinum—a wire of only 1-10th of an inch being strong enough to support a weight of 300 lbs. Its specific gravity is about 8·9, and its fusing-point 2000° Fahrenheit—that is, nearly a white heat. It is found occasionally in a native state in films, strings, or amorphous masses, but in no considerable quantity. The most remarkable masses of native copper hitherto dis-

* The English cutlery manufacture is very extensive, and is excelled by that of no other country, though now nearly approached by that of Belgium. We append the following account from Bigelow's 'Technology' in illustration of what may be termed one of the *ultimate applications* of the metal now under description:—'The inferior kinds of cutlery are made of blistered steel welded to iron. Tools of a better quality are manufactured from shear steel, while the sharpest and most delicate instruments are formed of cast steel. The first part of the process consists in forging, and is varied according to the kind of article to be formed. Common *table-knives* have the blade forged of steel, and welded to a piece of iron, out of which the shoulder, and part which enters the handle, are made, the shape being given to them by hammering in a die and swage. They are afterwards tempered and ground. *Forks* are made by forging the shank, and flattening the other end to the length intended for the prongs. The prongs are made by stamping the metal at a white heat between two dies, the uppermost of which is attached to a heavy weight, and falls from a height. The shape is thus given to the fork, leaving, however, a flat thin piece of metal between the prongs, which is afterwards cut out with a fly press. They are subsequently filed, pointed, bent, hardened, and polished.

Blades of *penknives* are forged from the end of a rod of steel, and cut off, together with metal enough to form the joint. The small recess in which the nail is inserted to open the knife, is made with a curved chisel while the steel is hot. *Razors* are forged from cast-steel, much in the same manner as knives. The anvil is commonly a little rounded at the sides, for the purpose of making the sides of the razor a little concave, and the edge thinner. In forging *scissors*, the shape is given to the different parts by hammering them upon different indented surfaces called "bosses." The bows, which receive the finger and thumb, are made by punching a hole in the metal, and enlarging it by hammering it round a tool called a "beak" iron. The halves are finished by filing and grinding, and afterwards united by a joint. *Saws* are made from steel-plates rolled for the purpose, and have their teeth cut or struck by a machine, finished by filing, and set by a suitable instrument. *Axes, adzes*, and other large tools, are forged from iron, and have a steel-piece welded on of the proper size, to form the edge.

To enable the steel to be wrought, it is brought to its softest state; but after the shape is given to the instrument, the steel is hardened and tempered by the methods already described. The remaining part of the manufacture consists in grinding, polishing, and setting the instrument, to produce a smooth surface and a sharp edge. The *grinding* is performed upon stones of various kinds, among which freestone is perhaps the most common. These stones are made to revolve by machinery, and move with prodigious velocity, so that the surface, in some cases, passes over six or seven hundred feet in a second, and stones have been burst by their own centrifugal force. For grinding flat surfaces, like those of saws, the largest stones are used; while for concave surfaces, like the sides of razors, smaller stones are used, on account of their greater convexity. The internal surfaces of scissors, forks, &c. which cannot be applied to the stone, are ground with sand and emery, applied with instruments of wood, leather, and other elastic substances. The last polish is given by a material composed chiefly of the oxide of iron. The edges are lastly *set* with hones and whetstones, according to the degree of keenness required. The test used by cutlers for determining the goodness of the edge and point of a lancet is, that it shall pass through a piece of soft leather without sensible resistance. *Needles* are polished by tying them in large bundles with emery and oil, and rolling them under a heavy plank till they become smooth by mutual attrition. The shape is previously given, and the eye made with a steel punch.

covered are said to be one in Brazil, which weighed about 2620 lbs., and another in the bed of a stream to the south of Lake Superior, which measured not less than 15 feet in circumference! The great source of the commercial supply is, as in the case of the other metals, from ores, of which the most common and productive are copper pyrites—that is, copper in certain combinations with sulphur and other metallic impurities. In this state it is found in almost every mineral district in beds—as the *kupfer-schiefer*, or copper-slate, of Germany—but more commonly in veins in primitive and secondary mountains. Copper mines are largely worked in England, Chili, Cuba, Germany, Sweden, and Siberia; less extensively in France, Spain, Hungary, and Norway; and recently, with great promise, in the southern parts of Australia.

The English mines, says an authority already quoted, were scarcely worked prior to last century; they are chiefly situated in Cornwall, where the most common ore consists of copper, iron, and sulphur, in nearly equal proportions, and is called yellow copper ore, or copper pyrites; veins are also worked in the counties of Devon, Anglesea, and Stafford. Owing to the want of fuel in Cornwall and Devon, the ores, after being dressed—that is, ground and sifted—are shipped from these counties to South Wales, to be calcined and smelted, principally to works situated on the navigable rivers of Swansea and Neath; the smaller quantity of material being thus carried to the greater, while the vessels load back with coal for the use of the mining steam-engines. The reduction of the ore is a tedious and complex process. 'It is first roasted in a reverberatory furnace, by which much of the sulphuret of iron is converted into oxide, while the sulphuret of copper remains unaltered. The product of this operation is then strongly heated with siliceous sand; the latter combines with the oxide of iron to a fusible *slag*, and separates from the heavier copper compound. When the iron has, by a repetition of these processes, been got rid of, the sulphuret of copper begins to decompose in the flame-furnace, losing its sulphur, and absorbing oxygen; the temperature is then raised sufficiently to reduce the oxide thus produced by the aid of carbonaceous matter. The last part of the operation consists in thrusting into the melted metal a pole of birchwood, the object of which is probably to reduce a little remaining oxide by the combustible gases thus generated.' The quantity of copper yielded by the ore is commonly about 8 or 9 per cent.; and the fuel consumed ranges from 15 to 18 parts for every part of metal produced.

The quantity of copper mined in Britain in 1820 amounted to 8127 tons; now it is considerably more than double that quantity, and valued at little short of £2,000,000. This supply is more than sufficient for the demand of the United Kingdom; hence considerable shipments in pigs, sheets, nails, wires, &c. are made to the East Indies, China, United States, West Indies, Brazil, Canada, and Holland. Besides the produce of British mines, considerable quantities of ore have of late been imported from Chili, Cuba, and Australia. All this, however, is likely to be materially affected by the recently patented process of smelting the ore by electricity—a process which is said to effect in a couple of days what formerly required the labour of three weeks! The saving of fuel, besides, will be so vast, that, in Swansea alone, the smelters estimate their annual saving in coals at no less than five hundred thousand pounds. Hence it is clear that the price of copper must be so enormously reduced, as to bring it into use for a variety of purposes from which its cost at present excludes it. The facility and cheapness of the process, too, will enable the ore to be largely smelted on the spot. The Cornish mine proprietors are anxiously expecting the moment when they can bring the ore which lay in the mine yesterday into a state to be sent to market to-morrow, and this at the very mouth of the mine. In Australia, also, the operation of this discovery will be of the utmost importance. Ten thousand tons of copper ore were sent from Australia to England in 1846, to be smelted at Swansea; and the result was only 1600 tons of copper. But Australia in future will smelt her own copper by a 36 hours' process: saving all this useless freight of the 8400 tons of refuse, and saving also the cost of the old and expensive process of reduction.

The uses of copper are numerous and highly important, the metal ranking next to iron in real commercial value. It is used, as is well known, for coin, for sheeting or sheathing the bottoms of vessels, for boilers, and a great variety of implements and utensils; in the manufacture of blue and green colours; and in medicine. Alloyed with zinc, it forms *brass* and *pinchbeck*—the former containing from 28 to 34 per cent. of zinc. In the formation of brass, the zinc may either be added directly to the melted copper, or granulated copper may be heated with calamine and charcoal powder. *Gun-metal*, a strong and valuable alloy, consists of 90 parts copper and 10 of tin; *bell* and *speculum metal* contain a much larger proportion of tin, and are consequently brittle and less durable. A good *bronze* for statues is made of 91 parts copper, 2 parts tin, 6 parts zinc, and 1 part lead. The bronze of the ancients was an alloy of copper and tin; and the *argentane* or German silver of the moderns is a compound of copper, tin, and nickel. *Or-molu* is the name given to a particular alloy of 52 parts zinc and 48 copper; and the *Bidery-ware* of India—so called from a town of that name—is a compound of copper, lead, tin, and zinc, rendered black by immersion in a solution of sal-ammoniac, saltpetre, common salt, and blue vitriol. All these alloys are of infinite use, entering into the fabrication of almost every species of machinery, implement, utensil, and ornament—from the drawing, pointing, and heading of a pin, or the stamping of a button, to the casting of a statue, or the founding of a ponderous field-piece. Though thus vieing with iron in its applicability to the purposes of civilised life, its salts and solutions, unlike those of that metal, are highly poisonous; hence the frequent evils arising from the use of neglected or ill-cleaned culinary utensils of copper. Water containing copper in solution is changed into a bright blue by the addition of a little hartshorn or liquid ammonia; and by immersing a piece of polished steel in any liquid containing copper, the surface will soon become coated with a film of the latter metal.

What is called *bronzing* is a method of colouring wood, iron, plaster of Paris, or other material, so as to imitate bronze, but which has, in reality, little connection with that alloy. The process is thus indicated in Webster's Cyclopædia: 'First, the article is to be painted of a dark colour, such as bronze acquires when it has been very long exposed to the air, or when buried under ground. This colour is produced by grinding a mixture of Prussian blue, verditer (a precipitate of oxide of copper with lime), and spruce ochre in oil. What is called *bronze powder*, sold in the shops, is now to be applied, just before the oil-paint is quite dry, to the prominent parts, where the metal is supposed to have acquired some lustre by being rubbed against. The bronze powder may be laid on by a ball of cotton wool, or in a similar manner.' Bronzing thus effected is now much in request; it has the advantage of wearing well, keeping clean, and giving effect to other colours. *Lacquering* is a somewhat allied process, and consists in applying a peculiar varnish either to brass-work, to prevent its tarnishing, or to give tin and articles covered with silver-leaf the appearance of brass. The ingredients of such a varnish are wholly non-metallic, consisting chiefly of turmeric, anotto, saffron, gum-lac, amber, and the like, dissolved in alcohol.

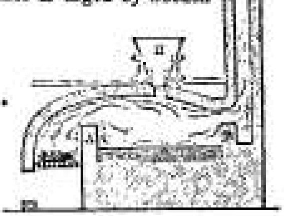
Lead.

This is another of the metals which have been long and extensively used in the arts of civilised life. It has a grayish-blue colour, with a bright metallic lustre when newly cut, but soon tarnishes, and assumes a dull earthy aspect on exposure to the air. Its texture is close, like that of gold and silver; its specific gravity is about 11·45; and it is very malleable and ductile, but soft and unelastic. It is one of the least sonorous of the metals; melts at the low degree of 610° Fahrenheit; soils the fingers when rubbed; and emits a peculiar odour. Though readily oxidised by exposure to the air, the oxidisation does not proceed far; hence its durability for roofing, and other external purposes. 'Perfectly pure water,' says Brande, 'put into a clean leaden vessel, and exposed to the air, soon oxidises and corrodes it, and delicate tests discover oxide of lead in *solution* in the water; but river and spring water exert no such solvent power. Hence it is that leaden cisterns are used with impunity for the preservation of common water; and that the crust which forms upon the metal effectually prevents all further action. As this crust partly consists of carbonate of lead, which is very poisonous, great care should be taken to prevent its diffusion through the water upon any occasion, as by scraping or cleaning the cistern.' Natural water, highly charged with carbonic acid, cannot, however, under any circumstances, be kept in lead, or passed through leaden pipes with safety.

Fourteen or fifteen ores of lead are known to mineralogists; but that of *galena*, a sulphuret of the metal, is the only one occurring in sufficient quantities to become an object of mining and metallurgy. It is found but sparingly in the primitive crystalline rocks, more plentifully in the transition schists and slates, and most abundantly in the transition and mountain limestones. The principal lead-mining countries are Britain, Saxony, Bohemia, and other states of Germany; Spain, France; and Missouri in the United States. The lead mines of Britain are of great importance; and those of Derbyshire are said to have been worked prior to the Roman invasion. The most productive at present are situated in Northumberland, Cumberland, Durham, Derbyshire, Flintshire, Isle of Man, and at Leadhills in Scotland. Nearly the whole produce is derived from galena, in the proportion of about 85 per cent. of pure metal.

When lead ore comes from the mine, the first operation is to wash and sort it into heaps of different qualities; this is done either by putting the ore into a trough, and stirring it, or filling a sieve, the meshes of which are made of iron, and immersing it in a vat full of water. Another process is to put the ore upon a *grid* or screen, which consists of a number of bars of iron placed parallel to each other, about an inch apart. Over this grating a stream of water flows, which washes away all impurities, and also separates the small pieces of ore from the large. The smaller pieces are then collected into a finer sieve, and washed again, and all pure ore which may still be amongst them is carefully picked out with an iron scraper or *crimp*. This washing is greatly facilitated by the specific gravity of the metal. The ore containing most galena sinks first, and is found next the bottom of the vat; a second quality of ore will be found on the top of this, and the inferior kinds above it. When the sieve is immersed in the water, it is shaken pretty severely, which causes the ore in a manner to float, and allows the heavier pieces to sink to the bottom. The mixed ore—that is, such as contains stone and other impurities in the lump, along with pure galena—is then sent to the grinding-mill. This consists either of a series of stampers, which pound the ore, or of a pair of fluted cylinders, through which the ore is made to pass: it is afterwards ground to the requisite fineness by smooth rollers. The mixed ore, after being ground, is again washed, and the pure galena separated from the impurities.

There are two kinds of furnaces used in the smelting of lead ore—a reverberatory furnace, (see fig.), called a *cupola*, and the other known by the name of the *Scotch furnace*. The former, in the interior, is generally 8 feet long, 6 wide, and 2 high at the centre. The fire is placed at one extremity, and is separated from the smelting part by a wall, A, which is built about half the height of the furnace. The hearth upon which the ore is placed is composed of furnace slags, and it slopes from the wall which separates it from the fire to the other end, B, of the furnace, and is hollowed from the sides to the centre. This is enclosed by an arched roof, in the middle of which is a small aperture for admitting the ore from a hopper, H, placed above it. The Scotch furnace is much of the same nature as the above, except that the hearth, sides, and sole-plate are made of cast-iron, from two to three inches thick. The roasting is performed with peat and coke, and the furnace is urged by wooden bellows. About 20 cwts. of ore are usually put into the furnace at a time, which is spread equally over the hearth with a rake. For the first two hours no regular fire is made, a gentle heat merely being kept up by putting small coal on the furnace, the doors of which are kept shut. This is called the roasting process, which is performed principally for the purpose of dispelling all sulphureous vapours from the ore. At the end of two hours the fire is raised, and the metallic lead soon begins to flow from the ore. The smelter and his assistant now stir the ore at intervals, and a shovelful of quicklime is thrown in. This is done in order to liberate the oxide of lead from the ore, and allow it to react upon any sulphuret which may have resisted the roasting. The heat is again increased, and the stirring continued. In about four hours from the commencement the furnace receives its greatest heat, after which a tap-hole is opened, and the lead runs into an outer basin. From this it is cast in semi-cylindrical moulds, and receives the name of *pigs* or bars.



Metallic lead is employed for numerous purposes in the arts:—rolled into *sheets*, it is used for roofing, lining of cisterns, tea-boxes, &c.; cast into *pipes*, it is employed for conducting of water, gas, and the like; and alloyed with arsenic, and dropped through perforated trays from lofty towers, it forms *shot* of various sizes. Alloyed with tin in different proportions, it constitutes *solder* and *pewter;* and with antimony and tin, it forms *type* and *stereotype metal*. Combined with oxygen, it constitutes *massicot*, a protoxide of a pale yellow colour; *litharge*, also a semicrystalline protoxide, obtained in separating silver from lead ores, enters largely into the composition of flint-glass; *red-lead*, a deutoxide, is extensively employed as a pigment, and also in the manufacture of flint-glass; *white-lead*, a carbonate of the metal (See 'CHEMISTRY,' p. 302), is a well-known paint; as is also the beautiful yellow chromate; while the acetate of lead, commonly known as *sugar-of-lead*, is employed for various purposes in the arts and in medicine.

In the reduction and application of lead to the above purposes, a considerable amount of mechanical and chemical ingenuity is required. Thus in the preparation of sheet-lead, a plate is first cast, and then subjected to successive 'millings' between heavy rollers, which extend and reduce it to the desired thickness. The thickness is regulated by screw-work, which keeps the rollers apart, so as to produce a sheet varying from half an inch to the thinness of the finest writing-paper. Still greater ingenuity is exhibited in pipe-drawing. A 'plug,' or thick short pipe, is first cast in a mould; a mandril, or steel rod, of the desired bore is inserted in this pipe, which is then drawn by machinery through a succession of gradually-decreasing holes on a steel-plate or die. 'In producing a two-inch pipe, no fewer than sixteen dies are employed, the diameters of which descend in a regular series. The hole through the die is conical—that is, larger on one side of the die than on the other; and the lead enters the hole at the widest part, whereby a process of compression is undergone; but at a certain point in the operations a 'cutting die' is introduced—that is, one wherein the lead is at once exposed to a cutting edge, the result of which is, that a thin film is cut or scraped from the whole surface of the pipe.[1] The elongated pipe is now removed from the mandril, coiled up, and sent to the plumber. We have stated that shot is formed by dropping an alloy of lead and arsenic through perforated trays or colanders, from the top of lofty towers, into a cistern of water beneath; the same result is more economically obtained by dropping the metal from the surface to the bottom of some waste coal-shaft, as is done at Newcastle. The perforations of the colanders are of sizes ranging from 1-5th to 1-20th of an inch in diameter; and on passing through these, the melted metal assumes a globular form, cools partially in falling, and ultimately settles in the cistern in drops less or more spherical. These are next assorted by being passed through sieves, which retain all imperfect forms; and still further by being passed over an inclined plane of polished iron, when the well-shapen shot descend with an impetus sufficient to carry them into a trough at some distance from the end of the incline, while the imperfect forms travel slowly, and drop 'dead,' as the workmen express it, almost over the verge of the plane. The dark glossy hue of shot is obtained by churning it with powdered black-lead in revolving cast-iron barrels, a process which also assists in producing a still more spherical form. Leaden bullets are cast in moulds; but all the former modes of casting, cutting, and rolling shot are now abandoned. None of the chemical preparations of lead involve any peculiar difficulty either in their manufacture or application. The only contingent evil is their poisonous character, which manifests itself more or less on the constitutions of painters, plumbers, white-lead-makers, and the like. Lead indeed is a metal requiring very cautious use in any form, and ought to be avoided in the manufacture of all culinary, dairy, brewing, and other utensils employed in the preparation of human food.

The amount of lead annually smelted in Britain is estimated at 60,000 tons or thereby; which, at the present price, would make the value of the produce little short of £1,000,000 sterling. About 15,000 tons are annually exported, partly in pigs, and partly in sheet, shot, red-lead, and litharge.

Tin.

Tin was known to the ancient nations of the Levant, who obtained it chiefly from Spain and Britain. It is a white brilliant metal; has a slight taste and smell when rubbed; is malleable to a considerable degree, but is inferior in ductility and tenacity. Its hardness is intermediate between that of gold and lead; its specific gravity is about 7·3; it melts at 442° Fahrenheit, and at a white heat takes fire and burns with a bright flame. It oxidises but slowly on exposure to air and moisture; hence its value in coating or tinning more oxidisable metals, as iron. Tin is rather a rare metal; and is principally found in primitive rocks, where it occurs chiefly in veins, but partly also disseminated, and in beds. There are only two ores of the metal known—the double sulphuret, which is rare; and the native peroxide, from which the commercial supplies of the metal are obtained.

This latter ore is found abundantly in Cornwall and the western district of Devonshire; in Germany, Bohemia, and Hungary; in Chili and Mexico; and in Malacca and Banca in the East Indies. The tinstone of Britain is chiefly obtained from mines; but considerable quantities are sometimes discovered in alluvial soils—the debris of rocks in which the ore was originally imbedded. Repeated washings, by means of running water, being the chief process by which the ore is separated from such debris, the name of *stream work* is commonly applied to this method of obtaining it. On one occasion, the water being excluded from a branch of Falmouth harbour, a bed of rounded masses of tin ore, from two to ten feet thick, was found fifty feet below a bed of alluvium—£50,000 is said to have been made by this discovery.

The ore, in whatever way obtained, is first broken into small fragments, then pounded in stamping-mills, washed, sifted, and roasted. It is next reduced by smelting with coal and a flux of lime, under a very strong heat, which is kept up for eight or nine hours. The liquid tin, on being run off from the slag, is still mixed up with iron, arsenic, and other impurities, and has to undergo fresh smeltings, after which it is cast into granite moulds capable of containing about 3 cwts. each. In this form it is known as *block* or *bar-tin*—a term generally used in contradistinction to *grain-tin*, which is obtained from stream-ore, somewhat differently treated. After the stream-tin ore has been dressed and pounded, it is smelted with wood-charcoal, run off into iron vessels, and there kept liquid by a gentle heat, till, by repeated agitation with pieces of charcoal, all impurities are expelled. It is finally removed by ladles, and poured into small moulds. The grain or stream-tin so obtained is of superior quality, and is employed by dyers, and for the finer purposes.

The uses of tin are both numerous and important. Besides being employed in the formation of a variety of utensils, it is largely used in *tinning* copper and iron-plate, to protect them from rust—an art which originated in Saxony, and was made known in Britain about two centuries ago. It consists in carefully cleaning the surface of the plate with sal-ammoniac, or with muriatic acid, rubbing it well, and then immersing it in melted tin, by which it acquires a thin and equable coating. Vessels are coated internally by heating them, pouring in a certain quantity of melted tin, and then rotating them, so that the tin may come in contact with every part of the surface. Alloyed with antimony, copper, bismuth, and lead, tin forms *pewter;* it enters into the composition of *bell-metal, type-metal,* and *solder;* it is used in the process of enamelling; in silvering, or rather tinning, looking-glasses (see p. 330); in coating pins; by dyers and calico-printers as a *mordant* when solved in muriatic acid; largely in the form of *foil* or leaf, which is made by beating; its oxide is much used in polishing, under the name of *putty-powder;* and the *purple of Cassius*, so called from its inventor, is a union of protochloride of tin with perchloride of gold.

The annual produce of the British tin mines is estimated at 4000 tons, worth from £65 to £80 a ton. About 1500 tons of unwrought tin are annually exported, principally to France, Italy, and Russia; and this, exclusive of tin, pewter-wares, and tinplate, to the value of £400,000 yearly, sent to the United States, Italy, Germany, France, the colonies, &c. The amount of crude tin brought from the East is very variable, ranging generally between 500 and 1500 tons per annum.

Mercury or Quicksilver.

This is a well-known metal, of a brilliant silver-white colour, fluid and mobile at ordinary temperatures; hence the name *live*, or *quick*, silver. In this property of fluidity, it differs from all other metals—never being solid, unless when subjected to a degree of cold equal to 40° below zero. In this condition it has been obtained by arctic explorers, who, under extreme depressions of temperature, found their barometers and thermometers useless, and who, for curiosity's sake, have shot bullets of it from their muskets. When solid, it is found to be malleable, a fact of no practical importance, however, as it instantly passes into the fluid state on being brought under a higher temperature than — 40°; it boils and vaporises at about 660° Fahrenheit. Its specific gravity is about 13·57; thus ranking above all other metals, with the exception of platinum, gold, and tungsten. It is found native in small quantities—that is, in minute dewy globules; but for commercial purposes it is always extracted from the ore called *cinnabar*. This ore is a bisulphuret of the metal, of a red colour (except in the hepatic variety, which is gray), massive and crystallised, occurring in veins, and distributed variously through the matrix of the veinstone. It is found but sparingly in the primitive rocks; the principal deposits of the mercurial ores being, in all parts of the world, in the middle secondary strata; that is, in the upper portions of the coal-measures, and in the magnesian limestone and new red sandstone. In these formations the ore occurs either in irregular veins, or is combined with the sandstones, bituminous schists, and indurated clays.

The most productive mines of cinnabar are those of Almaden, near Cordova in Spain, of Idria in Austria; and of Huancavelica in Peru, at an elevation of 14,500 feet above the sea. Quicksilver is also produced in several of the Chinese provinces, and sparingly in one or two localities in Rhenish Bavaria, Bohemia, and Hungary. The mines of Idria, which were discovered in 1497, yield annually about 150 tons of the pure metal; but could readily supply four times that amount, were it not for certain absurd restrictions imposed upon the produce by the Austrian government. The veins at Almaden, which range from 12 to 20 feet in thickness, have been worked for nearly three thousand years; at all events, Pliny records that the Greeks imported red cinnabar from Spain seven hundred years before the Christian era, and that Rome in his time annually received 700,000 pounds from the same province. At present, the produce of metal may be from 1100 to 1200 tons, giving employment to upwards of 4000 miners and smelters. The usual method of reducing the ores is by distillation. The minerals brought out of the mine are broken up, picked by women and children, pulverised, and sometimes washed. In some places the richer ores are separately burnt; but it is more usual, and considered more economical, to mix the richer with the poorer ores, and expose the whole mass together to the action of heat in closed retorts, which also contain a certain proportion of limestone. The retorts, filled with the mixture of ore and limestone, are ranged, to the number of twenty or more, in recesses of a furnace; and heat being applied, each retort is made to communicate with a vessel of water, in which the vapours of the mercury are condensed. In the mines of Idria a ruder method is adopted; the ores are roasted in a kind of oven, and the vapours ascend into condensers, where the little drops of mercury collect, and are conducted into a porphyry vessel placed to receive them.

The imports of mercury into this country, chiefly from the mines of Almaden, are about 2,300,000 pounds annually, of which little more than an eighth are retained for home consumption. The remainder is re-exported, principally to South America, Mexico, the United States, and the East Indies; while smaller shipments are made to Russia, Belgium, and other countries. During the war, when the intercourse between Europe and America was interrupted, the price of quicksilver rose to such a height in the latter country that it answered to import it from China; but since the peace, this traffic, we believe, has been abandoned. From the peculiar character of the metal, it is transported either in iron bottles, in small leathern bags, or, as from China, in short joints of the bamboo. Mercury is often adulterated by an admixture of lead, bismuth, zinc, and tin; in which state it is less lustrous, becomes covered with a whitish film, and is not so mobile, or readily divisible into minute globules.

Mercury is principally employed for *amalgamation* with other metals, chiefly gold and silver, so as to extract them from their ores; and it is almost solely for this purpose that it is imported into South America and Mexico. It is used also in gilding, in silvering mirrors, in filling thermometer and barometer tubes, in various philosophical apparatus; and in chemistry it furnishes the only means of collecting, in the pneumatic trough, such gases as would be absorbed by water. In medicine it is employed in several forms: the whitish insipid powder termed *calomel* is the protochloride of mercury; and the acrid, nauseous, white substance known as *corrosive sublimate* is the bichloride. This sublimate has recently been extensively applied as an antiseptic in the prevention of the dry-rot in timber, in the mildewing of sailcloth, and the like (See No. 47). Mercury is also used in the making of *vermilion*, that beautiful pigment being prepared from an artificial cinnabar, composed of 8 parts of mercury and 1 of sulphur. When sulphur and mercury are triturated together in a mortar, the former gradually disappears, and the whole assumes the form of a black powder, denominated *ethiops mineral*; if this powder be heated red-hot, it sublimes, and on a proper vessel being placed to receive it, a cake is obtained, of a fine red colour, which, when reduced to powder, forms the vermilion of commerce. An amalgam of mercury and silver is generally used by dentists for stopping hollow and decayed teeth.

Antimony.

This metal was discovered by Basil Valentine in 1490, and has since been extensively employed in medicine, in the composition of printing types, stereotype plates, music plates, and the like; and also in the manufacture of the white metal utensils now so generally used as substitutes for silver. When pure, it is of a silver-white colour, is brittle, has a specific gravity of 6·7, and melts readily at a red heat. When heated in open crucibles, it gradually combines with the oxygen of the atmosphere, and flies off in the form of a white vapour. It is the oxide, or rather oxides of the metal (for there are several) which are used in medicine, their general effects being purgative, sudorific, and emetic. The metallic ore of commerce contains sulphur and other impurities, and is much more easily fused than the pure metal, which has a hardness about that of gold. Its tenacity is also considerable—a wire of 1-10th of an inch in diameter being capable of supporting a weight of 10 lbs.

Antimony ore is found at Rosenau in Hungary, in Saxony and the Hartz, in Spain, France, Siberia, Mexico, the Indian Archipelago, and in Cornwall and Ayrshire in our own island. As yet the ore has been imported into this country chiefly from the East; but the recently-discovered veins in Ayrshire are likely soon to yield the main supply. It is usually of a lead-gray colour, is crystallised, possesses considerable splendour, and is very apt by the uninitiated to be mistaken for an ore of lead. *Crude* antimony is the name given in commerce to the sulphuret of the metal, after being separated from the impurities of the ore by fusion with charcoal; and *regulus* of antimony is the pure metal, after being separated from the sulphur, by being mixed with tartar and exposed to heat. The powder of the sulphuret is very black, and was employed by women in ancient times to stain their eyebrows and eyelids.

Antimony is never applied to any useful purpose as an independent metal, in consequence of its brittleness and liability to corrosion; but it forms several valuable and extensively-employed alloys. Thus, alloyed with lead, in the proportion of 2 to 6, and a small addition of copper, it constitutes the metal used for printing types; mixed with lead alone, the compound forms the rather brittle plates upon which music is engraved; and an alloy of 112 lead, 18 antimony, and 2 block tin, forms the stereotypes from which the present sheet is printed. These alloys have the property of expanding as they cool: the consequence of which is, that the types come out of the moulds with sharp and well-defined edges. Hard pewter is made of 12 parts of tin and 1 of antimony; and the Britannia or white-metal spoons and teapots now so much in use are composed of 100 tin, 8 antimony, 2 bismuth, and 2 copper. Antimony also unites with iron, forming a hard whitish alloy; and the smallest portion entering into the composition of gold, renders that otherwise soft and ductile metal brittle and unmalleable. The manufacturer of pastes or factitious gems employs the oxide of antimony to give colour to his so-called beryls, Oriental topazes, and yellow diamonds. Six parts dry nitrate of potash, two sulphur, and one sulphuret of antimony, reduced to a fine powder, form the blue or Bengal light used as a signal at sea.

Bismuth.

This metal, known to Agricola in 1530, is of a brittle crystalline texture, brownish-white in colour, nearly 10 in specific gravity, and fusible at the temperature of 497°. Its hardness is between that of copper and lead; it is scarcely malleable, breaks under the hammer, and cannot be drawn into wire. Bismuth is by no means a common metal, and is usually obtained in a combined state in Cornwall, France, Bohemia, Saxony, and Sweden. As met with in commerce, it is generally mingled with impurities of iron, arsenic, or other metals.

It is used as a *flux*—that is, for communicating fusibility to other metals; *solder*, for example, consisting of 1 bismuth, 5 lead, and 3 tin—an alloy which melts at a lower temperature than lead. It is also employed in the formation of some kinds of pewter, printers' types, and various metallic mixtures. Eight parts of bismuth, 5 of lead, and 3 of tin, constitute the fusible metal, sometimes called Newton's, from its discoverer, which melts at little more than 200°, or under the heat of boiling water, and may be fused over a candle in a piece of stiff paper, without burning the paper. A small addition of mercury aids the fusibility; and such alloys are sometimes used in taking casts of anatomical preparations. Bismuth forms the basis of sympathetic ink; and the powder called *pearl-white*, used in medicine, is obtained from the nitrate of the metal, which, when dropped into water, falls down in that form. The nitrate has also been employed as a mordant for lilac and violet dyes in calico-printing. Some of its forms seem likewise to be employed in the preparation of cosmetics, for a story is told of a lady, who, on visiting one of the watering-places in Germany, emerged from the bath as a 'lady of colour,' the chemical action of the mineral water having turned almost to blackness a cosmetic containing bismuth, which had been previously applied to the face.

Zinc.

Though known as early as the beginning of the sixteenth century, the numerous and important applications of zinc, or *spelter* as it used to be called, are for the most part of very recent date. Its distinguishing characteristics are, bluish-white colour and lustre; specific gravity 7; at common temperatures, tough and intractable; but heated to between 220° and 320° Fahrenheit, it becomes malleable and ductile, so that it may be hammered out, rolled into sheets, and even drawn into wire of such tenacity, that 1-10th of an inch in diameter is capable of sustaining a weight of 26 pounds. Heated beyond that point—say between 400° and 500° Fahrenheit—it again becomes so brittle, that it may be reduced to powder in a mortar. It melts at 700°; and heated beyond this, it takes fire in the open air, and burns with a brilliant bluish flame. The metal is obtained from two ores—namely, *calamine*, a native carbonate; and *blende*, a native sulphuret. These ores occur in two geological positions—namely, either in the carboniferous or in the magnesian limestone, associated with galena, and sometimes with the ores of cadmium.

Zinc ores are found in Britain, especially in Flintshire, Derbyshire, and Cumberland; but the quality of the British metal is inferior to that of Germany, from whence, via Hamburg, about 170,000 cwt. are annually imported, commonly as ballast for ships bringing wool. Of this amount, about one-half is kept for home consumption, and the remainder for exportation, chiefly to India, which, previous to 1820, obtained her supply from China. 'These ores,' says Brande, 'are roasted and mixed with charcoal; the mixture is put into a kind of crucible, closed at top, and perforated at bottom by an iron tube, which passes through the grate of the furnace into water; and the vapour of the zinc distils downwards through the tube, and is condensed in the water. The first portions are impure, containing arsenic, and often cadmium, in which case the vapour burns with what the workmen call a *brown blaze*; when the *blue blaze* appears, the zinc is collected.' The above is the English method of reduction; in Germany and the Netherlands the principle is much the same, but somewhat differently applied.

Zinc being a cheap and light metal, its specific gravity varying from 6·8 to 7·9, and one which, when superficially oxidised, long resists the further action of air and water, it is now employed as a substitute for lead in lining cisterns and baths, covering roofs, forming water-spouts, and the like. It has also been used of late in the manufacture of kitchen and dairy utensils, but not without doubt as to its being deleteriously acted upon by the presence of acids. It is likewise wrought into buttons, and other small wares; and zinc-plates have been a considerable while in use in the transfer of printing, under the title of *zincography*. Its sulphate and oxide are employed in medicine; and with copper it forms, as already described, the well-known alloy, brass. Though the action of water upon zinc be scarcely appreciable, after it has once been coated with the oxide, yet the addition of a little acid (as sulphuric) dissolves and removes this coating, and further oxidation proceeds with rapidity. It is this action which renders zinc so powerful a generator of electricity in the voltaic pile or battery. (See VOLTAIC ELECTRICITY, pp. 265-8.)

Cobalt.

Cobalt, discovered by Brandt more than a century ago, is a reddish-gray brittle metal, somewhat soft, fusible at a temperature a little below that required for the fusion of iron, of 8·5 specific gravity, and possessing magnetic properties. The finest ores are found in Saxony, where it received its name (*kobold*, a devil); a term applied to it by the miners, who considered it unfavourable to the presence of the more important metals. It is never employed in the arts in the metallic or separate state; but the impure oxides of the metal, called *zaffre* and *smalts*, are extensively used as colouring materials.

Thus the oxide of cobalt is an invaluable article in the manufacture of porcelain and pottery, all the blue colours of which are derived from that substance. When fused with glass, it communicates a blue tint to that material, without impairing its transparency; and what is especially valuable, this colour is not impaired by very high temperatures. So great is the colouring power of oxide of cobalt on vitrifiable substances, that 1 grain gives a full blue to 240 of glass! Cobalt blue, or Thenard's blue, is a beautiful pigment, prepared from the phosphate of cobalt, and now largely employed by decorative painters, and sometimes by artists, as a substitute for ultramarine. Smalts, of which we annually import about 146,000 lbs., are prepared principally in Norway and Germany, by melting oxide of cobalt with siliceous earth and potash. *Zaffre*, of which we import more than double that amount, is manufactured chiefly in Saxony and Prussia.

Nickel.

This metal, discovered by Cronstad in 1751, is of a brilliant white colour resembling silver; ductile and malleable, and capable of receiving a high polish; specific gravity about that of cobalt. It is difficult of fusion, but melts at a lower temperature than iron: it undergoes little or no change by exposure to air and moisture. According to Brande, it is found in all meteoric iron; but its principal ore is a copper-coloured mineral found in Westphalia, and called *kupfer-nickel*, nickel being a term of detraction used by the German miners, who expected from the colour of the ore to find that it contained copper. The cobalt ores are the most fruitful sources of this kupfer-nickel, or speisse, which is reduced to the metallic state by roasting, dissolving, evaporating, and other processes. Alloyed with copper, nickel forms argentane, or German silver; and since this compound became an object of commercial importance, the extraction of the metal has been undertaken upon a considerable scale. It is also employed in potteries, and in the manufacture of porcelain. It is, to a certain degree, susceptible of magnetism, and mariners' compasses may be made of it. The alloys of nickel, from their whiteness, hardness, and infusibility, form excellent bases for the manufacture of electro-plate.

Manganese.

This is a very brittle metal, of a dusky white colour, and without either malleability or ductility, having a specific gravity of 7. The substance known in commerce under that name, however, is the peroxide, or the black oxide of the metal. It occurs native in the Hartz Mountains, in Piedmont, in the Mendip Hills in Somerset, and the counties of Devon and Aberdeen. It is found in a variety of forms: most commonly it is of an earthy appearance, and mixed with other ingredients; but sometimes in crystals of a black colour and metallic lustre. This mineral was described by Scheele, in 1774, as a peculiar earth; but in the same year Gahn showed that it was the oxide of a true metallic substance. The metal separately is of no known use, but the peroxide, as a source of oxygen, is largely employed in the decomposition of common salt for the production of chlorine for bleaching. It is also used by potters and glass-makers as a glaze or pigment; and lately it has been used in calico-printing as the source of certain brown colours. Still more recent investigations have shown that a certain proportion of manganese added to steel manufactured from British iron, produces a cast-steel nearly equal to that obtained from Swedish iron. From its cheapness, peroxide of manganese is now the only substance used by the chemist for the production of oxygen gas for experimental purposes. The ore of manganese, known in England by the name of *black wadd*, is remarkable for its spontaneous inflammation with oil. The pure metal can only be kept in closely-stoppered bottles, under naphtha, like potassium; because, when in contact with air, it is rapidly oxidised, and falls into a dark brown powder.

Arsenic.

This metal, discovered by Brandt in 1733, is exceedingly brittle, of a strong metallic lustre and white colour, running into steel-gray. Its specific gravity is 5·9; it volatilises, emitting a strong odour of garlic before it fuses, at a temperature of 365°, and is readily inflammable. The pure metal, however, being very soft, is of little value, and is not used in the arts. It is the softest of all the metallic bodies, and so brittle that it may be easily reduced to a very fine powder by trituration in a mortar. The arsenic of commerce is the white oxide of the metal, or, more accurately, *arsenious acid*—a compound which is obtained chiefly in Bohemia and Saxony, in roasting the cobalt ores for making zaffre, and also by sublimation from arsenical pyrites. In this state it is generally met with in cakes, brittle, white, faintly sweetish in taste, and more or less translucent; for medicinal purposes, these cakes undergo sublimation, in order to get rid of sulphur and other impurities. In the shops it is usually sold in the form of a white smooth powder, not unfrequently adulterated with chalk or gypsum—an adulteration, however, which can be easily detected by burning a little, when the arsenic volatilises, and the additions remain.

Arsenious acid, though one of the most virulent poisons, is used in medicine, forming a notable ingredient, for example, in what are called ague drops. It is also employed as an ingredient in *Scheele's green* and other dyes, in the manufacture of flint-glass, and by candlemakers, to impart to their candles a white and waxy appearance. With sulphur, arsenic forms two compounds, known in commerce by the names of *realgar* and *orpiment*; the former a red sulphuret found in Bohemia and Saxony, and used as a pigment, as well as in pyrotechnical compositions; and the latter a yellow sulphuret, found native in China, South America, &c. and produced artificially in Saxony, and employed in dyeing and calico-printing. The finer native varieties are reserved for artists.

With respect to the poisonous qualities of arsenic: 'When it has been taken in large doses,' says Mr Brande, 'it produces violent spasmodic pains of the stomach and bowels, attended by a sense of heat and constriction in the mouth and throat, an increased flow of saliva, tightness about the head, itching of the face and neck, and nausea. These symptoms are succeeded by vomiting and purging, and excruciating pains; the pulse, at first full, hard, and frequent, sinks, and becomes irregularly feeble; and clamminess of the skin, cold sweats, purple spots, and convulsions, precede death. Should the patient escape this catastrophe, it often happens that hectic fever, paralysis, and mental and bodily debility, attend him for the remainder of his days. It is often said that the bodies of persons poisoned by arsenic are very prone to putrefaction; but this does not appear to be always the case. After death, the stomach and bowels are usually found inflamed, but often slightly so; and it appears, from Sir Benjamin Brodie's observations, that this poison kills by some peculiar action upon the heart and nervous system. The treatment of persons thus poisoned consists in promoting the vomiting by an emetic, composed of a solution of twenty grains of sulphate of zinc in two ounces of water, aided by copious draughts of warm barley-water or gruel; but the most effective means of getting rid of the arsenic is by the use of the stomach-pump, which, when immediately resorted to, has often saved the patient. The only ready means of ascertaining the presence of white arsenic is by heating the suspected substance upon a red-hot coal, or in the flame of a candle, when it will emit the peculiar arsenical odour resembling that of garlic; but the treatment of persons poisoned by arsenic, and its detection in doubtful cases, must be left to the medical man and the chemist. It is impossible too strongly to represent the evil which results from the unfettered sale of arsenic, and from the unwarrantable use of it as a poison for rats, and as a veterinary remedy; for it is thus that it finds its way into culinary vessels, gets accidentally mixed with articles of food, and that bottles which have contained it are used for beer, wine, and other beverages. Its sale should be rigidly prohibited by all save regularly qualified druggists.'

Platinum.

Platinum, or platina, was unknown in Europe till about the middle of the last century, when it began to be imported in small quantities from South America. It is of a whitish silvery colour; hence its name, from the Spanish word *plata*, silver. It is the heaviest, the most difficult of fusion, the most ductile, and the most flexible of the known metals, having a specific gravity of 21·0, and capable of being hammered into leaves, or drawn into wires, of extreme tenuity. Its hardness is intermediate between that of copper and iron; and though very infusible, it is malleable, and capable of being welded at a white heat, either one piece to another, or to a bit of iron or steel. It is not in the least affected by the action of air or water, and is not attacked by any of the pure acids; but is dissolved by chlorine and nitro-muriatic acid. In scarcity, beauty, ductility, and indestructibility, it is thus hardly inferior to gold. When a perfectly clean surface of platinum is presented to a mixture of oxygen and hydrogen gas, it has the extraordinary quality of causing them to combine, so as to form water, and often with such rapidity as to render the metal red hot.

As already stated, platinum was discovered about 1741; but it attracted little notice until the mode of purifying it, and rendering it malleable, was discovered by Dr Wollaston. It is found in the metallic state in Brazil and Peru; at Antioquia in South America; in Estremadura in Spain; and latterly, in considerable quantities, in the Uralian Mountains. Its appearance, in the rough state in which it is imported, is that of small grains or scales, of a metallic lustre, darker than silver, and extremely heavy. In this state it is combined with palladium, rhodium, titanium, iron, gold, or other metals. The particles are seldom larger than a pea, but pieces have been found as large as a hazel-nut; and in 1831, a mass of native metal was discovered in Demidoff's gold mines in Russia, weighing upwards of 20 lbs.!

The perfection with which vessels of platinum resist the action of heat and air, of most of the acids, and of sulphur and mercury, renders them peculiarly valuable in many chemical applications; so that, notwithstanding the high value of the metal which is between four and five times its weight of silver, it is now much employed for crucibles, retorts for the distillation of sulphuric acid, mirrors for reflecting telescopes, by gunsmiths, and others. Its property of being welded, either one piece with another, or with iron and steel, admits of many useful applications in the arts. From its scarcity and indestructibility, it has been proposed to use it for coinage; and we believe coins of the respective values of 3, 6, and 20 silver roubles are now current in the Russian empire.

Palladium.

This rare substance was discovered in 1803 by Dr Wollaston, when experimenting on the ores of platinum, which it greatly resembles in colour and lustre. A native alloy of gold with palladium is found in Brazil, and imported into England. The pure metal is ductile and malleable, has a specific gravity of 11·5, and its fusibility is intermediate between that of gold and iron. It is oxidised and dissolved by nitric acid; its properties, however, are yet imperfectly known, nor is it, so far as we know, applied to any economical purpose, unless sometimes for the graduated scales of astronomical instruments. The Wollaston medal of the Geological Society of London is very appropriately made of palladium.

Rhodium.

Rhodium, so called from the Greek word *rhodon*, a rose, on account of the red colour of some of its salts, was discovered in 1803 by Dr Wollaston, associated with palladium in the ore of platinum. It is of a whitish colour, difficult of fusion, and extremely hard and durable, with a specific gravity somewhat less than that of palladium. It forms valuable alloys with the other metals, particularly steel, and would be extensively employed in the arts, could it be obtained in abundance. As an alloy with steel, it has been used for the points of metallic pens.

Chromium.

Chromium—from the Greek word *chroma*, colour—discovered by Vauquelin in 1797, is a metal resembling iron in colour, brittle, and difficult of fusion. It is rarely to be found in its metallic state; but several of its compounds, as chromate of iron, and chromate of lead, are well known in commerce. The former, a compound of oxide of chrome with protoxide of iron, is found in Unst in Shetland, in France, and near Baltimore in America. It appears massive, or in crystals of a dark colour and imperfect metallic lustre. It is employed in the manufacture of chromate of potash, a yellow salt, largely manufactured for the use of calico-printers. Chromate of lead is found native in the gold mines of Beresof in Siberia, in the Ural Mountains, and in Brazil, and is easily prepared, by mixing chromate of potash with a soluble salt of lead. It occurs massive and crystallised, of a deep orange-red colour; but when reduced to powder, it becomes orange-yellow. It forms an excellent pigment, and is used both in oil and water colours, in calico-printing, and in dyeing. The other compounds chiefly in use are the *oxide of chromium*, employed to give a green colour to glass and to porcelain; and *chromic acid*, which, from its property of destroying most vegetable and animal colouring matters, is advantageously employed in calico-printing. It is this acid which gives colour to the ruby; and the green of the emerald is owing to the oxide of chroma.

Cadmium.

This metal was discovered by Professor Stromeyer of Gottingen about the beginning of 1818. It occurs chiefly in Silesia, combined to the extent of between 2 and 11 per cent. with several ores of zinc, and is reduced to the metallic state by a somewhat complicated process of solutions and precipitations. The pure metal has the colour and lustre of tin, and is susceptible of a fine polish. It is soft, easily bent, filed, and cut, and soils like lead any surface rubbed with it. It is harder and more tenacious than tin, and emits a creaking sound, when heated, like that metal. It is very ductile, and may be drawn out into fine wire, and hammered into thin leaves without cracking at the edges. Its specific gravity is somewhat less than 9; it is very fusible, melting at a point much below redness. Its scarcity prevents its employment in the arts; but its oxide and sulphuret, which respectively produce fine brown and orange-yellow colours, are said to be used as pigments. The sulphate of cadmium has been applied to the eyes for removing specks of the cornea.

Vanadium.

Vanadium, from *Vanadis*, a Scandinavian deity, was discovered so recently as 1830 by Professor Sefström of Fahlun, in iron prepared from the iron of Jubberg in Sweden. It has also been detected in a lead ore from Wanlockhead in Scotland, and in a similar mineral from Zimapan in Mexico. 'Vanadium,' we quote Dr Ure, 'is white; and when its surface is polished, it resembles silver or molybdenum more than any other metal. It combines with oxygen into two oxides and an acid. The vanadate of ammonia, mixed with an infusion of nutgalls, forms a black liquid, which is the best writing ink hitherto known. The quantity of the salt requisite is so small, as to be of no importance when the vanadium comes to be more extensively extracted. The writing is perfectly black. The acids colour it blue, but do not remove it, as they do tannate of iron: the alkali, diluted so far as not to injure the paper, does not dissolve it; and chlorine, which destroys the black colour, does not, however, make the traces illegible, even when they are subsequently washed with a stream of water. It is perfectly fluent, and being a chemical solution, stands in want of no viscid gum to suspend the colour like common ink. The influence of time upon it remains to be tried.'

Osmium—Iridium—Tungsten, &c.

On account of their rarity, the remaining metals—osmium, iridium, tungsten, molybdenum, &c.—have not as yet been applied to any economical purpose. Even were they less rare, so far as their properties have been determined, they would not afford any advantage which may not be obtained by the use of the ordinary metals. As elementary substances, the reader will find details of their history, nature, and properties in the article 'Chemistry.'

The Metalloids.

This term is given to a class of substances which are undoubtedly metallic, but which cannot be kept in that state unless carefully excluded from the action of air and water. They are the rare and scanty products of the laboratory, and are of themselves of little practical value; but united with oxygen, they form the *alkalies*, *alkaline earths*, and *earths* so important in the operations both of nature and of human economy. They are the triumphs of modern chemistry, which has already determined the existence of fourteen, and hinted the probability of others. Those known are—potassium, sodium, lithium, barium, strontium, calcium, magnesium, aluminium, glucinium, yttrium, erbium, terbium, zirconium, and thorium. An account of the nature and properties of these substances has been given under 'Chemistry;' and the principal earths and alkalies of which they form the bases have been described in the sheet devoted to 'Mining and Minerals.'

THE STEAM-ENGINE.

The apparatus which, after numerous improvements by Watt and others, has assumed its complete form of a *Steam-Engine*, and has been universally adopted as a convenient and economical means of impelling machinery, is dependent on the properties of water and heat for its source of power. It seems necessary, therefore, that a preliminary account of these properties should be given, embracing some notice of the different kinds of fuel which are employed to convert the water into steam. These being understood, the reader will be better prepared to follow a description of the various parts which enter into the construction of the engine, taken in the widest sense of the word, and the mode in which these are arranged so as to obtain the maximum of power, in their application to machinery, navigation, locomotion, and the like.

PROPERTIES OF WATER—STEAM.

Water, which forms the grand agent in the steam-engine, is not a simple substance, but consists of two elements (see Chemistry), the natural condition of which, when free under the ordinary circumstances of our globe, is uniformly gaseous. These two distinct elements are oxygen and hydrogen; which combining together in the proportion of one by bulk of the former, with two by bulk of the latter, constitute the compound *water*. But water, as it is found in nature, though it is essentially composed of the gases now mentioned, does not consist solely of these, inasmuch as whether it be taken from springs, from lakes, from the sea, from rivers, from melted snow or ice, or from rain, or from any other source, it contains other substances held in solution, and which affect its character—rendering it, indeed, often totally unfit for those purposes to which it is usually applied. When freed from these substances—which may be accomplished by careful distillation—the water is considered by chemists as *pure*.

The substances which are dissolved by the water, and which render it impure, are either solid—such as lime, magnesia, and iron; or gaseous—such as the elements of the air, oxygen and nitrogen, and carbonic acid. The proportion of solid matter varies considerably. In the waters of the sea which surrounds our shores, the amount of solid matter is estimated at about 3½ per cent.; while in river water, which has been allowed to settle or precipitate its mechanical impurities, the proportion is often less than one or even one-half per cent. The quantity of gaseous matter varies, but not so much as that of the solid matter. In rain water, there is usually noticed 2½ per cent. of atmospheric air, but in which the usual proportion between the oxygen and nitrogen is not preserved, as there is 32 of oxygen out of the 100, the remainder being nitrogen, whereas 21 is the proportion of oxygen in atmospheric air. Carbonic acid gas also is found in water; and notably so in that of certain mineral springs.

On boiling the water, these gaseous bodies are set at liberty, and the solid substances, such as the compounds of lime, are deposited, and form thick incrustations on the boiler. It is only the pure matter of oxygen and hydrogen—the actual water, as it may be termed—which is required in the working of the steam-engine; the other substances, whether aëriform or solid, being not only useless, but even injurious. It will be seen that there are particular contrivances devised in the structure of the steam-engine to remove these.

Water is a fluid at ordinary temperatures, but may become *solid* on the one hand, or *aëriform* on the other, by changes in the amount of caloric (heat) with which it is supplied. These two remarkable changes in the condition of water occur at specific temperatures: it becomes solid at 32° Fahrenheit, and passes off in the state of vapour or steam when the temperature is raised to 212°. On the fluid being cooled down to 32°, it becomes ice—this temperature being named the *freezing point* of water. When the temperature is increased so that the thermometer indicates 212°, or the *boiling point*, the water becomes steam or vapour, assuming that condition in which its elastic force is applied to act as a moving power.

On the water passing off in this new form or condition, two very remarkable phenomena take place—namely, the fluid expands to a very great extent, the vapour occupying nearly 1700 times the space which the fluid occupied from which it was generated; and at the same moment an immense quantity of caloric or heat enters into the water while becoming steam, and disappears—which heat, from the circumstance that it cannot be discovered by the thermometer, is usually termed *latent*, in contradistinction to that which affects the thermometer, and which is accordingly designated *sensible*.

When the water has assumed the state of vapour, it is invisible, being as perfectly transparent as atmospheric air; and in this form it becomes obedient to those laws which affect gaseous or aëriform bodies, supposing always that the usual increased temperature is maintained (212° Fahrenheit) to preserve it in this new state; for on withdrawing the caloric, it then returns or *condenses* to its liquid inelastic condition. This elastic state of the vapour may be suddenly destroyed by bringing it in contact with a large quantity of cold water—a process essentially a part of the greater number of steam-engines. In this state of vapour the temperature is 212°, or the same as that of the water from which it is generated. This may be easily determined by placing a thermometer in boiling water, and then in the steam which arises from it.

Under the usual conditions in which water is made to boil, as in an open vessel on the fire, the temperature indicated by the thermometer is commonly about 212°, the water acquiring at that temperature sufficient elastic force to overcome the weight of the atmosphere. But it is to be observed that the pressure of the air must tend to retard the water expanding into vapour: it will follow, therefore, that if we reduce the pressure on the surface of the water, the escape into the state of vapour will take place at a lower temperature, as was first observed by Dr Cullen, and subsequently more minutely detailed by the late Professor Robison. The latter has, indeed, established the general proposition, that vapours are produced from fluids *in vacuo* (where all atmospheric pressure is removed) at 140° of Fahrenheit below the temperature at which these fluids naturally pass into vapour, under the usual pressure of the air. Water, for instance, which usually boils at 212°, in this case would boil at 72°—a temperature of the atmosphere frequently observed in the summer months of this country; and ether, which boils at 96°, a temperature nearly corresponding with that of the human body (being lower only by 2°), *in vacuo* would boil at 44° below zero, or at a temperature lower than that which would suffice to render mercury solid.

The thin aërial fluid called the *atmosphere*, or commonly the air, is a distinct material substance surrounding the globe, and possessing considerable weight. That the air is actually a material substance, may be easily shown by connecting a thin glass flask, provided with a good stopcock, with the exhausting tube of an air-pump. The air can in this manner be withdrawn, and the flask will be found to weigh less than before. One hundred cubic inches of air, when perfectly dry, weigh, according to the very careful investigations of

Dr Prout, 31·0117 grains; the temperature of the air being 60° Fahrenheit, and the pressure of the air, as indicated by the barometer, being equal to 30 inches of mercury. If, instead of air (the oxygen and nitrogen which constitute the atmosphere), an atmosphere of mercury were to envelop the globe, which would have the same weight as the air, it would be about 30 inches above the level of the sea; and if, in like manner, instead of the air, the fluid water were substituted, it would be nearly 34 feet above the level of the sea. Hence we say that the pressure of the air is equal to a column of mercury 30 inches in height, or to a column of water 34 feet high; or, in other words, whatever extent of surface we have, the pressure of the atmosphere is equal to the pressure or weight of 30 inches of mercury, or of 34 feet of water, over a similar surface.

The amount of this pressure, estimated by the extent of surface, is as 14·67 lbs. on the square inch, or nearly 15 lbs. In other terms, the weight of air pressing on a square inch is 15 lbs., and the weight of the column of mercury is 15 lbs., and the weight of the column of water is also 15 lbs. That is, the column of air, whose basis is exactly a square inch, extending from the surface of the globe to the highest or extreme range of the atmosphere (nearly forty-five miles), is equivalent to the column of mercury which is only thirty inches in height, or to a weight of 14·67 lbs. It is this weight, then, which the water has to overcome before it can pass into vapour. The greatest pressure of the atmosphere will be at the surface of the earth; and as we ascend above the sea level, this pressure will gradually decrease, less air being above us, and in a corresponding ratio the atmospheric volume will become thinner or more rare.

By attending to these circumstances, we perceive that when the pressure is lessened, water boils at a lower temperature than 212°; and therefore that we have not merely to consider the temperature to which the water is exposed, but also the amount of the weight of the atmosphere at the time, or the height of the mercury in the barometer tube. For example, at Quito, which is 10,000 feet above the level of the sea, water boils at 194°; while at Geneva, ebullition begins at 209°, that city being 1200 feet above the sea.

The law, then, as regards the pressure of the atmosphere is, that the boiling temperature is uniformly the same when the barometer is at the same height. If we employ the thermometer of Fahrenheit, it will be found that the boiling point is exactly 212° if the barometer indicate 30 inches; but if the boiling point rise to 213°, then the barometer also will ascend to about 30½; and conversely, if it be 211°, the barometer conversely also will fall to about 29½. It is obvious, then, from these facts, that the boiling point is an index of the height of the barometer; and, on the other hand, that the height of the barometer will give the point of ebullition according to the thermometer of Fahrenheit, or any other which may be used. (See Meteorology and Pneumatics).

Experimentally, the effect of a diminution of pressure on the temperature at which water boils may be shown by the common air-pump. If a jar of water, at the temperature of 178°, be placed under the large bell receiver, and the air be withdrawn so as to reduce the pressure very speedily, the water will be found to boil at the reduced temperature. The pressure at which this takes place, as measured by the barometer, is equal to half the ordinary weight of the air, or 7½ lbs. on the square inch. If the barometer be retained in the jar, it will be found to indicate 15 inches when the ebullition takes place. Should the barometer fall lower before the boiling commences, then it will also be noticed that the thermometer points to a lower temperature, corresponding always in an exact ratio.

Steam, or the vapour of water, when produced at the usual pressure of the atmosphere, is commonly denominated *low-pressure*, in opposition to that which is formed at a higher pressure than that of the air, and accordingly named *high-pressure* steam. In common language, however, the term low-pressure is applied to the steam which has even a force of several pounds on the square inch, and therefore formed at a temperature higher than 212°. The steam is in this case condensed in working the engine, and receives this general name because the pressure does not range higher than a few pounds.

In order to produce steam of greater pressure or force than that obtained by boiling water in the open air, means must be adopted to confine the vapour as it is generated from the water. If we have a stout copper vessel, containing a considerable quantity of water, and provided with stopcocks which can be properly closed, and then expose it to heat, a quantity of vapour will be disengaged; but as it cannot fly off, all the stopcocks being closed, it must necessarily, in proportion to its density, compress the fluid below, and proportionately prevent any further escape of vapour. But the heat being continued and increased, vapour will then rise, which in like manner will increase the degree of compression on the water, for the density of the first disengaged vapour will now be increased by this new accession of vapour, and the further formation of vapour will be checked until the heat is again so far increased as to be able to overcome resistance offered by the pressure of the vapours. In this manner steam, of any degree of elasticity, may be generated from water merely by having a firm and stout vessel capable of bearing great pressure, in which the vapour is to be formed.

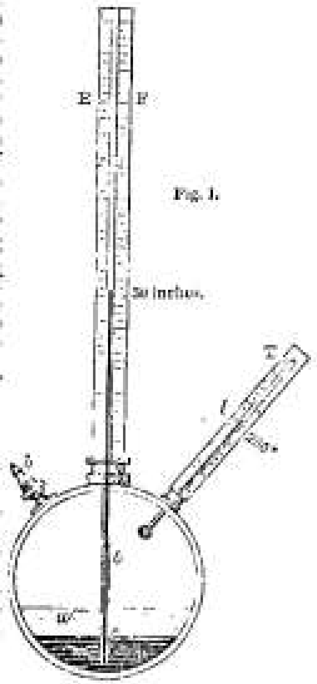


Fig. 1.

The generation of steam in this manner, and the relation between the temperature at which it is produced and the pressure upon it, and its consequent force or elasticity, may be illustrated by the apparatus represented in the adjoining cut, fig. 1. A copper vessel is procured, sufficiently strong to bear a considerable heat and a great degree of pressure. It is provided with three apertures, as in the figure. The aperture at the summit has a barometer tube (E F) fixed in it, open at both ends, but at the same time perfectly air-tight, so as to prevent all communication between the interior of the vessel and the external atmosphere. The upper extremity of the tube is immediately in contact with the atmosphere, while the lower is very near the bottom of the vessel. In the lower part of the vessel there is a quantity of mercury (*m*), into which the under extremity of the barometer tube dips. At one side of the vessel an aperture receives a thermometer (T), which is securely fixed, so as to be perfectly air-tight, and introduced obliquely, so that the bulb rests a little above the middle height of the vessel. The other or third aperture (*b*) is provided with a stopcock, which admits of being opened or closed at pleasure. The vessel is now to be supplied with water (*w*), filling it to the middle, and heat is to be applied by a furnace below. It is apparent that if the heat be applied and continued while the stopcock (*b*) is open, the air will fill the upper portion of the boiler, and the ordinary pressure of that body will be exerted on the surface of the water. The water will therefore, as already noticed, boil when the temperature 212° of Fahrenheit is indicated by the thermometer. But if we now shut the stopcock, so that there is no longer escape for the steam, the temperature of the water gradually rises, because the heat is continued, and the steam accumulating in the upper part of the boiler, exerts, first on the water, and immediately on the mercury beneath, a force or pressure equal to its increased elasticity. The mercury is, however, in an open tube, or rather is placed between the extremity of an open tube and the water and its vapour. Accordingly, if the force of this vapour is greater than what is requisite to overcome the pressure of the atmosphere, the mercury will be forced into the tube, and in proportion to the increasing force which the steam possesses, will the mercurial liquid ascend. In proportion, then, as the heat continues to be applied, the mercury will be seen to rise in the barometer tube, indicating the force which the steam exerts on the surface of the water in the boiler, while the actual amount of the heat at which the water is passing off into vapour will be shown by the thermometer.

But, as already stated, if the height at which the mercury stands corresponds in a distinct ratio with the temperature, it will be sufficient to ascertain either the one or the other, so as to know both. Suppose the column of mercury has risen nearly 15 inches, then we know that the pressure which the steam has is equal to half an atmosphere, as indicated by the mercurial tube, over and above the actual pressure of the atmosphere, so that the whole pressure exactly amounts to an atmosphere and a half. But the thermometer will also have risen, and now will point out a temperature of 230° Fahrenheit—water at that temperature, when converted into vapour, having a force equal to an atmosphere and a half, according to the usual mode of expression. If the heat be still continued, the further ascent both of the mercury in the barometer tube and of the mercury in the thermometer will be observed; and when the former stands at 30 inches, the latter will indicate exactly 250°, as may be seen in the diagram. But as 30 inches is equal to one atmosphere, and as the tube was open admitting the pressure of the air, the vapour of water was able to overcome the resistance of two atmospheres; or water under a pressure of two atmospheres boils at a temperature of 250° Fahrenheit, and the vapour possesses that strength in elastic force.

Suppose the thermometer (T) now stands at 250° (*l*), and the stopcock (*b*) be suddenly turned, an immense volume of steam, formed under the high pressure, suddenly escapes; the mercury in the tube (*t*) falls rapidly, and the thermometer also equally descends, until it attains the temperature of 212°. The mercury will fall down to the level it had immediately under the water, and steam will now be produced as under ordinary circumstances. The moment, however, the stopcock is shut (the heat still being kept steadily applied), the thermometer will begin to rise, and the column of mercury begin to ascend.

The application of the heat may be continued, in a good stout vessel, up to a greater elevation than what is now described, causing the production of steam of a still higher pressure, and, of consequence, greater elastic force, the barometer and thermometer mutually reflecting each other. It is in this manner that the high-pressure steam, as it is ordinarily called, is generated; but in proportion to the temperature at which it is produced, so is the danger to be apprehended from the bursting of the boiler, unless proper precautions are adopted.

The accompanying table gives the correspondence observed between the temperature at which the water boils, the density of the steam generated, and the force or elasticity it possesses in inches of mercury and atmospheres:—

Temperature Fahrenheit.	Sp. gr., air at 60° being 1.	Pressure in inches of a column of mercury.	Pressure in pounds on the square inch.
212°	0·404	30	14·7
222	0·453	35·00	17·15
233·80	0·557	45·00	22·05
242·50	0·61	52·50	25·785
250·20	0·915	60·00	29·4
274·70	1·33	90·00	44·1
320·60	2·5	180·00	88·2
350·00	3·61	270·00	132·3
450·00	10·75	900·00	441·

By this table we observe that the elastic force of the vapour produced from water rises in a rapid ratio above the ordinary temperature of boiling. If, for example, we take the temperature of water at 350°, the specific gravity of the vapour produced, air at 60° being 1, will be 3·6; and it would have a force equal to maintain a column of mercury 270 inches high, or 22 feet 6 inches, if no atmosphere pressed on the mercury; and 240 inches of mercury, if the atmosphere pressed on the fluid in the tube; the total sum of pressure on the square inch being then equal to 132·3 lbs., or corresponding exactly with the weight of nine atmospheres.

Tables have also been drawn up from experiments, illustrating the force of vapour from water at temperatures below the ordinary boiling point, thus—

Temperature.	Force of vapour in inches of mercury.
32°	·200
50	·375
80	1·00
100	1·86
150	7·42
180	15·15
200	23·64
212	30°

From these tables, it is apparent that there is an invariable correspondence between the force of the vapour of steam and the temperature at which it is generated; hence the one may be given as the rule of the other. For instance, if it is required to know the force with which the steam is working in any machine, the thermometer, which is preserved in a case air-tight, and introduced into the boiler where the steam is generated, will indicate the temperature of the water, or of the steam (for they are always the same; that is, at whatever temperature water boils to afford steam, the steam so produced is of the same temperature). On ascertaining, then, the temperature by a reference to the table, we find the corresponding force of the elastic vapour (the steam). An example will be sufficient to show this most clearly:—When the thermometer stands at 212°, and steam escapes from the water, we know it is then able to support a column of mercury 30 inches high; and a column of mercury 30 inches high is equivalent to the pressure of 1 atmosphere. The steam, then, is of the kind called low-pressure. If, however, the temperature indicated be 250°, then opposite in the table we find 29·4 lbs. pressure on the square inch, and 60 inches of mercury; but as 29·4 lbs. is double the weight of the atmosphere on the square inch, and also as 60 inches of mercury is double the height of the column which the air will support, the steam must then be acting with a force equal to 2 atmospheres.

The force with which steam acts increases in a greater ratio than the temperature at which it is generated. If, for example, the pressure be equivalent to 1 atmosphere at 212°, at 250° it will be equal to 2 atmospheres; that is, in the addition of heat equal to 38° of Fahrenheit above 212°; and at 293·7, which is little more than the difference between 212° and 250°, which gives only an increase of 1 atmosphere, the pressure is equal in all to 4 atmospheres, or double that above 250°; and so on, as will be seen in the former of the preceding tables.

Mr Tredgold gives the following rule to ascertain the elastic force of the vapour of water, in inches of mercury, at any given temperature of Fahrenheit's thermometer:—To the given temperature 100 is to be added, and the sum divided by 177. The quotient is to be raised to the sixth power, which is the force required. If, for example, the temperature be 307°; to this 100 added gives 407. This, divided by 177, gives 2·3, of which the sixth power is nearly 148, the elasticity of the vapour, in inches of mercury, almost equivalent to 5 atmospheres. This rule, it is to be observed, only refers to the vapour produced from pure water; when it is mixed with a considerable proportion of saline matter, as in the case of sea-water, a different divisor must be adopted, which is to be regulated by the temperature at which the water boils, for the point of boiling varies with the amount of salt in the water. Water saturated with common salt contains about $\frac{12}{32}$ portions of that matter, and its boiling point is about 226°. The divisor to be used in this case is 185 instead of 177, and the elastic force of the steam will then be found not to exceed 113 inches.

The existence of any body in the aëriform state is only a contingent condition of matter; some, called *gases*, have naturally no tendency to pass into the fluid or solid form; others, however, called *vapours*, are maintained in the gaseous state by the influence of heat—and on withdrawing it, speedily resume their ordinary condition. Steam belongs to this class of bodies, and on being cooled, immediately condenses or returns to the fluid state. The white cloud produced on steam escaping from the safety-valves of boilers, or from high-pressure engines, is *not* steam, in the strict acceptation of the word, for steam is invisible, but the water formed by the condensation of the steam in consequence of the cold air with which it now mixes. The extent to which the water expands is variously estimated; but it seems to be very nearly that 1 cubic inch of water becomes 1 cubic foot of steam, or the space occupied by 1 cubic inch of water, when converted into steam, is nearly 1700 times greater—correctly as 1 to 1696.

In the state of vapour, steam may be in two distinct and very different conditions: it may be immediately in contact with the water whence it is formed, or it may be in a vessel distinct and separate from all connection with the water. In either condition it is a distinct aëriform body, and possesses all these properties peculiar to that class of bodies, it being always understood that the heat is maintained sufficiently high to preserve it in this particular condition—namely, of vapour. Aëriform bodies—and consequently water, when in the aëriform condition—have a property quite peculiar, denominated their elasticity. This essentially consists in a disposition of all the particles, whereby they have a tendency to recede outwards, or fly from the centre, so that they spread themselves out into a more extended space. If, for instance, we have a bladder partially filled with air under the receiver of an air-pump, and then exhaust the air, it will be found, that as the exhaustion proceeds, the bladder expands, and ultimately will be burst, by the expansive force of the air within. Aëriform bodies have a tendency, accordingly, to expand indefinitely, were there not causes which counteract this disposition.

The first of these is the pressure to which they are subject, and the second is the attraction of gravitation, by which all particles of matter are drawn down towards a centre, and which is incessant in its action. A similar power is also exercised by the application of cold, which diminishes the repulsive tendency. As there is a constant force counteracting this disposition to expand, the elasticity of a gas or vapour is in the exact ratio of this counteracting force. Gases, as they are capable of expansion, so they may also be condensed or diminished in bulk. But in this condensed state, as they then occupy a less space, there necessarily must be an increase in the density or specific gravity. Thus, if the space occupied by any gaseous body be equal to 100 cubic inches, and these 100 cubic inches weigh 31 grains, on compressing these to one-half, so that they only occupy 50 cubic inches, each cubic inch will obviously contain double the amount of matter it previously had, and therefore, whatever was previously the weight of the cubic inch, it will now be double. But with this increase of density there is an increase of elasticity; for as the elasticity of a gas is directly proportionate to the force which compresses it, and as this force has diminished the bulk by one-half, hence, as the density is doubled, the elasticity is increased in the same ratio. The elastic force of a gas, therefore, is directly in proportion to its density, and in the inverse proportion of its bulk.

Incidental to the formation of steam, it has been observed that there is a great quantity of heat which disappears on the vapour being formed, and which cannot be discovered by the thermometer, but is again given out when the vapour returns to the state of water. The most singular and most important practical fact connected with this property is, that whatever be the temperature at which the water is boiled to form steam, the sum of that temperature, and the number of degrees of latent caloric, is always the same. Suppose the water boils at 212°, and the quantity of latent caloric absorbed be equal to 1000°, the sum of these will be exactly 1212°. But if the water boil at 112° (under diminished pressure), the latent caloric will then be 1100°, to make up the aggregate sum 1212°; and in like manner, if, under increased pressure, the water be made to boil at 312°, the quantity of latent caloric will only be 900°. Hence steam formed at a low pressure, or at the ordinary temperature of the air, does not require a different amount of fuel that it may undergo this change, than the same vapour generated at 100° higher, or any other temperature; for the sum of the latent and sensible heat is always the same—1212°, as measured by the thermometer of Fahrenheit. To convert, accordingly, a given weight of water into steam, the same amount of fuel is required at all temperatures.

The condensation of steam by water may be easily shown by taking a flask with a small quantity of water in it, and, exposing it to a temperature sufficient to produce ebullition, steam will rapidly be formed, and all the atmospheric air expelled. A cork (previously ascertained to fit accurately) is then introduced into the neck of the flask, which is at the same time withdrawn from the fire. The flask, now full of the vapour of water, is introduced into a vessel of cold water with the neck inverted; on the cork being withdrawn, the cold water immediately absorbs the heat of the expanded vapour, and is forced in by the pressure of the atmosphere, so as completely to fill the vessel, if it contained nothing but steam. The application of this additional property of steam, and the mode of bringing it into play, will be specially detailed under the description of the steam-engine. It is owing to this important property—namely, the great degree to which it can be condensed by cold water—that a vacuum is produced, and the steam-engine rendered complete in almost all its parts.

The chief properties of water, then, as converted into steam or vapour, may be briefly enumerated:—Expansion—the matter in this new condition of vapour occupying about 1700 times the space it occupied as water; the disappearance of a great amount of caloric, which bears always a definite proportion to the temperature at which the water passes into steam; the exertion or display of a definite elastic power, bearing a fixed ratio to the temperature at which it is generated; the natural return of steam to the state of water, either on gradually withdrawing the heat, or on suddenly bringing it in contact with cold water.

Fuel—Heat.

Accessory to the consideration of water and its various properties, physical as well as chemical, is the history of the different matters which are employed to give out heat, and to convert it into steam. The consumpt of coal or fuel, of whatever kind it may be, constitutes one of the most serious obstacles in the extension of the steam-engine, and especially in its application to long voyages. The great object is to produce the greatest amount of heat at the least possible expense of fuel. Charcoal, or the substance carbon, is, properly speaking, the principal ingredient in the combustible matters which are usually taken to produce heat. It constitutes the main bulk of coal, of coke, of anthracite, which is a species of natural coke, and of wood in all its varieties. (See No. 29.)

During the process of combustion, the quantity of heat which is disengaged can be precisely determined; as, for instance, by ascertaining how much of a given amount of combustible matter is required to raise the temperature of water from 32° to the boiling point (212°). In a series of experiments made on this subject, Despretz obtained the following results, which are here arranged in a tabular form:—

		Pounds of water.
1 Pound of charcoal	heats from 32° to 212°	78
... ... charcoal from baked wood	... ...	75
... ... baked wood	... ...	36
... ... wood containing 20 per cent. water	... ...	27
... ... bituminous coal	... ...	60
... ... turf	... ...	25 to 30
... ... alcohol	... ...	67·5
... ... olive oil, wax	... ...	90 to 95
... ... ether	... ...	80
... ... hydrogen	... ...	236·4

In this process of combustion, the chemical action consists in the union of the oxygen supplied from the air with the inflammable matter, whether carbon alone, hydrogen alone, or both together. The amount of heat depends exclusively on the quantity of the oxygen consumed, as the important fact has been determined, that the heat evolved was always in a direct ratio with the oxygen lost. Thus in a series of experiments, it was discovered that

		Pounds of water.
1 Pound of oxygen with hydrogen	raises from 32° to 212°	29½
... ... charcoal	... ...	29
... ... alcohol	... ...	28
... ... ether	... ...	28½

The importance of this subject is sufficiently obvious, when we consider the immense number of steam-engines incessantly at work, and the enormous annual consumpt of coal. In long voyages in steam-vessels, the greater part of the cargo is necessarily composed of coal instead of merchandise, and thereby one of the chief objects of steaming is virtually defeated.

It is here to be carefully noted, that to raise water to the boiling point, and to convert water into steam, do not imply the same thing, though they both imply the application of heat steadily to the fluid matter. This arises from the great quantity of latent caloric which the steam requires, and which amounts by calculation, as well as by careful experiment, nearly to 1000° of Fahrenheit; that is to say, if it takes a given time, with an equal and uniform quantity of heat, to raise water from 32° to 212° (180°), it will require that time multiplied by 5½ to convert the water into steam. But in one period (namely, the time required to raise the water to the boiling point), as much heat as raised the water 180° was added, and 180° multiplied by 5½ gives exactly 1000°. It is to supply this great quantity of latent caloric that so immense an amount of coal is consumed by the steam-engine. For if 1 lb. of the best coal raises 33·3 lbs. of water from 32° to 212°, then 1 lb. will only suffice to convert 5·5 lbs. of water into steam. Or while 1 lb. of coal raises 33·3 lbs. of water to the boiling point, it will require about 5½ lbs. more of the same kind of fuel to convert all that water into steam.

To convert the coal into those chemical compounds, during which the evolution of heat takes place, a very great proportion of air is required. For the atmospheric air contains four-fifths of its bulk of matter, which does not in any manner assist combustion. Two and a half pounds of oxygen, or nearly 30 cubic feet, are requisite for the combustion of 1 lb. of coal; 150 cubic feet, therefore, of atmospheric air will supply this. It has, however, been found that one-third of the air which enters the furnace passes through it without directly contributing to the process of combustion, but withdraws heat. The actual amount, therefore, of air required is in round numbers about 220 cubic feet.

In these observations made regarding the boiling point of water, whether in the open air or under varying degrees of pressure, the water is to be held as pure, or nearly so. For when it is mixed with much saline matter, the temperature at which it boils is raised. Water, it may be noticed, saturated with common salt, boils at a temperature of 226° Fahrenheit. The temperature at which water containing various proportions of salt boils is given in the annexed table:—

	Amount of salt.	Temp.
Common water,	0	212°
Sea water,	1/33	213·2
Boiler water,	2/33	214·4
... ...	4/33	216·7
... ...	6/33	219
... ...	8/33	221·4
... ...	10/33	223·7
Salinated water,	12/33	226

In steam-boilers, where the water used contains a great quantity of saline matter, a particular process is resorted to called *blowing out*, by which the heavy water impregnated with saline matter is removed, and the salts prevented from accumulating. From such a mechanism not being known at the time, the 'City of Edinburgh' steam-ship, on her first voyage to Leith, had her boilers so obstructed and rendered useless by the immense accumulation of salts, that it was found necessary to clear the boiler out on the voyage, while she proceeded under canvas during the time. Some further remarks are to be found under the description of the marine steam-boiler.

HISTORY OF THE STEAM-ENGINE.

It appears, by careful examination of the records of history, that the action of steam for producing motion (though not then proposed to be applied to practical purposes) was known as early as 130 years B. C. This was produced by an instrument denominated an *æolipyle*, described by Hero of Alexandria, of which a figure is annexed, and which may be considered the original of the steam-engine. The æolipyle is formed by a globular metallic vessel, which rests on pivots, at and where it can revolve with perfect facility. Two tubes proceed from this ball at right angles to the pivots, shut at the extremities, but with a small aperture at the side, whence steam may escape. The pivots are the extremities of tubes connected with a boiler below, as marked in the sketch. On the boiler being heated, steam passes by the pivot tubes (C B) into the cylinder, from which it issues by the little aperture (F) at the side of the cylinder tube (E). As the steam escapes, it rushes out with great force; and as it acts on the side opposite to the aperture, it forces it and the cylinder to move round in the contrary direction. One tube will suffice. The same action may be shown even in a more simple manner, as is often done by glass-blowers. A small glass globe is formed, and two arms

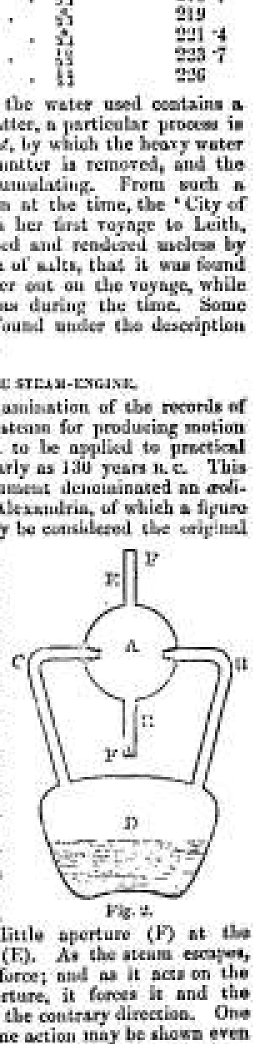

Fig. 2.

are attached to it, which are cylindrical tubes. In the globe a quantity of water is introduced, and on applying heat below, the same action takes place. It is of course necessary that the globe should be properly balanced and supported.

The next notice of steam-power worthy of our attention is in the seventeenth century. In the year 1663, a work was published by the Marquis of Worcester, named, in the language of that period, 'A Century of the Names and Scantlings of such Inventions as at present I can call to mind to have Tried and Perfected.' The following extract, describing what he terms a 'fire waterwork,' seems distinctly to convey the idea of a steam-engine:—'An admirable and most forcible way is to drive up water by fire, not by drawing or sucking it upwards, for that must be as the philosopher calleth it, *intra sphæram activitatis*, which is best at such a distance. But this way *hath no bounder* if the vessel be strong enough; for I have taken a piece of a whole cannon, whereof the end was burst, and filled it three-quarters full of water, stopping and screwing up the broken end, as also the touch-hole, and making a constant fire under it; within twenty-four hours it burst, and made a great crack; so that, having a way to make my vessels so that they are strengthened by the force within them, and the one to fill after the other, I have seen the water run like a constant fountain stream forty feet high; one vessel of water, rarefied by fire, driveth up forty of cold water. And a man that tends the work is but to turn two cocks, that one vessel of water being consumed, another begins to force and refill with cold water; and so successively; the fire being tended and kept constant, which the self-same person may likewise abundantly preform in the interim between the necessity of turning the said cocks.'

In 1698, Mr Savery, or Captain Savery, obtained a patent for a steam-engine, which was the first introduced to raise water. The principle of his plan consisted in injecting steam into a vessel connected with a vertical pipe, dipping into the water to be raised, and then condensing it by cold water, so as to form a vacuum, or at all events a space in which there is vapour of very feeble elastic force. By the pressure of the atmosphere, the water was then driven up until it attained a height proportionate to the pressure of the atmosphere, diminished by the force of the uncondensed vapour. By a peculiar but simple disposition of the valves, the return of the water was prevented; but as the water could not in this manner be elevated higher than 26 feet (64 feet by force of steam), the plan was not adopted to any extent.

The next decided and most important improvement which took place in the progressive advance of the steam-engine, was that of having a piston introduced into a cylinder, and when it is at the bottom, directing a current of steam so as to raise it, this steam to be condensed by being cooled. A vacuum is thereby produced, and the pressure of the atmosphere forces the piston down to the bottom of the cylinder. A rude and imperfect idea of this plan was suggested by Papin (a celebrated Frenchman, who discovered the Digester, and invented the safety-valve) about 1690, but laid aside. Engines were invented and constructed on this principle in the year 1713 by Newcomen and Cawley.

The engine so constituted is commonly called the *atmospheric engine*, because the power is derived from the pressure of the air, the steam being used merely to form a vacuum against which the atmosphere is to act. As this engine constituted a very important era in the history of steam, a short account, with a diagram of it, is subjoined (fig. 3), more especially as it shows in bold contrast the many and great advantages that resulted from the application of the genius of Watt to the steam-engine. There are three essential parts in the engine—the boiler, in which the steam is produced; the cylinder, in which it is condensed; and the beam, where its movements alternate with the ascent and descent. The boiler (B) is placed over a proper furnace, and built in with bricks. The summit of the boiler has a pipe or tube which communicates with the cylinder (C), situated immediately above. The

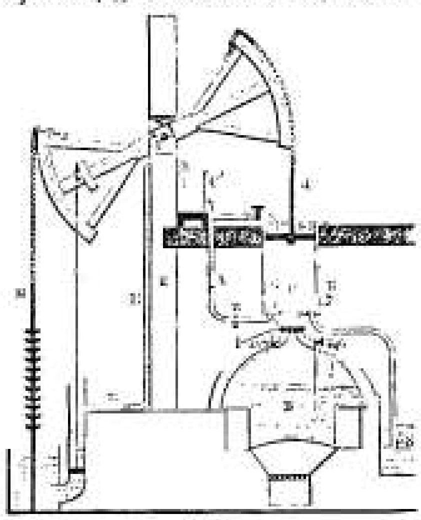

Fig. 3.

communication between the cylinder and the boiler is protected by a valve (V), called the *regulator*, or regulating-valve, so that the admission of steam may be regulated at will. The boiler is provided with gauge-cocks (G G), as will be noticed under the head of *boiler*, and also with a safety-valve (S V), which is not loaded to any great extent, as the engine works at a low pressure. The cylinder, which is placed above, is made of cast-iron, and nicely bored, so as to permit the free working of the metallic piston, but at the same time to prevent the access of air or steam. The piston (P), in short, works like the piston of a common syringe. There are four apertures in the cylinder, while it is also open at the summit. There are, first, that marked V, the valve of communication between the boiler and cylinder; second, that at the left inferior angle in the opening of the pipe (A), which transmits the water for condensation, armed with the stopcock (R) named the *injection-cock*. This pipe leads from the cistern (C'), which is kept constantly supplied with cold water by the action of the small pump attached to the beam, raising the water, and carrying it along the tube or water-pipe (E E).

At the opposite angle, below H, an aperture is observed, being the commencement of the eduction-pipe, by which the water injected for condensation is removed to a cistern beneath. This pipe is conveyed a considerable way down into the cistern, and is protected with a valve at its extremity, opening outwards, so as to permit free passage of the water from the cylinder, but none to regurgitate from the cistern. The fourth aperture, opposite the opening of the injection-pipe (H), is also supplied with a valve opening outwards. It is commonly known by the name of the *blowing-valve* or *snifting-valve*. It is through this valve that any air in the cylinder is expelled before the engine operates.

On a large support (E) a beam (I) is placed transversely across, which moves on an axis at I. This beam has one arched head at either extremity, to both of which chains are attached. On the one immediately above the cylinder the chain is continued down to the piston-rod (M), into which it is fixed, so that, as the piston ascends and descends, there will be a similar movement of the arched head of the beam. To the other end the chain is connected with the pump-rod, by which the water is to be brought up. But the pump-rod is made heavy, so that it naturally draws down this extremity, and elevates the piston-rod.

The mode in which this engine is worked is the following:—The fire being properly raised, and steam freely formed, the valve (V) is opened, to allow the entrance of the steam. The snifting-valve (H) is now forced open, and the air escapes along with the steam, until the cylinder is full of steam. The regulator-valve (V) is now shut, and the stopcock (R) on the pipe A being opened, the cold water is injected, and condenses on the steam. But as a vacuum is effected by the condensation of the steam, the pressure of the air, now acting with a force equal to 15 lbs. on the square inch on the surface of the piston, carries it down to the bottom of the cylinder, and consequently raises the other end of the beam to which the pump-rod (N) is attached. In this manner the water is raised from the mine; and by a repetition of the movements already noticed, a constant discharge of water results.

There were not a few impediments to the free working of this engine, one of the most laborious of which was the incessant attendance of a person to open and shut the stopcocks alternately as it was required. This was accomplished by catches (scoggans) worked by the beam, or strings connected with the lever of the valves and the beam—an invention of a boy, Humphrey Potter, to avoid the trouble that constant attendance on the levers demanded. By means of a plug frame fixed to the beam, invented by Beighton, the engine was made to work the valves with great regularity—a most important practical advance in making the steam-engine work itself, and adjust its own valves. The analogous part of this machinery in the modern double-acting engine is to be observed in the eccentric.

This, the atmospheric or Newcomen's engine, had many and very striking advantages over all others previously proposed. It may indeed be considered the basis of the engine subsequently modelled by Watt. But there were very serious defects in it, as the reader will shortly find from the description of Watt's engine. It is here sufficient briefly to enumerate them:—Much steam must, then, be lost during the process of the heating of the cylinder after each condensation; for it must always at least be raised to the temperature of the steam before the steam can, as such, continue in it, and be in any degree efficient; and on the other hand, the cold air which follows the descent of the piston must necessarily withdraw a considerable portion of heat. By the calculations of Watt, it was estimated that *three* times as much steam was expended in this manner as would have been equal to work the engine—a loss, therefore, equal to 75 per cent. Nevertheless this, as has been correctly observed, 'was the first really efficient steam-engine; that is, the first engine which could be applied *profitably* and *safely* to the most important purposes for which such machines were required at the time of its invention.'

The happy conception which formed the first step in the career which has immortalised the name of Watt, was that of *condensing the steam without cooling the cylinder.* After the notion of separate condensation had occurred to him, all the other details of the engine were of comparatively easy introduction. His first improvement constituted what has been termed the 'single-acting engine.' In this form of the engine the steam was admitted only above the piston, at first the vacuum being below it. When the piston had gained the lower part of the cylinder, the communications between the steam-pipe and cylinder, and also between the condenser and cylinder, were closed; and through the medium of a tube communicating laterally, the steam which was above, diffused itself below the piston, so that on either side it was subject to an equal force. But on the other extremity of the beam there was a weight, which raised the piston up, and the steam all necessarily flowed below the piston. On the communication between the condenser and cylinder being made free, a vacuum was induced, and the steam-pipe being then opened, a rush or current of steam proceeded to the upper part of the piston, and the movements were repeated as before.

This form of engine was not by any means well suited for the purposes of communicating motion to machinery, in consequence of the inequality of its action; but it served admirably for the purpose to which it had been first applied—namely, that of raising water from mines. It is, however, in a great measure, even for that latter purpose, superseded by the double-acting engine of Watt, which we shall now describe in detail.

DESCRIPTION OF THE STEAM-ENGINE.

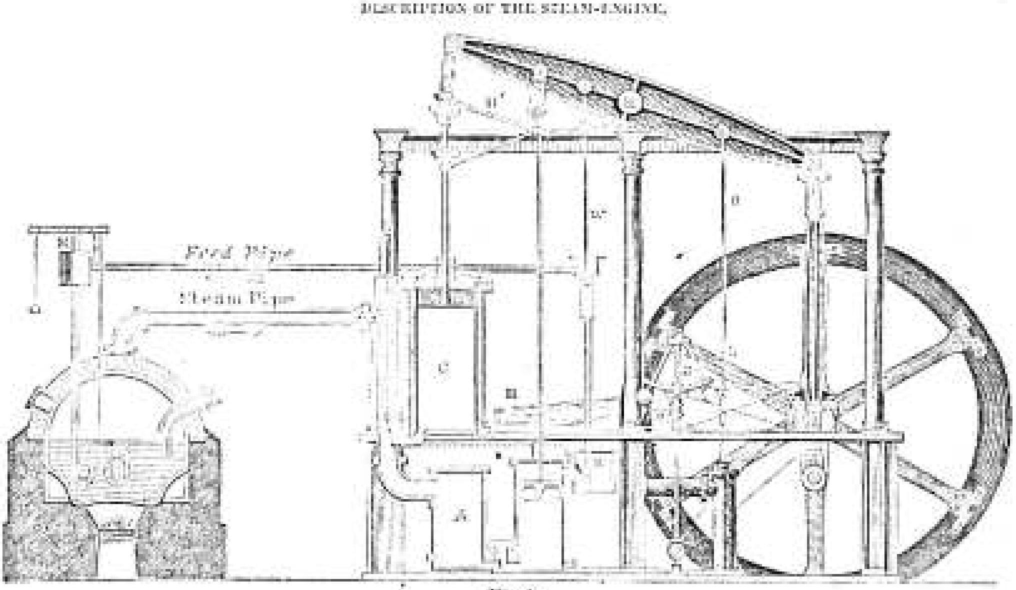

Fig. 4.

The entire apparatus of a steam-engine is comprehended in two distinct parts—the *boiler*, which generates the steam, and the *engine*, by which the duty of the steam is performed. It is necessary, however, to remark, that there are various kinds of engines, differing as to mechanism. Two grand divisions may be formed of them—1*st*, Those in which condensation takes place, or low-pressure engines; and 2*d*, Those in which there is no condensation, or high-pressure engines. In the first class we have the common atmospheric engine, invented by Newcomen; then the double-acting engine of Watt, working by pressure and condensation, or working by pressure, expansion, and condensation; so, also, in the second class, we have engines working only by pressure, and engines working by pressure and expansion. Fig. 4 is an outline of what may be esteemed the most complete engine of the condensing class, with the boiler and connecting pipes.

We shall now proceed to describe the various parts of this most ingenious apparatus. And first, of

The Boiler.

The boiler, as its name implies, is the large iron vessel in which the water is exposed to the action of heat, so as to be converted into steam. In its structure and connection with the cylinder (that part of the engine in which the steam acts), it constitutes a very beautiful illustration of different pieces and forms of machinery all happily arranged, so as to contribute to one important end. In examining the boiler, we have to attend to the following leading parts or portions of mechanism:—The form of the boiler, the feed-pipe, the steam-pipe, the damper, the steam-gauge, the gauge-cocks, the safety-valve, the internal safety-valve, the man-hole, and the furnace. Fig. 5 is a representation of the several parts on a minute scale:—

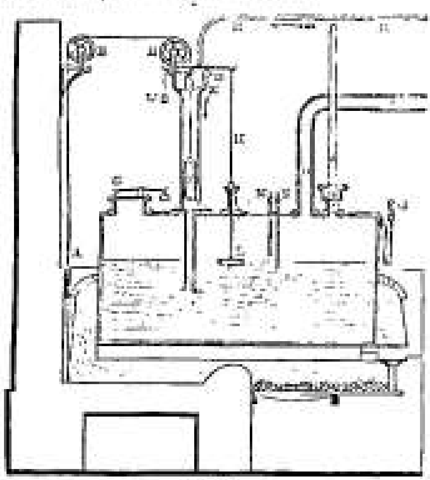

Fig. 5.

Various forms have been proposed for the low-pressure boiler. That which is chiefly used, as here represented, is called the wagon-shaped; it is fashioned in a semi-cylindrical manner above, the sides being nearly perpendicular, while the face is gently concave or hollow. When the pressure is not great—that is, does not exceed six or eight pounds on the inch—this form of boiler is sufficient for the generality of purposes. The chief object in selecting the form of the boiler is, that it may permit the water to pass speedily into vapour with the smallest amount of caloric, as little as possible being given off to the surrounding matters and atmosphere. For it is here to be observed, that when two bodies at different temperatures are placed contiguous to each other, the warmer of the two soon becomes cooler, and the colder becomes warmer, so that, after a given lapse of time, they both have the same or a common temperature. It becomes, therefore, an object of the utmost moment to place the boiler in such a position that as little heat as may be can escape from it. This is effected by building it in brickwork, or matters which are bad conductors of caloric.

Whatever form may be selected for it, it has two main pipes—one which conveys the steam from it (O), and the other which, as it supplies it with water to generate the steam, is called the *feed-pipe* (R).

It is further provided with several other highly important and essential parts; these are, the *steam-gauge*, which indicates the elasticity or force of the steam which is formed; the *gauge-cocks*, by which it is known whether the boiler is supplied with the proper amount of water or otherwise; the *safety-valve*, so denominated by way of distinction, which allows a free egress to the steam when pressing beyond a certain force, and thereby preventing any danger from explosion; the *internal safety-valve*, which obviates any risk of the sides of the boiler collapsing by the pressure of the atmosphere, should, from any circumstance, the force of the steam become inferior to that of the external air. To these there is to be added the *man-hole*, which is for the object of cleaning the boiler out when requisite.

The feed-pipe is a very ingenious arrangement by which water is brought to the boiler. It proceeds from a cistern (E) situated immediately above the boiler, and extends into the boiler a little lower than its middle height.

The water which is conveyed to this cistern is drawn from the hot well (H)—(a part of the engine connected directly with the condenser, and afterwards to be noticed)—by means of a pump worked by the engine (W), fig. 4. As this water is of considerable warmth, a proportionate saving accrues in using it. The water, however, does not enter this tube to pass to the boiler always in a continuous stream, independent of the condition of the boiler as to its being scantily or liberally supplied with water; but, by an ingenious arrangement, it is made to descend in such a continuous current, so as exactly to be equivalent to the amount of water expended in the formation of steam. This is accomplished in the following mode:—A valve is situated at the bottom of the cistern, which is made to open upwards, on the rod being raised which connects it with a lever (D). This lever is so placed as to move on a fixed point at the upper part of the cistern. At one extremity of it a small wire (K) is attached, running through a steam-tight aperture in the boiler, having a float (L) at its termination resting on the water. To counterpoise this, there is a weight (W) suspended at the other extremity of the lever connected with the cistern. As this float is balanced in the water, when it is rapidly evaporated, it will follow the water level, and as it descends, will necessarily bring down the arm of the lever to which it was connected; the other arm will be elevated in a corresponding manner. But the valve in the feed-pipe being attached to a rod which is fixed to the lever, will be carried upwards as it is raised, and the water will pass down, until the float, being raised in a corresponding degree, will enable the other arm of the lever to which the counterpoise was attached to fall, and thereby bring down the other end of the lever, and close the valve. By this arrangement, as long as there is a sufficient supply of water, from which the cistern can be filled, there will always be a sufficiency running down in a continuous stream to feed the boiler for the production of steam.

The steam-gauge (Q) is adapted to the boiler, in order that the engineer may always be able to know the elastic force of the steam. Its form and principle are illustrated by fig. 6. A tube, curved in the form of the letter U, is connected with the boiler from which the steam is disengaged. This tube is open at both extremities—(perfectly analogous to the tube rising from the centre of the stout copper vessel in which the principle of the formation of high-pressure steam was explained, p. 386)—one of which is immediately exposed to the air or vapour in the vessel, while the other is directly under the influence of the pressure of the atmosphere, whatever that may be. Into this tube mercury is introduced, which, supposing the boiler to be full of air, or of steam having the same tension as the atmospheric air, will have the same level in both legs of the tube; should, however, the fluid ascend in A, that in B falling in a corresponding degree, the steam pressing on B must have a greater force than the external atmosphere, and the difference in the levels of the mercury in the two limbs will indicate the excess of the force of the steam above one atmosphere. Every two inches' difference in the levels indicates a pressure of 1 lb. on the square inch. Conversely, the fluid mercury falling in A, and rising in B, indicates that the steam is *not* of pressure equal to that of the air, the proportion of which is to be determined in the same manner. This tube may be constructed either of glass or of iron. If a metal tube is employed, a thin wooden rod is introduced, with a float in the open end A, so that the distance of the mercury from the level of the summit of the tube is easily ascertained.

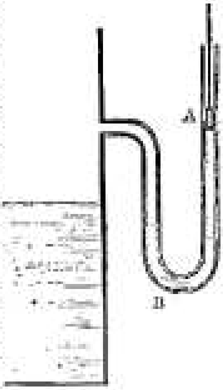

Fig. 6.

The gauge-cocks (M N) are two pipes or tubes armed with stopcocks, passing vertically downwards into the boiler. These tubes are of unequal length. One descends somewhat more than the third of the depth of the boiler from the summit, the other somewhat less; so that the former dips in the water, while the other opens into the air or steam a little above the water level. When the boiler is filled with its proper amount of water, and steam duly formed, on opening the stopcock of the longer tube, water will be discharged; and on opening the shorter, steam will escape. If, however, there be an excess of water, so that the less also dips into it, water will be projected from both; and again, if from inadvertency the water be deficient, so that the longer tube dips into air or vapour, the water-level being below it, steam, on both the stopcocks being opened, will escape freely.

The safety-valve (G) is designed to permit the free escape of the steam when it is generated of greater elasticity than is required, or the sides of the boiler are well able to resist. If we suppose the boiler can bear a pressure of 20 lbs. on the square inch at every part of its surface, and there were no valves, should the force of the steam be increased so as to exert a pressure of twenty-one lbs., the walls would necessarily yield, and an explosion be the result. If, on the other hand, we suppose that the engine will work well with an elasticity of 4 or 5 lbs. on the square inch, it is apparent, that so long as the elasticity does not increase, the steam will pass by the steam-pipe freely to the cylinder, and the steam-gauge in the boiler will indicate the pressure to be that now stated. But, while things are in this state, if we were to render one point of the boiler so weak that a force of 10 lbs. would be too great for it, and the steam were to acquire an elasticity sufficient to overcome that, a rupture necessarily would take place at that point, or the boiler would burst. The valve is then to be considered as a part of the boiler, which yields to a pressure much less than that which would be capable of bursting the boiler, but which permits a pressure to be made sufficiently strong to allow the free working of the cylinder with steam of or under a definite pressure. The mode in which the valve is frequently made to work is by the steelyard. This is a lever having a support fixed close by a tube communicating with the boiler. The aperture of this tube is closed by a plug or plate, which is fixed to the lever, and weights are arranged in the usual manner to the extremity of the lever. If the atmosphere and the weight fixed to the end of the lever are unable to resist the elasticity of the steam which is generated in the boiler, its greater pressure forces the plug upwards, and the tube being opened, the steam escapes.

It is apparent that if the tube were open, steam could not be generated of higher pressure than one atmosphere; again, if the boiler were made of sufficient strength to bear the pressure of 16 atmospheres, it could be heated sufficiently so as to give steam to that force without danger. But as the safety-valve may be loaded with a pressure ranging from 1 lb. on the square inch to 100 or more, it is evident, that so long as we are secure of the positive strength of the boiler, we may cause steam to be generated of any given strength, within the range determined, merely by adding or subtracting from the pressure on the safety-valve. From different causes—as, for instance, the valve adhering to the tube, or corrosion taking place, or the aperture being too small—it is occasionally inefficient, and from this explosions may arise, should the force of the steam be greatly augmented.

In some boilers two safety-valves are employed, the one being at a much lower pressure than the other; so that when it yields, the engineer has a clear intimation of the increasing elasticity of the steam, and then can easily adopt precautionary measures. It has been strongly recommended that in every instance there should be two valves. Justly, indeed, has the observation been made, that the more valves the better, as it is altogether improbable that they can all be obstructed at the same moment.

A plug of fusible metal is occasionally used in boilers which are raised to a very high temperature. The fusible metal is an alloy of different metals, which are so apportioned to each other, that the mass will melt at any given temperature. (See METALLURGY.) Now, it has been already stated that steam of higher elastic force than that of the air can only be formed at a higher temperature than 212°; when, therefore, steam is generated of a greater elastic force, it must be at a proportionally higher temperature; and if, then, there is a fusible plug which liquefies or melts at that particular degree of heat, it will be melted, and an outlet at once given to the vapour and water; it will be, in other words, the same as a valve. However ingenious in theory this invention may seem (and it certainly has considerable credit), it does not so happily correspond in practice, as it is found that the metals melt unequally; or, in other words, that the most fusible melts at the low temperature, and is retained in the small cells of the less fusible, so that the whole may not be fused until a temperature is obtained 100 or 200° higher than what was arranged or anticipated; and accordingly, by trusting to this alone, every danger that might occur from an explosion is to be apprehended.*

* 'The bursting of boilers'—we quote the Penny Cyclopædia—'present very different phenomena, being sometimes a simple rent in the metal, allowing the harmless escape of steam and water; and at others accompanied by an explosion in its violence equal to that produced by gunpowder. It has hence been conjectured that on these occasions some explosive gases are formed in the boiler; but this does not appear probable, nor is reconcileable with any known physical laws, while the elastic force of steam is capable of indefinite increase, and is quite adequate to produce any mechanical effect whatever. It is always difficult to get any satisfactory evidence as to the facts of an explosion of a boiler; the terror of the moment prevents the survivors from accurately recalling the phenomena immediately antecedent, while those who, from their proximity, would be best capable of affording this evidence, are either killed, or are too interested in exculpating themselves to be impartial witnesses. With regard to the formation of explosive gaseous compounds in the boiler, it is generally admitted that hydrogen gas is the only ingredient of such that can be formed; and that is obtained by the decomposition of the steam when in contact with the red-hot iron; but pure hydrogen is not explosive; and to render it so, it must be mixed with oxygen or atmospheric air. It has been suggested that the latter may be introduced along with the water by a defect in the feeding-pump; but the proportions of the air and of the hydrogen must be definite to produce an explosion; and it is difficult to suppose that in such a situation either should continue to accumulate till the quantity is exactly that necessary to produce an explosion. In short, this explanation of the subject is beset with difficulties which have not yet been removed, though the attention of scientific men both in Europe and America has been frequently directed to it.'

The furnace under the boiler is so arranged that the fuel is thoroughly consumed; and further, so that a draught of air may have free access to the fuel, which may be increased or diminished by means of a damper (A), worked on the wheels B B, when the steam is coming off too rapidly or too slowly for the demands of the engine. This object is effected by a contrivance somewhat analogous to the mode in which the supply of water is regulated for the feed-pipe, through the medium of the float and valve connected with the cistern. (See p. 392.)

The Engine

Is that part of the steam-engine where the force or power is developed by the action of the steam, and thence, by appropriate machinery, adapted to whatever objects it is desirous to give the impulse of a first moving power. There are a number of parts essentially belonging to the engine, each of which requires to be considered separately, in order that the mechanism of the whole may be rightly understood. These parts are —the cylinder, the condenser, the air-pump, the hot well, the cold water-pump, the beam, the crank, the fly-wheel, the governor, the eccentric and valves, and the indicator. For the convenience of description, these parts and the minor subordinate pieces of mechanism may all be arranged under two heads—*1st*, Those relating to the steam; and *2d*, Those connected with the motion, the regulation of the valves, &c. The engine now to be described is that called the *double-acting engine*, so named in opposition to the *single-acting engine*, in which the piston is forced downwards by the steam, but is elevated by a weight attached to the remote extremity of the beam. It is so called because the motion *downwards* and the motion *upwards* are both effected solely by the agency of the steam.

The *cylinder* (C, fig. 4) is the stout iron vessel into which the steam is introduced, and by its elastic force, according as it is alternately admitted and withdrawn below and above, causes the piston-rod to ascend and descend by an alternate and almost uniform movement. This iron vessel is steam-tight at the aperture where the piston-rod moves, and is equally so at the different apertures by which the steam either enters or escapes, these apertures all being securely protected by valves. When the piston has arrived at the top of the cylinder, the lower part is full of steam. To produce a vacuum, so that the piston may be readily depressed by the introduction of steam above, this vapour below must be removed. For this purpose the cylinder has a valve at its lower surface connected with the condenser (an apparatus immediately to be described), and on this being opened, the steam rushes into it and is condensed. But while this has taken place, the passage to admit the steam above the piston is opened, and as it enters immediately, by its elasticity it depresses the piston to the bottom part of the cylinder, constituting the downward movement.

But the piston has now arrived at the lower part of the cylinder, and it is required to raise it to the summit again. This is effected by the very same arrangement as that employed to bring it down. The steam which is in the cylinder above the piston is now, by the shifting of the valve, allowed to communicate freely with the condenser, escaping from the upper aperture in the cylinder. In this manner a vacuum is produced above, and the steam simultaneously being admitted from below, the ascent of the piston takes place to the upper part of the cylinder. By a continued succession of this alternate ascent and descent, motion is communicated to the beam, and thence transferred to whatever object it is desired to affect.

The *condenser* (A, fig. 4) is the next part to be described. The position of it is under and at a little distance from the cylinder, with which it communicates directly by a pipe or tube. The condensation of the steam by the aid of cold water, it will be remarked, is effected at a distance from the cylinder. This, indeed, constituted the chief improvement of Watt. The condenser may be considered as a vessel with three apertures in it—one leading from the cylinder, protected by a valve; another leading from it to the air-pump, also protected by a valve, permitting the free passage of matter, whether water or gases, to the air-pump, but not allowing any backwards into the condenser; and the third or last tube, which allows fluids also to escape, but has no communication with the air-pump, the fluids being discharged into the cold water which surrounds all this part of the machinery: this is usually named the *snifting-valve*. But there is also another aperture, through which the cold water is admitted to the condenser; this is regulated by the injection-cock. This cold water, when it is thrown in, immediately condenses or absorbs the vapour of steam, so that a vacuum, comparatively speaking, is formed.

The condenser-gauge is intended to determine the force of the vapour which may be in the condenser, for it must be observed, that a complete vacuum is scarcely ever produced. The extent of the vacuum it is essential to know, in order that the engineer may precisely ascertain how far it is working correctly. It may here be observed, that water can exist in the form of vapour even at very low temperatures. The force or elasticity it possesses is to be determined in the ordinary mode by a bent tube containing mercury, open at one extremity to the condenser, and at the other to the atmospheric air—the same principle, in short, as was applied to the estimation of the force of steam in the boiler.

Immediately contiguous to the *air-pump* is the hot well (H), into which the hot water from the condenser is brought, and any aëriform bodies remaining in the condenser. The piston of this air-pump being drawn up by means of the connection it has with the great cross-beam, a vacuum is produced; but at the lower part of the air-pump there is the valve communicating between it and the condenser. This valve, however, opening towards the air-pump, not in the other direction, the fluids pass immediately towards the air-pump. On the descent of the pump, the fluids are necessarily driven back, but their return to the condenser is altogether prevented by the structure of the valve; accordingly, from the compression they are exposed to, they open the valves of the air-pump piston, and are carried to the upper part, where they are gathered together. On the ascent of the piston taking place, they are carried up by it and brought into the hot well.

As the piston which works the air-pump is attached to the great arm of the beam, it is apparent that its operation is carried on steadily while the engine is acting; and accordingly, that the water formed by the condensed steam, as well as the water which produced the condensation, is incessantly being removed from the condenser, and successively brought to the hot well.

To supply this part of the engine, there is a pump which brings cold water into the cistern in which the condenser is placed. From the character of the water which it conveys, it is technically named the *cold-water pump* (O, fig. 4). At the point, then, where the heated water is drawn from the condenser, and brought into the hot well, the course of the water, proceeding from its fluid state in the boiler, then as steam, and finally condensed, may be said to be concluded. The water, however, it was observed, in the state of steam, acquires a great amount of heat, somewhat more than five times the heat required to raise it from the freezing to the boiling point. It is then returned by means of a tube to the cistern which is placed above the boiler, and supplies the feed-pipe leading to the boiler. The mechanism employed here has already been detailed. It will therefore be apparent, that a quantity of the water which was at the beginning in the boiler, is returned again to it, having previously passed through the state of steam, and having been condensed—performing a complete circle of changes.

The air-pump is not merely subservient to removing the water generated in the condenser, but it effectually removes the gases which are found associated with the steam, and which exist always in a certain amount, more or less, in water. These, indeed, were they to accumulate in the condenser, would as effectually interfere with the production of the vacuum there, and the consequent efficiency of the engine, as the accumulation of heated water, which would be incapable of dissolving the steam or condensing it, as the common term is. The air-pump is usually made to equal one-fourth of the cubic contents of the cylinder.

There is not, perhaps, any piece of mechanism so complete in all its various parts as the steam-boiler, or all these parts which are immediately subservient to the purpose of forming the steam—conveying the steam to the cylinder, condensing it, and again returning it in the form of water, from which it was originally produced, to be again converted into the same powerfully elastic body by the agency of heat. If, indeed, the condensation could be effected by other means than the agency of water, all the steam might be returned to the boiler, and thus, in an unceasing circle, the amount of water at first started with would suffice.

At first sight it might appear that these were all sufficient to determine the movements of the steam-engine, but there are other parts which are no less essential to the perfection and uniformity of its movements. These are, the eccentric rod, the governor, and the indicator.

The *eccentric rod* (R, fig. 4) is designed to work the valves, which were formerly managed in a very different manner, by means of catches or lappets fixed to the air-pump, and so placed as to elevate levers, which opened and closed the valves at the proper intervals. These valves require to be worked in a vertical manner, so that the steam may alternately enter and be shut off from the aperture into the cylinder at the top and bottom; and the regularity of the movement of these valves is indispensable to the permanent uniformity of action in the engine.

The eccentric consists of a circle of metal connected with a revolving axle, while the centre of the circle differs from the centre round which the revolutions of the axle are performed. It receives the name *eccentric*, because it is out of the centre (*ex*, the Latin for *out of*, or *away from*). If we suppose a circular metallic plate made with a shaft fixed in it, on which it revolves, but which is not in the mathematical centre—that is, the real centre of the circular plate—and if we suppose the diameter of the circle to be four inches, the exact centre will be two inches, or the radius of the circle will have that length. If, then, the shaft is fixed into the metallic plate firm in the middle of the radius—that is, at one inch from the circumference, and therefore at the same distance from the centre—it is obvious that, as the metal plate revolves so as to complete half a circle, three-fourths of the whole diameter will be placed exactly to the outer side of the axis on which it revolves; and on the revolutions being completed, the three-fourths will then be on the interior side, as the axis on which the plate revolves is permanently a fixed point. Round this eccentric a ring is adjusted with screws, to which metallic rods are fixed. As the eccentric revolves, the ring does not associate in the rotatory movement; it will, however, be carried to the right and left by the movement of the centre of the eccentric, as it comes round the axle. And as, in the case we have proposed for illustration, the distance between the real centre of the ring and the centre of revolution is one inch, the attached rod will be moved twice that space to either side during the revolution which the horizontal axle performs.

In this manner a rectilineal movement is procured from one that is circular; and by means of levers arranged at the extremity of the rod around the eccentric, the valves are alternately elevated and depressed, so as to permit the free entrance of the steam to the cylinder above the piston, while free exit is given to it below to the condenser, and then to permit the equally free ingress of the steam below the piston, while the escape of it from above is equally free to the condenser. Whatever variation may be given to the levers employed, the principle is the same, in so far as a horizontal lateral movement is obtained through the medium of the eccentric.

In the escape of the steam, either of increased elasticity or increased quantity, it is obvious that the movements of the engine will become more rapid, and so much accelerated as not to be adapted to the work it is intended that it should perform. It became, therefore, an object of the highest importance to regulate the quantity of steam as it was transmitted from the boiler by the steam-pipe to the cylinder. To accomplish this, Watt ingeniously applied the mechanism so long employed in water-mills, and which is almost universally known by the name of the *governor* (Z, fig. 4). The nature of this piece of mechanism will be understood by the annexed fig. A spindle or upright rod, with a pulley on its lower part by which it is moved, receiving motion through a strap attached to the shaft or axle, has two balls, which revolve along with it.

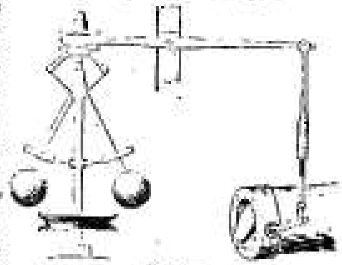

Fig. 7.

Those balls, by the means of joints, may be separated considerably from, or brought nearer to, the spindle. Two levers are connected with the rods to which the balls are attached, having a free movement on other levers similar in length and thickness, but which meet in a metallic ring movable upwards and downwards on the spindle. Immediately above the ring, a lever is placed transversely across the ring, fixed at one point, but connected to another which is bent, to the end of which the throttle-valve of the steam-pipe is attached. This valve, it may be here noticed, is intended to regulate the supply of steam, allowing it to escape when horizontal in full stream, and obstructing it proportionately as it assumes a vertical direction. When, therefore, the engine acts with increased speed or velocity, and the main shaft to which this spindle is attached is revolved with a proportionate degree of rapidity, the balls will recede to a greater distance from each other, and accordingly the levers acting on the throttle-valve will raise it so as to diminish the flow of steam. But if the shaft revolves slowly, the spindle also having its velocity regulated by it, the balls will naturally approximate each other, and the lever will now so act on the valve as to throw it completely open, and thereby permit the steam to enter in a full current to the cylinder, and accelerate the motion. Whatever is the velocity of the axle, such also will be in a proportionate ratio the velocity of the spindle, and in a corresponding manner will the position of the throttle-valve, either to close or enlarge the opening, be modified.

The *indicator* is a piece of mechanism devised by Watt, by means of which the force of the steam, and the state of exhaustion in the cylinder, are known at the different periods of the stroke of the piston. It is a small cylinder 8 inches long and $1\frac{3}{4}$ inch in diameter, communicating directly with the cylinder, and supplied with a piston. If the force of the steam in the cylinder exceeds the pressure of the atmosphere, the piston of the indicator then rises, and if it be less, is depressed. A tracer is connected with the indicator, by which a curve is drawn on paper, indicating the variations occurring in the pressure of the steam.

Hitherto those parts only have been detailed which are immediately related to the course of the steam. There remain now to be described those parts more directly, or rather essentially, connected with the regulation of the motion: these are the beam, the crank, and the fly-wheel.

The *beam* is the large and strong mass of iron moving on a centre, and resting on a large pillar or pillars, firmly secured to the base of the machinery and floor. It is so fixed on the summit of the pillar, that it may move freely on its centre, so that the extremities can alternately rise and fall with the alternate elevation and descent of the piston: the pump-rods attached to the beam are also worked in the same manner, and so were the valves formerly; but the latter are now generally acted on by the eccentric, which has been already explained.

In the single-acting engine, where the steam is employed to depress the piston, and a weight at the end of the beam to elevate, the connection between the piston and the beam is by means of a chain, as the force acted on the beam only during the descent of the piston. When the double-acting engine is in play, the beam is pulled down by the piston-rod, and a chain would be sufficient for this end; but when the piston ascends, any force communicated from it to the beam, through the medium of the chain, would be totally lost; for as the piston was carried upwards, the chain would relax, and the beam remain in the condition it was at the beginning of the movement upwards. A different mode of connection, therefore, is required, of such a mechanism, that the inflexible connection between the arch-head of the beam and the piston-rod may push the beam upwards.

A number of different plans were proposed to effect this end, one of which was the suggestion of Watt—namely, to attach to the end of the piston-rod a straight rack, which could play in a similar rack formed on the arch-head of the beam. But this did not suit well, for the movement in the stuffing box of the cylinder, if not of the most equable and smooth character, rendered the working of the cylinder inefficient, by allowing the steam to escape, or the air to enter. This plan, then, was ineffectual; and it, as well as others, have all yielded to that most elegant disposition of mechanical forces to which the term *parallel motion* is given (H, fig. 4).

The movement produced by the ascent of the piston and its descent, acting on the beam alternately, causing its elevation and descent, is to be converted into a perpetual circular movement, in order to adapt the engine for the great number of purposes for which it is usually employed. This is effected by the *crank*. This piece of mechanical apparatus is to be held merely as the handle of a wheel, which turns it round on any power being applied, as the hand of a man. The line stretching out like one of the radii of the wheel from the axis is called the *crank*; the rod, again, at right angles to it is called the *crank-pin*; while the rod at the other extremity is the *crank-axle*. In the steam-engine, then, a rod is attached to this crank, which (through the beam) is connected with the piston-rod in the steam cylinder; as it ascends and descends, an impulse is necessarily given to the crank, which causes one-half of a circle in the one movement, and one-half in the other. When we reflect on the nature of the movements produced, it is apparent that there are two distinct movements—one upwards and the other downwards; and consequently that there is a cessation of impulse at the alternate change of the direction of the force. For when the steam enters above the piston, it depresses naturally the piston to the bottom of the cylinder. It is then, however, intercepted previous to its being introduced below the piston, during which time there can be no moving power exerted. Again, when the steam is introduced below, the same succession of actions arise; and when the piston is at the summit of the cylinder, there is, for the same reason as in the movement downwards, no force exerted. These two points, then, at which there is no power acting on the crank so as to turn it round in either direction, are usually denominated *dead points*.

How, then, is the movement continuously carried on? What is it that prevents the action of the crank ceasing at these two points? The crank and axle have received from the engine a certain amount of motion, and as the motion which it has received continues after it has come to one or other of the dead points, it continues still to move in consequence of the momentum it has received, and with force sufficient to carry it beyond the range of the immovable point. But now that it is liberated from these points, it becomes immediately acted on by the piston-rod's connection through the connecting-rod. In this manner it is carried through the other half of the circle, until it comes to the other dead point, where, from a similar cause, it does not stand, but is urged round, and in this manner a continuous circular movement is effected. The fly-wheel, also, in a similar manner assists in clearing the dead points. The velocity with which the movement is carried on is not equal, for, in the first place, there are the two dead points through which the crank is worked solely by the impulse or momentum it had already received; and, in the second place, from the mode in which the connecting-rod plays on the crank, it must be greatest where the angle of these two is a right angle, and diminish proportionally as it recedes from that position to the dead point, where it is least. The reality of these dead points, and also of the unequal velocity, any one may easily see if he attend to the commencement of the motion of the engine, when the steam has not got sufficient force, when he will find that it cannot carry the crank beyond the point until it is urged with increased force; and the same will conversely be seen as the engine is stopping. The continuous movement being effected in this manner, it is apparent that it is not always at every point produced with the same force; and therefore that the action, though, in as far as the amount of force exerted be the same, yet it is unequally divided over a given time, as, for instance, a revolution of the crank. But this would not suffice in the very nice and equable movements and applications of force to which the steam-engine is now so universally applied in the various manufactures of this country. To render the machine as perfect as possible, the *fly-wheel* was constructed for this object. This is merely a large iron wheel attached to the axis turned by the crank, and consequently carried along with it in its revolutions. This wheel is made very heavy, with the object that it may produce uniformity in the motion by the momentum which it receives (L, fig. 4).

This arrangement has been found sufficiently perfect in the more ordinary cases, where an extreme degree of equality and nicety of movement is not required. Where such is an essential point, then the plan devised by Mr Buckle of Soho is that which is to be put in execution. By means of a wheel working in the rack of another and smaller wheel, the action of the engine is made subservient to draw a piston from the bottom of a cylinder, so as to leave a vacuum. When this piston was at the summit, and the vacuum below, the action of the steam being withdrawn, it necessarily was carried down by the pressure of the atmosphere, acting with a force of 14·67 lbs. on the square inch. A considerable amount of power was thus employed in producing a vacuum, which was regained by the atmospheric pressure. This arrangement was next adopted in flour mills with the most complete success, and subsequently has been carried into effect in other mills with equal success. From the uniformity of the movement so obtained, the quality of the material produced has been greatly enhanced.

Having described all the parts connected with the engine, we have now to consider the mode in which it is worked. The first point, after the steam has begun to be freely produced in the boiler, is to expel all the air which may be in the different parts of the apparatus by opening the valves, and allowing the steam a free transit, finally permitting it to escape by the snifting-valve. When nothing but steam fills the different cylinders, then the noise at the snifting-valve ceases, and the injecting-cock for the cold water is to be trimmed for the purpose of throwing in the cold water to produce the condensation of the steam.

The steam is now ready to act on the piston, and when it has moved it (whether admitted in a full stream, or expansively, it matters not) to the extremity of the cylinder, by the mode in which the valves are disposed, it passes immediately to the condenser, where the cold water playing on it, converts it to its original condition of water. The alternate elevation and depression of the piston being continued, and the steam passing eventually to the condenser, this latter part would soon be completely filled by the condensed water, so as to be totally unfit for its duty. This is obviated by the action of the air-pump, the valves of which are arranged so as to open only upwards. By means of the piston of this air-pump, the fluids are carried to the hot well. To this hot well a pump is attached, by which the water, which is of considerable warmth, is conveyed to the cistern (M, fig. 4) situated over the boiler immediately at the summit of the feed-pipe. The beam of the engine carries a rod by which this pump is worked, as well as another through which cold water is continually supplied. The valves by which the steam escapes from above and from below the piston, during its alternate ascent and descent, are opened and closed by the eccentric (R, fig. 4), and the force or power with which the engine should work is determined by the governor (Z), in the mode already explained, the continuity and the uniformity of the movement being mainly controlled by the fly-wheel and crank, or by the crank and pneumatic pump of Mr Buckle.

In this manner the engine continues its action as long as it is supplied with a due proportion of steam; and if there is a definite force with which it should act, on the supposition that there is always abundance of fuel and water, the amount of steam is definitely maintained by the governor and throttle-valve, and by the float in the piston the exact quantity of water is duly preserved; and also by the damper, a greater or less current of air enters the flues, either to increase the production of steam when it is tardy, or diminish it when generated in excess. By the proper arrangement of the valves, likewise, no danger can result from the boiler, and thus, in the strict sense of the word, it is a self-acting and self-adjusting machine; it does, in short, as has been truly said, everything but speak.

Marine Engine.

In the steam-engines employed in the navigation of vessels, there are certain modifications which it is requisite here to notice, and then briefly to point out the leading circumstances connected with this important application of steam, which will be more fully treated in a subsequent number.

The most striking peculiarity is the position of the beam in British steamers, which, instead of being placed above, is situated below, chiefly with the view of saving room, and is not single, but two, one at either side of the cylinder. To the upper portion of the piston-rod there is a cross bar, which is placed transversely across the cylinder, at right angles to the long axis of the ship, or from starboard to larboard, in nautical language. From the extremities of this transverse bar rods stretch down, connected interiorly to the termination of the beams, moving on pivots at both their connections with the cross head and beams. The other extremities of the beams are attached to a cross piece, on the centre of which the rod is fixed by which the crank is worked. The shaft of the paddles is firmly connected to this crank, so that it is worked along with the rod. In small vessels, only one engine is usually employed; but in vessels of considerable tonnage there are two, and their action is so adjusted, that while the one is at its fullest strain the other is in the reverse condition. In this manner the motion of the wheels is preserved uniform and equal. These forms of engine are usually called condensing, the steam being worked at high-pressure, and then condensed, a result which is very readily accomplished in consequence of the abundance of water.

Another form of engine is what is called the 'direct acting engine;' and as it emerges considerably above the level of the deck, it has also been designated by the apt name of the *steeple engine*. Engines of this kind are worked with air-pumps and condensers, and, as in the other marine engines, there is no fly-wheel. The chief advantage they possess is the small space they occupy, and thereby not only afford room for more merchandise, but further save the great weight necessarily incurred where the beam is employed. The peculiar kind of steam-engine called the *rotatory* (p. 396) has in some instances been applied to the propelling of vessels, but as yet with very indifferent success.

Another modification adapted to the steamboat, by which it is rendered unnecessary to have the beam and its appendages, is that proposed by Mr Witty, and termed the *vibrating engine*. The object is to obtain a circular movement from the vertical motion of the piston-rod. This is effected by the cylinder being suspended on an axis at its middle, so that it has an alternate movement forwards and backwards, vibrating in a manner analogous to a beam on its axis. In this manner there are two distinct movements of the piston-rod—the common one upwards and downwards, and this lateral movement, in which it is immediately connected with the crank.

In this form of the engine, the axes on which the cylinder moves are hollow tubes, one being the steam-pipe by which the steam passes to the cylinder, and the other being the eduction pipe, by which it is transmitted to the condenser.

There is a peculiarity in the arrangement of marine boilers, which it is necessary here to point out. This consists in the process of *blowing out*, as it is technically named. In sea water there is a considerable quantity of saline matter, about 3 per cent., which, accumulating in the boiler, not only retards the process of boiling, but is apt to give rise to explosions. To obviate these imperfections, hot water is permitted to escape freely from the boiler at stated intervals, and as the discharge takes place from the interior surface, the greater portion of the saline matter is carried off. In this mode a very serious obstacle was effectually removed; but this was not done but at a considerable expense, the loss being estimated at nearly 1-54th part by Mr Tredgold. For it is apparent that an immense quantity of heat must have been lost in the warm water employed for this purpose, and not subsequently converted into steam. After all, the plan is only partially effective, as a solid incrustation remains on the bottom of the boiler so hard as frequently to break the shovels employed in its removal. This incrustation is the cause of much waste, for, from its bad conducting power, the bottom of the boiler is often heated to redness before the required amount of steam is produced, thus causing not only loss of fuel, but rapid wearing of the boiler-plates.

A very ingenious method has been invented by Messieurs Maudsley and Field, which preserves a uniform standard of the quantity of salt in the water of marine steam-boilers. This is effected by means of pumps, called *brine-pumps*, which are worked by the engine, and remove from the boiler the strong solution of salt and water. These pumps discharge as much salt, combined with the small quantity of water, as the feed-pumps supply to the boiler, so that the quantity of salt remains almost always the same. Further, before this hot brine is discharged into the sea, it passes through a tube included in another, which is the feed-pipe supplying the boiler from the sea, so that the greater amount of its caloric is imparted to the water, and it is reduced to nearly 100° before it is thrown out.

If the steam can be condensed merely by the application of cold water to the outside of the vessel containing it, it is evident that a boiler might be filled with pure fresh water on leaving port, and this water be converted into steam, back again into water, a second time into steam, and so on in succession, without ever coming in contact with salt. This has been effected by Mr Samuel Hall, who is the patentee of several improvements in connection with marine-engines. His condenser consists of a flat vessel, in the bottom of which are a number of small apertures, and from these pipes in tubes are led to another similar flat vessel. Both vessels are air-tight. Into the top vessel the steam to be condensed is admitted, and passing through the tubes which are immersed in cold sea water, it is perfectly condensed on reaching the under vessel, from which the newly-formed water is drawn off by an air-pump. As the cold sea water becomes heated, it is pumped off, and a fresh supply admitted. This invention, which affords a more perfect vacuum than the old system, has been adopted in a number of cases with success, and is likely to come into extensive use. Various minor improvements have of late been effected on marine-engines, chiefly with a view to save space in the vessel's hold, and to dispense as much as possible with the cumbersome item of coal. Our space, however, will not permit us to notice these inventions.

The paddle-wheel by which the steam-vessel is propelled has undergone many modifications, for in the common mode in which the flat boards or float-boards are disposed, they both enter the water obliquely and leave it obliquely, occasioning a considerable loss of power; for it is apparent that their greatest effect must be when they are nearly in a vertical position. The complex nature of several of these wheels prevents their general employment.

The most important modification of the propelling apparatus is what is termed the *Archimedean Screw*, patented a few years ago by Mr F. P. Smith, and now very generally adopted. Vessels fitted up with screw-propellers present no unseemly paddle-boxes, are not so liable to be damaged by collisions or by shot, and are as swift and easily managed as those propelled by the old paddles. The screw is formed by radial arms or blades, twisted, as it were, round a central iron axis. The screw thus formed is fixed parallel with the keel, at the stern of the vessel, below the water, and consequently out of sight. A variety of forms of the 'screw' have been patented, chiefly differing as to the *pitch* or angle at which the blades are fixed on the axis. For sea-going vessels the screw will soon, in all likelihood, be the only mode of propulsion adopted, as its advantages, either alone or as an adjunct to ordinary sailing, are numerous and decided.

In Great Britain the engines adopted are those called *condensing*, and they usually work with a pressure of about 40 lbs. on the square inch. In America, the high-pressure engine is generally used; and Stevenson states he was in a vessel on the Ohio, where the common pressure used was 130 lbs. on the square inch!

High-Pressure Engines.

The distinguishing feature of this class of engines is the absence of all contrivances for forming a vacuum in the cylinder; and from the fact of no condenser being used, they are frequently termed *non-condensing engines*. As the steam used for moving the piston has to overcome the ordinary atmospheric pressure acting on it, its elasticity must be greater than in condensing engines. Thus, while in the latter steam of 3 to 5 lbs. on the square inch is used, steam of 40 to 50 lbs. is used in the former; and in some cases steam even of the great pressure of 120 lbs. to the square inch is employed. As the condenser, cold water pump, air-pump, cistern, &c. are dispensed with in the high-pressure engine, it is rendered more compact, and consequently less space is taken up by it. So early as 1720, Leupold produced a high-pressure engine; but the first invention which came into extensive use, was the engine of Messrs Trevithick and Vivian, constructed by them in 1802. Since that period they have come into very general use, being much cheaper than condensing engines; and we may add, that the steam, after working the engine, instead of being projected into the atmosphere, may be used for warming premises, heating water for baths, and similar purposes.

The forms of high-pressure engines are various. The crank-overhead-engine is the simplest form, and is very effective; engines with the crank under the cylinder are also much used; and a small size of this form, represented in fig. 8, is much used for driving small coffee-mills in grocers' shops. Their cost varies from £20 to £50 without the boiler. The most complex of all is the beam high-pressure engine. In general appearance it is much like the double-acting engine of Watt; but of course there is no condenser and its associated apparatus. High-pressure horizontal engines, the whole machinery of which lies horizontally, are coming much into use. Brunel's oblique-acting engine, we believe, is a very efficient form of high-pressure.

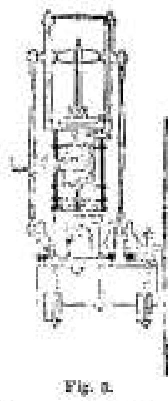

Fig. 8.

As there is greater danger to be apprehended from the use of high-pressure steam, the boilers of the engines are generally provided with two safety-valves—one locked up from the control of the engineer. The boilers are generally not so complex in their arrangements as those of low-pressure; indeed in all their arrangements simplicity is the leading characteristic. They perform their work well, do not require such close attention, and with a reasonable degree of care no danger of explosion need be apprehended. It may be mentioned here that locomotive engines for road and railway are all on the high-pressure system.

Rotatory Engines.

In this form of engine the cylinder, piston, crank, and fly-wheel, are all dispensed with; and a series of chambers or cavities, supplied with valves and traps, revolving round or turning with a central shaft, constitute the engine. As its name imports, the motion derived from the steam traversing these chambers is at once circular or rotatory, no reciprocating motion being produced; and in this lies the chief merit of the invention. Engines of this kind admit of being made very simple, free from complex arrangements, and their power can at once be applied without the intervention of other machinery. The varieties of rotatory engines patented are very numerous; but whether from any inherent error in their principle, amount of friction, or from some other cause, few of them have come into anything like extensive use. The simplest form of all is that introduced by Mr Ruthven of Edinburgh. It is the same in principle as the æolipyle of Hero; and we believe the engines fitted up by this gentleman are powerful, and give satisfaction. One of these which has come under our notice works with great efficiency, the pressure being from 30 to 70 lbs. on the inch. The length of the arms is five feet, the breadth five and a half inches, and the apertures from which the steam issues are one-fourth inch in diameter.

Locomotive Engines.

The form of engine adapted to the railway differs from those already described, these being stationary or fixed in large vessels, while here the smallest bulk possible is essentially required, at the same time as little weight as convenient. Accordingly we find, that in the arrangement of these engines, all that apparatus is rejected which is intended for condensation, and therefore high-pressure steam is used.

In the arrangement or disposition of the parts of the boiler and engine, there are certain peculiarities which require to be described. It is necessary to premise, that the great object is to effect as speedily as possible the conversion of a large quantity of water into vapour. This is accomplished by arranging the boiler in a peculiar manner. It is not one large mass, as in the marine boiler, or land boiler, with a great quantity of water in the centre, but an oblong cylinder, through which are disposed a vast number of brass tubes of a cylindrical shape, amounting to about ninety in number, arranged horizontally. These tubes communicate with the furnace, and the heated air passes through them as it proceeds to the chimney, in which manner an immense quantity of the caloric is applied to assist in the evaporation of the water; so that the boiler might, nevertheless, be considered merely the same as the common one, but with the chimney subdivided into an immense number of small tubes passing through it to the large vent hole or grand chimney. These tubes were suggested by Mr Booth, secretary of the Liverpool and Manchester Railway, and improved upon by Mr R. Stephenson, and constituted a great advance in the efficiency of the locomotive steam-engine.

In the sketch, fig. 10, is given a general exterior view of a locomotive, and in fig. 9 a longitudinal section of the apparatus. The boiler is seen forming the great bulk of the engine; its form is cylindrical, being about three feet in diameter, and eight in length. The numerous tubes, as they proceed through this part of the apparatus, are seen in transverse section in fig. 9, and longitudinal section, fig. 11. At the front of the engine is the smoke-box terminating in the chimney above, and below, there is the steam tube, and the cylinder and piston, which lie horizontally (A). At the back of the engine is the fire-box,

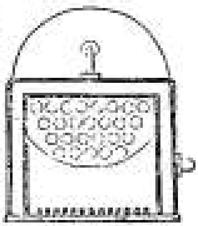

Fig. 9.

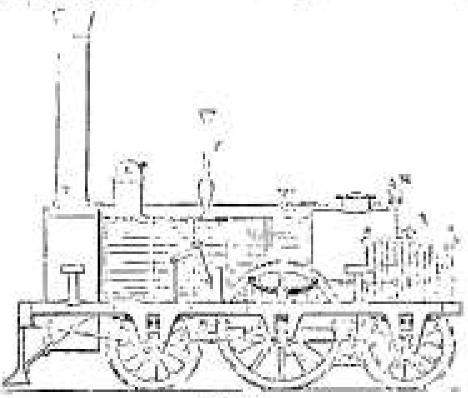

Fig. 10.

almost completely surrounded by water, and immediately behind this is the railed space (P) on which the engineer stands. On the upper surface of the engine, proceeding from the hind part forwards, there is the steam whistle (X), by which notice is given of the approach of the engine. A little anterior to it is the man-hole, by which the boiler can be cleaned, and such repairs made as are requisite. Still farther forwards, we arrive successively at the two valves (V' V), by which the safety of the boiler is secured. The first (V') is always under the control of the engineer; but the second, nearer the chimney (V), is loaded higher, but completely shut up. A round spherical eminence (B) is then perceived immediately behind the chimney, called the *separator*, in which the steam gathers before it is conveyed by the tubes to the cylinder. The cylinders (two in number) are placed below the chimney, and lie immediately before the front wheels (A, fig. 11), and the steam passes to them by the steam pipe (S) into the two cylinders, whence it escapes afterwards into the chimney. The reason why this tube rises so high in the large chamber is, that no water may descend to the cylinder, which might likely arise from the agitation the water suffers from the motion. At the point where the steam tube in the hot air chamber meets the connecting pipe with the boiler, a regulator is placed, for increasing or diminishing the flow of steam.

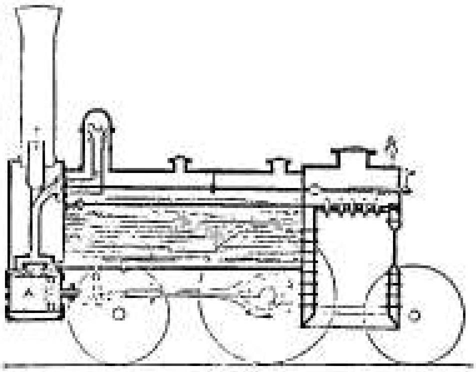

Fig. 11.

The steam, as it escapes from the cylinder by two pipes, meets in the common tube, and rushing upwards into the chimney, is in part condensed, and mainly contributes to the draught of the chimney, which otherwise would be totally inefficient to work the fire.

From the great number of the tubes which fill up the boiler, the locomotive engine is not attended with much danger in bursting; for these tubes being weak, compared with the external casing of the boiler, yield readily on any unusual increase of the elastic force of the vapour; the consequence is, that the fire is put out gradually. When one yields, a plug of wood is introduced, which is generally sufficient till the end of the run, or till arrival at the next station.

The eccentrics for working the valves, and allowing the steam to gain either side of the piston, are fixed to the main crank axle. Sometimes there are two pair of eccentrics, the additional one being for the movement backwards, when the engine makes a retrograde movement. The size of the steam cylinder is about twelve inches in diameter, and eighteen inches' stroke. The driving wheels are usually six feet diameter; and some of ten feet diameter have been tried on the Great Western Railway. Three cylinder engines of great power have been introduced by Mr Stephenson, their speed being upwards of seventy miles an hour!

The engine is always attended by a tender, in which the coke and water are conveyed. The mode in which the different coaches are arranged may be seen in the following number (26), where a train is figured with the engine and tender.

The power of a locomotive is estimated by the quantity of water which the boiler can convert into steam within a given time. Between 70 and 80 cubic feet is the average amount; but in the Bristol railway, so much as 200 cubic feet are evaporated within the same time. The quantity of fuel consumed in Stephenson's engine is about $\frac{1}{2}$ lb. for every ton per mile.

Duty of Engines.

The term *duty* is adopted to express the load which may be raised a given perpendicular height by the consumption of a given quantity of fuel. In engines used for the purposes of manufactures, or for navigation, it is difficult to calculate exactly the amount of resistance which the machine encounters; but where employed for pumping water, their performance is more easily determined. The highest duty performed by an engine in Cornwall, at Wheal Hope Mine, was raising nearly 47,000,000 lbs. one foot high by the combustion of one bushel of coals. Another engine at St Austell raised 95,000,000 lbs. one foot high by one bushel of coal. This enormous mechanical effect was so unusual, that doubts arose as to the correctness of the report; and in the presence of a number of witnesses the engine was again tried, when the result was, that it raised 125,500,000 lbs. one foot high, by the consumption of one bushel of coal.

Expansive Action of Steam.

Steam, as already observed, being a vapour, possesses consequently the expansive property peculiar to such bodies; and as the piston either descends or ascends by the impulse of the steam, it follows that the velocity of the stroke is not equal throughout. Suppose the piston is at the summit of the cylinder, and the steam enters above, the piston will then begin to descend, opposed only by its inertia and friction against the sides of the cylinder. But as the motion downwards continues, this becomes accelerated from its own inertia, and therefore the resistance being less than at first, the steam forces it downwards with increased velocity. The velocity will be at the *maximum*, or nearly so, when it has completed the descent. Watt, ever alive to all the modes of bringing the greatest effect from the steam, considered that a moving power, in addition to that obtained by the stroke of the piston, might be obtained and rendered practically available. We refer to a method of still doubling the effect of the steam, and that tolerably easy, by using the power of steam rushing into a vacuum—at present lost. This would do little more than double the effect, but it would too much enlarge the vessels to use it all: it is particularly applicable to wheel engines, and may supply the want of a condenser where the force of steam only is used. Open one of the steam valves, and admit steam until one-fourth of the distance between it and the next valve is filled with steam; then shut the valve, and the steam will continue to expand and to press round the wheel with a diminishing power, ending in one-fourth of its first exertion. The sum of the series will be found greater than one-half, though only one-fourth of steam was used.

This mode of using the steam expansively may be illustrated in the following manner:—If the piston is pressed by a weight of one ton, and can be raised four feet when the cylinder is supplied with steam of the ordinary pressure of one atmosphere, the same piston loaded with four tons will be raised one foot, if the cylinder be one-fourth full of steam of four atmospheres. When the steam of four atmospheres is admitted, it is cut off when the piston is raised one foot. But the piston has now received an impulse, and the steam, beginning to expand under it with a gradually diminishing force, is raised to the second foot, the volume now being doubled, and its elasticity only equal to two atmospheres. On the piston being elevated to the third foot, the volume of the steam will be trebled, and its pressure or elasticity now reduced to one atmosphere and a third. But when the piston is raised the fourth foot, the steam will have been quadrupled in volume, and the force equal to that of one atmosphere.

This principle is now much employed, and particularly in the Cornish mines, where it has been used with great success, the pressure of the steam in the pumping or drainage engines being four atmospheres. The benefit of working a steam-engine in this mode increases the earlier the steam is cut off, but not much after it is rarefied four times.

Steam cut off.	Power multiplied.
½	1·7

¼	2·4
⅕	2·6
⅙	2·8
⅐	3·0
⅛	3·2

Horse Power.

In forming the estimate of the power of a steam-engine, it is usual to refer to horse power as a standard. Different values have been given of the power of a horse;* but that generally adopted is, that it can raise a weight of 33,000 lbs. one foot per minute, and therefore a steam-engine capable of executing that work is rated at one-horse power. On a railway, this power is considered equal to transport 400 tons 1 mile per day; or a horse draws 200 lbs. at the rate of 2½ miles in an hour, continuously, over a pulley. The evaporation of a cubic inch of water, when converted into steam, affords a mechanical force capable of raising a ton one foot high. Fifteen cubic inches of water, therefore, when converted into steam, are equal to the power of one horse per minute, or 900 cubic inches per hour for each horse power.

To evaporate this, from 7 to 12 lbs. of fuel are required in the same time (one hour); but in marine engines, the quantity consumed is about 8 lbs.; the proportion of fuel they consume being as 2 to 3 compared with other engines.

Engineers possess rules for calculating the elastic force of steam and power of engines. The following may give an idea of the method of calculation:—

To find the power of an engine, multiply double the length of the stroke† by the number of strokes per minute, and we get the velocity of the piston per minute. If the engine works expansively, the mean effective pressure must be found. Multiply the square of the cylinder's diameter in inches by the mean effective pressure on the piston in pounds on the square inch, and by the velocity of the piston, point off these figures, and divide the product by 42, and the quotient will express the number of horses' power. Let the diameter of the cylinder be 36 inches, the length of stroke 4 ft., the number of strokes per minute 24, and the mean effective pressure on the piston 4 lbs. per sq. inch, then

```
8 Feet × 24 = 192 per minute.

Of the steam power at present employed in Great Britain, it is almost impossible to form an accurate estimate. Statisticians, however, reckon it as equal to about 2,000,000 horse power—an amount of animal force which could never, in reality, be brought into full operation without extensive derangement of our whole economic system. It is indeed beyond the scope of the ordinary terms of language to express the advantages resulting from the perfection and employment of the steam-engine. We have only to look abroad on the world, and see what mighty applications of this wonderful machine are everywhere visible. Steam navigation, railway travelling, automatic factory-labour, steam-printing, mining, and a hundred of other arts, have been brought to their present state only by means of its wonderful assistance. In its adaptation to mills and factories, steam is doubtless more costly than water-power; but being independent of situation or seasons, it is in general circumstances preferable. Its placid steadiness, and the ease with which it may be managed, are also great recommendations in its favour. As a motive power in the industrial arts, steam takes the precedence of all others; and viewing it as an economiser of labour and time, it must be assuredly pronounced as the greatest of modern mechanical contributors to human progress and comfort.

* The medium power of the horse is rated at 22,000 lbs. raised one foot per minute; but 33,000 is the standard applied by engineers to the steam-engine.

† The length of the stroke of an engine implies the space moved through by the piston in its ascent and descent, and consequently is equal to one complete revolution of the crank shaft; hence the reason why the length of the stroke must be doubled.

INLAND CONVEYANCE.

The artificial conveyance of person and property from one locality to another may be treated under two great heads—*Inland* and *Maritime*. To these science may in time add a third—namely, *Aërial;* but as yet, all the schemes and experiments in this department have been without any available result.* Confining our remarks, therefore, to what is real and practicable—roads, rivers, canals, and railways may be regarded as the main channels of inland transport; while the ocean alone forms the highway of maritime intercommunication. In the present sheet, we mean to direct attention to the history, construction, and maintenance of the former channels—subjects which belong exclusively to the recent science of Civil Engineering; reserving consideration of ocean transport, which requires the conjoint aid of the navigator and civil engineer, for a subsequent number. As a fitting introduction, both in point of information and interest, we may briefly advert to the modes of conveyance adopted by nations but little advanced in the arts of civilisation.

PRIMITIVE MODES OF CONVEYANCE.

The means adopted in early times for artificial transport were, as may be supposed, of the rudest kind, as is still the case in those countries which are little advanced in the useful arts. The most degrading species of conveyance that seems to have been practised, was the employment of human labour in bearing litters or palanquins, specimens of which, on a scale of barbarous splendour, are now seen in India, Burmah, and China.

The first and most obvious improvement in modes of transport, was the substitution of brute for human labour; and it is reasonable to conclude that the value of this practice could not have been long in being pressed on the attention of mankind. We find the term 'beasts of burden' used in the most ancient records, the animals meant being the ass, the horse, and the camel. No trace, however, exists of the progress from *burden* to *draught*, though it also must have taken place at a very early period. The ass and horse are equally adapted for carrying or drawing, but the camel exerts its power only by carrying; draught alone is suitable for the reindeer and ox, the backs of these animals not being fitted by nature for burden.

Burden.

From the earliest times, the camel, in its two varieties of camel and dromedary—respectively two-hunched and one-hunched—has been employed in the sandy regions of Asia as a beast of burden; and without its invaluable services in this respect, these countries could scarcely have been habitable. In ancient times, it formed the engine of carriage among the merchants of Arabia, and conveyed the products of India across the deserts to the populous and wealthy land of Egypt.

The camel is expressly suited by nature for inhabiting and traversing sandy and parched deserts, in which there are places of rest and refreshment only at wide intervals. 'It is the most temperate of all animals,' says Goldsmith, 'and can continue to travel several days without drinking. In those vast deserts, where the earth is everywhere dry and sandy—where there are neither birds nor beasts, neither insects nor vegetables—where nothing is to be seen but hills of sand and heaps of bones—there the camel travels, posting forward, without requiring either drink or pasture, and is often found six or seven days without any sustenance whatsoever. Its feet are formed for travelling upon sand, and utterly unfit for moist or marshy places; the inhabitants, therefore, find a most useful assistant in this animal, where no other could subsist, and by its means cross those deserts with safety which would be impassable by any other method of conveyance.

Camels are easily instructed in the methods of taking up and supporting their burdens; their legs, a few days after they are produced, are bent under their belly; they are in this manner loaded, and taught to rise; their burden is every day thus increased, by insensible degrees, till the animal is capable of supporting a weight adequate to its strength. The same care is taken in making them patient of hunger and thirst: while other animals receive their food at stated times, the camel is restrained for days together, and these intervals of famine are increased in proportion as the animal seems capable of sustaining them. By this method of education, they live five or six days without food or water; and their stomach is formed most admirably by nature to fit them for long abstinence. Besides the four stomachs which all animals have that chew the cud (and the camel is of the number), it has a fifth stomach, which serves as a reservoir to hold a greater quantity of water than the animal has an immediate occasion for. It is of sufficient capacity to contain a large quantity of water, where the fluid remains without corrupting, or without being adulterated by the other aliments. When the camel finds itself pressed with thirst, it has here an easy resource for quenching it: it throws up a quantity of this water, by a simple contraction of the muscles, into the other stomachs, and this serves to macerate its dry and simple food.

In Turkey, Persia, Arabia, Barbary, and Egypt, the whole commerce is carried on by means of camels; and no carriage is more speedy or less expensive in these countries. Merchants and travellers unite themselves into a body, furnished with camels, to secure themselves from the insults of the robbers that infest the countries in which they live. This assemblage is called a *caravan*, in which the numbers are sometimes known to amount to above ten thousand, and the number of camels is often greater than that of the men. Each of these animals is loaded according to his strength, and he is so sensible of it himself, that when his burden is too great, he remains still upon his belly, refusing to rise till his burden be lessened or taken away. In general, the larger camels are capable of carrying one thousand pounds' weight, and sometimes twelve hundred; the dromedary from six to seven hundred. In these trading journeys they travel but slowly; their stages are generally regulated, and they seldom go above thirty, or at most about thirty-five miles a-day. Every evening, when they arrive at a stage, which is usually some spot of verdure where water and shrubs are in plenty, they are permitted to feed at liberty: they are then seen to eat as much in an hour as will supply them for twenty-four. They seem to prefer the coarsest weeds to the softest pasture—the thistle, the nettle, the cassia, and other prickly vegetables are their favourite food; but their drivers take care to supply them with a kind of paste composition, which serves as a more permanent nourishment. As these animals have often gone the same track, they are said to know their way precisely, and to pursue their passage when their guides are utterly astray. When they come within a few miles of their baiting-place in the evening, they sagaciously scent it at a distance, and increasing their speed, are often seen to trot with vivacity to their stage.

The patience of this animal is most extraordinary; and it is probable that its sufferings are great, for when it is loaded, it sends forth most lamentable cries, but never offers to resist the tyrant that oppresses it. At

* For the principles of *aërostation*, or the art of moving through the atmosphere, see PNEUMATICS, page 240.

the slightest sign, it bends its knees, and lies upon its belly, suffering itself to be loaded in this position: by this practice the burden is more easily laid upon it than if lifted up while standing. At another sign it rises with its load, and the driver getting upon its back, between the two panniers—which, like hampers, are placed upon each side—he encourages the camel to proceed with his voice and with a song. In this manner the creature proceeds contentedly forward, with a slow uneasy walk of about four miles an hour, and when it comes to its stage, lies down to be unloaded.'

From Major Skinner's account of his 'Journey to India,' in the course of which he travelled twenty days with a numerous caravan from Damascus to Bagdad, we have the following lively picture of the mode of conveyance by camels:—

'I must give a description of our equipage, now that we are fairly launched on the great waste. I ride a white camel, with my saddle-bags under me, and a pair of water-skins, quite full, beneath them: over the saddle is my bed. A thick cherry-stick, with a cross at the end of it, serves to guide the animal: a gentle tap on the side of his neck sends him to the left, and one on the opposite makes him turn back again to the right: a knock on the back of his head stops him, and a few taps between the ears bring him to his knees, if accompanied by a guttural sound, resembling, as the Arabs say, the pronunciation of their letter *ikhe*. To make him move quickly, it is necessary to prick him with the point of the stick.

We passed over a perfect level this morning, strewed with flowers, and thick with pasture for the camels, where we are now resting. It is not usual here, as in many parts of the East, for the camels to wind in long strings, one after the other. Our numbers, amounting to fifteen hundred, are scattered over the surface in all directions, as far as the eye can trace. In travelling, the sheiks, or chiefs of the caravan, attended by the military part of their equipage, mounted on dromedaries, move in advance, while the loaded camels follow at some distance, in parallel masses, opening out, or changing the form, as the grass renders it necessary. They fall so naturally into military figures, that it is difficult to conceive their doing it without direction. We have several tents in the caravan. They are pitched so as to permit the camels belonging to each to lie in the intervals, where they are placed in *squads* for the night. They are by no means agreeable neighbours: for although they are not able to move from their place, they make a most unpleasant gurgling noise.

The rate at which a loaded camel travels is estimated at two and a-half miles an hour by almost every traveller. Our caravan has not, I think, exceeded this; but the variety of its movements has been very tiresome. There is so strong a resemblance to a voyage at sea in a passage across the desert, that I cannot divest myself of the belief that the moving mass is but a collection of small vessels, carried into a heap by the tide. Every man is ready with his stick to fend off the animal that approaches him: one push separates the camels, as it would separate a couple of boats; and they move away, quite unconscious of the circumstance, till another movement swings them together again.'

Turning to the new world, we find, from the remotest period to which the Peruvian records extend, that the aborigines not only used the llama and alpaca for food and clothing, but also employed them in their military and domestic service, as the Arabs do the camel. The llama was principally destined to carry burdens, although, compared with the Asiatic drudge, the difference in size and strength is considerable. Its load, according to Mr Walton, never exceeded 150 lbs., with which it was not required to travel more than three leagues per day; whereas in the working part of the twenty-four hours, the camel journeys double that distance with 800 lbs. or more upon his back. For this difference the Peruvians made up in the greater number of their beasts of burden, one drove sometimes exceeding five hundred head, whose subsistence on the road was entirely left to chance. Neither whip nor goad was used to urge them on: one llama, older and more experienced than the rest, led the way, the others following irregularly but quietly after. Owing to its docility and knowledge of its keeper, this animal evidently requires less training than the camel. It needs no rein—not even a pack-saddle—so long as the panniers or packages are well poised.

We need scarcely advert to the fact, that wherever civilisation has made any progress, the horse, the ass, and their hybrid the mule, have been used as beasts of burden—that is to say, in those countries which form their natural habitats. At what period the horse was first subjected to the purposes of man, we have no authentic record. He is mentioned by the oldest writers, and it is probable that his domestication was nearly coeval with the earliest state of society. Trimmed and decorated chargers appear on Egyptian monuments more than four thousand years old; and on sculptures equally, if not more ancient, along the banks of the Euphrates. One of the oldest books of Scripture contains the most powerful description of the war-horse; Joseph gave the Egyptians bread in exchange for horses; and the people of Israel are said to have gone out under Joshua against hosts armed with 'horses and chariots very many.' At a later date, Solomon obtained horses 'out of Egypt, and out of all lands,' and had 'four thousand stalls for horses and chariots, and twelve thousand horsemen.' Thus we find, that in the plains of the Euphrates, Nile, and Jordan, the horse was early the associate of man, bearing him with rapidity from place to place, and aiding in the carnage and tumult of battle. He does not appear, however, to have been employed in the more useful arts of agriculture and commerce; these supposed drudgeries being imposed on the more patient ox, ass, and camel. Even in refined Greece and Rome, he was merely yoked to the war-chariot, placed under the saddle of the soldier, or trained for the race-course. As civilisation spread westward over Europe, the demands upon the strength and endurance of the horse were multiplied, and in time he was called upon to lend his shoulder indiscriminately to the carriage and wagon, to the mill, plough, and other implements of husbandry. It is in this servant-of-all-work capacity that we must now regard him; and certainly a more docile, steady, and willing assistant it is impossible to find. For burden, the ass perhaps is more steady and enduring; but both are surpassed by the mule, which in Spain, South America, Mexico, and other countries destitute of good roads, affords one of the most available modes of commercial transport. Headed by one of superior sagacity, they move in long cavalcades, like the camel and llama, and with their gay caparisons, tinkling bells, and jauntily-dressed drivers, form a very picturesque object in the landscape.

Another primitive mode of carriage, and the last which we shall mention, is the employment of the huge and unwieldy but powerful elephant. At which time this animal was first subjugated, and trained to take part in the court and military equipage of the East, we have no means of knowing. His form appears on the most ancient Hindoo sculptures; he figures in their mythology; and he is spoken of with pride and veneration in their earliest records. In that fertile and luxurious region he had been trained for centuries before the names of Greece and Rome were known, and even long before the people of western Asia had passed from the primitive or pastoral condition. It was to Alexander the Conqueror that the western world was first indebted for the elephant;—he it was that made the sports of Persia and India familiar to the Greeks and Macedonians. The acquisition of the war-elephant gave new pomp and splendour to his squadrons, and his example was followed by degrees by other nations. In time, the Egyptians, Carthaginians, Romans, all made use of elephants, both to assist in the march, by carrying enormous loads of baggage, and to join the ranks, mounted by numbers of archers and spearmen, as here represented:—

Since the introduction of firearms and artillery, the war-elephant has been greatly abandoned even in the East, and is now chiefly used in carrying baggage, in doing other heavy work, and, above all, in adding to the 'pomp and circumstance' of Oriental authority. The present employment of the elephant in India, according to Von Orlich and other recent writers, is exceedingly varied—from the piling of firewood and the drawing of water, to the dragging of artillery and the carriage of royalty. When placed under the *howdah* (a covered seat for persons of rank), his back is protected by a thickly-stuffed hair cushion, over which is spread an ornamental covering. The howdah is made to contain two persons, and this is the amount of the travelling elephant's burden. The driver sits on his neck, immediately behind his ears, and guides him with an iron prong; and he is in general so docile, as to kneel for the parties to mount him. His great use, however, is as a beast of burden in a country where there are few or no roads; and since an ordinary elephant will carry as much as five camels, we can readily perceive their value in marching not only with the commanders and sick, but with the tents and furniture. He is equally serviceable as a beast of draught, pulling with ease what it would take ten horses to move; and it is for this reason that the Indian army have recently yoked him to their heavy artillery. Another power which the animal possesses, and one which is unknown to the horse or ox, is that of pushing; and if his forehead be protected by a pad, he will push forward weights which perhaps he could not draw. These, and many other duties, the elephant performs willingly, and, if gently treated and well fed, with a regularity of disposition which seems almost mechanical.

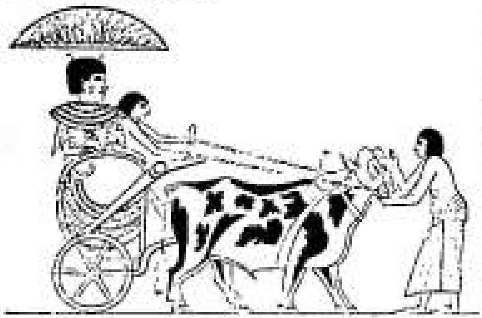
Draught.

The draught of the reindeer is employed in Lapland as the chief means of artificial locomotion, and is always exerted on a species of sledge, which, by its form, is suitable for gliding easily over the frozen ground or snow. The shape of the sledge somewhat resembles a small boat with a sharp prow, and flat in the rear, against which the inmate of the vehicle rests. The traveller is swathed in his carriage like an infant in a cradle, with a stick in his hand to steer the vessel, and disengage it from pieces of rock or stumps of trees that may happen to obstruct the route. He must also balance the sledge with his body, otherwise he will be in danger of being overturned. The traces by which this carriage is fastened to the reindeer are fixed to a collar about the animal's neck, and run down over the breast, between the fore and hind legs, to be connected with the prow of the sledge; the reins, managed by the traveller, are tied to the horns; and the trappings are usually furnished with little bells, the sound of which is agreeable to the animal. With this draught, the reindeer, if pressed, will travel from sixty to eighty miles in a day; but more frequently he does not travel more than forty or fifty, which is a good day's journey. Before he sets out, the Laplander whispers in his ear the way he has to go, and the place at which he has to halt, firmly persuaded that the beast understands his meaning. In the beginning of winter the Laplanders mark the most frequented paths, by strewing them with fir boughs; which, being frequently covered with new snow, alternately pressed by the sleighs, hardens them into a kind of causeway, which is the more smooth if the surface has felt a partial thaw, and been crusted by a subsequent frost. It requires great caution to follow these tracks; for if the carriage deviates to the right or left, the traveller is plunged into an abyss of snow. In less frequented parts, where there is no such beaten road, the Laplander directs his course by certain marks made on the trees.

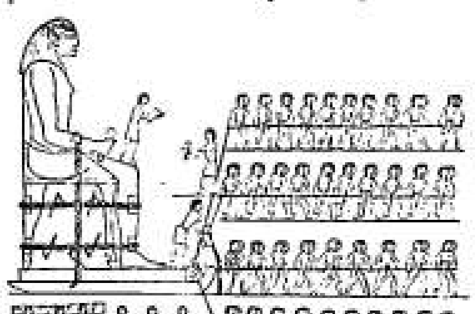
Amongst the Kamschatdales, Esquimaux, and other northern tribes, a peculiar variety of dog is almost universally employed as a beast of draught, and occasionally as one of burden. These animals are trained to draw the rude sledges that the Esquimaux, for example, are able to construct, which are about five feet long and two wide. The runners are generally made of pieces of wood and bone lashed together, with the interstices stuffed with moss, and the whole secured by a coating of ice, which is readily produced by the severity of the climate. The runner is shod with a plate of hard bone, and over this water is poured, to form another coating of ice, and this is renewed as often as it is worn off—a mode of shoeing which serves very well for nearly eight months out of the twelve. The dogs are harnessed by a collar, and a single trace running over their backs. They are not tied to each other, but each one is attached separately to the sledge, and at unequal distances, some even at twenty feet. The most docile dog is the leader, and his is the longest trace. A good leader is very attentive to the words of the conductor, and looks back over his shoulder with great earnestness to catch the word of command. Ten dogs make a full team, and will draw a sledge twelve miles an hour; and nine of them have been known to draw 1611 lbs. a mile in nine minutes. Three dogs drew Captain Lyon, in a sledge weighing 100 lbs., a mile in six minutes. On a good surface, six or seven dogs will perform in a day a journey of sixty miles, with nearly 1000 lbs. to draw. When there is no snow, the dogs are sometimes made to carry burdens in a kind of panniers, and one will travel thus with 25 lbs.

In Russia, and also in Canada, sleighs are used in winter for conveyance from place to place, the beast of draught being the horse. As the roads in many parts of Canada are very unsuitable for any species of travelling, it happens that sleighing over the hardened surface of the snow in winter is by far the best mode of communication in that country. It is almost unnecessary to add, that the sledge, which is the rudest kind of carriage for draught, has disappeared in all countries considerably advanced in improvement.

From the rude sledge, drawn with an incalculable degree of labour over the rough ground, the next important step in mechanical construction is to apply wheels, for the purpose of lessening the friction of the moving body. The first application of wheels to carriages is beyond the reach of record. Wagons are spoken of in the book of Genesis, from which it may be inferred that a knowledge of wheels was common in a very early age. It is further known that the making of wheels formed a distinct trade among the citizens of Thebes in ancient Egypt, three or four thousand years ago. The most elegant of the Egyptian carriages was a kind of gig, or light open chariot, on two wheels, called the *plaustrum*, which is thus described by Mr Wilkinson in his work on the Manners and Customs of the Ancient Egyptians:—'The plaustrum was very similar to the war-chariot and the curricle, but the sides appear to have been closed, and it was drawn by a pair of oxen instead of horses. The harness was much the same, and the wheels had six spokes. In a journey, it was occasionally furnished with a sort of umbrella, fixed upon a rod rising from the centre or back of the car; the reins were the same as those used for horses, and apparently furnished with a bit; and besides the driver, a groom or runner sometimes attended on foot, at the head of the animals, perhaps feeding them as they went. The annexed engraving represents an Ethiopian princess, who is on her journey through Upper Egypt to Thebes, where the court then resided:'—



From the researches of the same authority, we are enabled to form some estimate of the enormous trouble incurred by the ancient Egyptians in the transport of the heavy stones which they employed in building their temples. Some of these blocks weighed three or four thousand tons, and were usually conveyed from the quarries from which they were cut in flat-bottomed boats, on canals made for the purpose. Occasionally, however, when this mode of transport was unsuitable, the stone was drawn on sledges, perhaps some hundreds of miles, by oxen, or by human labour. The accompanying woodcut represents, in an abridged form, the mode of conveying colossal figures in stone from the quarries to the temples in which they were to be set up. 'One hundred and seventy-two men, in four rows



of forty-three each [we represent only as far as twenty each row], pull the ropes attached to the front of the sledge; and a liquid, probably grease, is poured from a vase by a person standing on the pedestal of the statue, in order to facilitate its progress as it slides over the ground, which was probably covered with a bed of planks, though they are not indicated in the painting. Some of the persons employed in this laborious duty appear to be Egyptians, the others are foreign slaves, who are clad in the costume of their country. Below are persons carrying vases of the liquid, or perhaps water, for the use of the workmen, and some implements connected with the transport of the statue, followed by taskmasters with their wands of office [but which we have not had space to include]. On the knee of the figure stands a man, who claps his hands to the measured cadence of a song, to mark the time, and insure their simultaneous draught. The height of the statue appears to have been about twenty-four feet, including the pedestal. It was bound to the sledge by ropes, which were tightened by means of pegs inserted between them, and twisted round until completely braced; and to prevent injury from the friction of the ropes upon the stone, a compress of leather or other substance was introduced at the part where they touched the statue.' Besides the great number of persons employed in drawing these huge blocks, it was customary for a band of some hundreds of soldiers to attend, perhaps for the purpose of overawing the slaves, and compelling obedience in their odious task. A more degrading means of mechanical conveyance it would be impossible to represent.

TRAVELLING IN PAST TIMES IN BRITAIN.

The modes of travelling and conveyance in Britain were of a comparatively rude and primitive kind till the latter part of the seventeenth century; and anything like comfortable and quick travelling cannot be said to have been known till a century later, when mail-coaching was introduced. In old times, people of a humble rank travelled only on foot, and those of a higher station on horseback. Noblemen and gentlemen, as much for ostentation as use, kept running footmen—a class of servants active in limb, who ran before them on a journey, or went upon errands of special import. The pedestrian powers of these footmen were often surprising. For instance, in the Duke of Lauderdale's house at Thirlstane, near Lauder, on the tablecloth being one morning laid for a large dinner-party, it was discovered that there was a deficiency of silver spoons. Instantly the footman was sent off to the duke's other seat of Lethington, near Haddington, fully seventeen miles off, and across hills and moors, for a supply of the necessary article. He returned with a bundle of spoons in time for dinner. Again—at Hume Castle in Berwickshire, the Earl of Home had one night given his footman a commission to proceed to Edinburgh (thirty-five miles off), in order to deliver a message of high political consequence. Next morning early, when his lordship entered the hall, he saw the man sleeping on a bench, and conceiving that he had neglected his duty, was about to commit some rash act, when the poor fellow awoke, and informed Lord Home that his commission had been executed, and that, having returned before his lordship was stirring, he had only taken leave to rest himself a little. The earl, equally astonished and gratified by the activity of his faithful vassal, rewarded him with a little piece of ground, which to this day bears the name of the *Post Rig*—a term equivalent to the postman's field, and an unquestionable proof, as all the villagers at Hume devoutly believe, of the truth of the anecdote. The custom of keeping a running footman did not cease amongst noble families in Scotland till towards the middle of the last century.

When the matter of communication was of particular importance, or required to be despatched to a considerable distance, horsemen were employed; and these, by means of relays of fresh animals, and great toil of body, would proceed journeys of some hundreds of miles to accomplish what would now be much better done by a post letter. Some journeys performed on horseback in former days would be considered wonderful even in modern times with good roads. Queen Elizabeth died at one o'clock of the morning of Thursday the 24th of March 1603. Between nine and ten, Sir Robert Carey left London (after having been up all night), for the purpose of conveying the intelligence to her successor James at Edinburgh. That night he rode to Doncaster, a hundred and fifty-five miles. Next night he reached Witherington, near Morpeth. Early on Saturday morning he proceeded by Norham across the Border; and that evening, at no late hour, kneeled beside the king's bed at Holyrood, and saluted him as king of England, France, and Ireland. He had thus travelled four hundred miles in three days, resting during the two intermediate nights. But it must not be supposed that speed like this was attained on all occasions. At the commencement of the religious troubles in the reign of Charles I., when matters of the utmost importance were debated between the king and his northern subjects, it uniformly appears that a communication from Edinburgh to London, however pressing might be the occasion, was not answered in less than a fortnight. The crowds of nobles, clergymen, gentlemen, and burghers, who at that time assembled in Edinburgh to concert measures for opposing the designs of the court, always dispersed back to their homes after despatching a message to King Charles, and assembled again a fortnight thereafter, in order to receive the reply and take such measures as it might call for. And even till the last century was pretty far advanced, the ordinary riding post between London and Edinburgh regularly took a week to the journey.

In consequence of the inattention of our ancestors to roads, and the wretched state in which these were usually kept, it was long before coaching of any kind came much into fashion. Though wheeled vehicles of various kinds were in use among the ancients, the close carriage or coach is of modern invention. The word *coach* is Hungarian, and the vehicle itself is supposed to have originated in Hungary. Germany certainly appears to have taken the precedence of the nations of Western Europe in using coaches. They were introduced thence into England some time in the sixteenth century, but were, after all, so little in vogue throughout the whole reign of Elizabeth, that there is no trace of her having ever used one. Lord Grey de Wilton, who died in 1593, introduced a coach into Ireland, the first ever used in that country. One was introduced into Scotland—we rather think from France—about the year 1571. It belonged to the famous Secretary Maitland of Lethington, who, during the horrid civil war between the adherents of Mary and those of her son James, made a journey in that vehicle from Edinburgh Castle, which he was holding out for the queen, to Niddry in West Lothian, for the purpose of holding a consultation with some others of her friends—the first time, it is believed, that a close carriage was ever used in Scotland. Fynes Morison, who wrote in the year 1617, speaks of coaches as recently introduced, and still rare in Scotland. For a long time these conveniences were only used by old people, who could not well bear riding. The young and active despised them, as tending to effeminacy, and as not being so quick of movement as the horse. The Duke of Buckingham, in 1619, first used a coach with six horses—a piece of pomp which the Duke of Northumberland thought proper to ridicule by setting up one with eight. Charles I. was the first British sovereign who had a state carriage. Although Henri IV. was killed in a coach—the only one, by the way, he possessed—his ordinary way of appearing in the streets of Paris was on horseback, with a large cloak strapped on behind, to be used in case of rain. In Scotland, previous to the civil war, coaches were only used by persons of high estate.

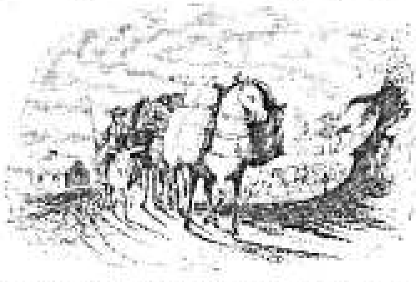
In a pamphlet called 'The Grand Concern of England Explained,' published in 1673, the writer very gravely attempts to make out that the introduction of coaches was ruining the trade of England. The following is an example of his mode of reasoning:—'Before the coaches were set up, travellers rode on horseback, and men had boots, spurs, saddles, bridles, saddle-cloths, and good riding-suits, coats and cloaks, stockings and hats, whereby the wool and leather of the kingdom were consumed. Besides, most gentlemen, when they travelled on horseback, used to ride with swords, belts, pistols, holsters, portmanteaus, and hat-cases, which in these coaches they have little or no occasion for. For when they rode on horseback, they rode in one suit, and carried another to wear when they came to their journey's end, or lay by the way; but in coaches, they ride in a silk suit, with an Indian gown, with a sash, silk stockings, and the beaver hats men ride in, and carry no other with them. This is because they escape the wet and dirt which on horseback they cannot avoid; whereas in two or three journeys on horseback, these clothes and hats were wont to be spoiled; which done, they were forced to have new very often, and that increased the consumption of manufacture. If they were women that travelled, they used to have safeguards and hoods, side-saddles and pillions, with strappings, saddle or pillion cloths, which, for the most part, were laced and embroidered; to the making of which there went many several trades, now ruined.' But the writer has other reasons to urge against coach travelling. 'Those who travel in this manner,' he observes, 'become weary and listless when they ride a few miles, unwilling to get on horseback, and unable to endure frost, snow, or rain, or to lodge in the fields.' Besides, he asks, 'what advantage it can be to a man's health to be called out of bed into these coaches an hour or two before day in the morning!—to be hurried in them from place to place till one, two, or three hours within night; insomuch that, after sitting all day, in the summer time, stifled with heat and choked with dust—or in the winter time, starving or freezing with cold, or choked with filthy fogs, they are often brought into their inns by torchlight, when it is too late to sit up to get supper, and next morning they are forced into the coach so early, that they can get no breakfast! What addition is it to men's health or business to ride all day with strangers, oftentimes sick, ancient, diseased persons, or young children crying; all whose humours he is obliged to put up with, and is often poisoned with their nasty scents, and crippled with boxes and bundles! Is it for a man's health *to be laid fast in the foul ways, and forced to wade up to the knees in mire; afterwards* sit in the cold till teams of horses can be sent to pull the coach out? Is it for their health to travel in rotten coaches, and to have their tackle, or perch, or axle-tree broken; and then to wait three or four hours (sometimes half the day), and afterwards to travel the whole of the night to make good their stage?'

These, however, do not exhaust the patriotic clamours of the writer against the odious innovation of stage-coaching. He says that the practice 'discourages the breed of horses,' an argument which, it is amusing to observe, has also been used in opposition to the introduction of railways in recent times. In certain very peculiar circumstances, he allows, stage-coaching might be tolerated, but in no other. 'If some few stage-coaches were continued—to wit, one to every shire-town in England, to go once a-week backward and forward, and to go through with the same horses they set forth with, and not travel above thirty miles a day in the summer, and twenty-five in the winter, and to shift inns every journey, that so trade might be diffused—these would be sufficient to carry the sick and the lame, that they pretend cannot travel on horseback; and being thus regulated, they would do little or no harm; especially if all be suppressed within fifty miles of London, where they are noway necessary, and yet so highly destructive.'

We have thought fit to introduce these extracts here, not so much for the purpose of amusing the reader with their absurdity, as to afford a caution to the general opponents of improvement. Arguments of a similar illogical nature are now used in reference to almost every proposed melioration in our social condition, and will doubtless, in a century hence, be quoted for their shortsighted folly, though at present meeting with countenance from a large class of the community.

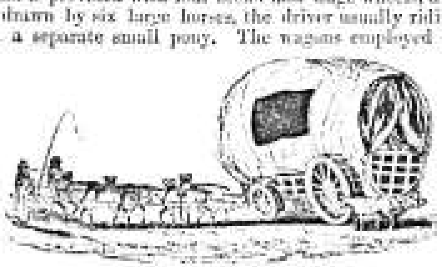
Notwithstanding the introduction of stage-coaches in the seventeenth century, they were placed only on the principal roads, and used almost exclusively by persons of refined taste and wealth. The popular mode of conveyance continued for at least a century afterwards to be by stage-wagons; these were very large and cumbersome machines, drawn by six or eight horses, and devoted chiefly to the carriage of goods to and from the metropolis. The only part of the vehicle which afforded accommodation to passengers was the tail of the wagon, as it was called, a reserved space with a hooped-up cover at the hinder part of the machine; and here, sitting upon straw as they best could, some half-dozen passengers were slowly conveyed—we should rather say jolted—on their journey.

The wagons thus employed in the double office of carrying both goods and passengers were, as we have said, confined chiefly to the great lines of road in England. On all the less important routes, and particularly in Scotland, the only means of conveyance for goods was by pack-horses. These animals were loaded



with sacks thrown across the back; and if not too heavy, piled to a considerable height. A number together were generally conducted in a line along the narrow and badly-constructed paths, that which went before carrying a bell, by the tinkling sound of which the cavalcade was kept from straggling after nightfall. This primitive mode of conveyance continued in operation in some parts of the country till the year 1780 or thereabouts, when one-horse carts came into use.

The old-fashioned wagons still remain in use in England, notwithstanding the numerous improvements in modes of conveyance and locomotion. They are chiefly employed for the carriage of goods between the metropolis and country towns which are at a distance from any line of canal or railway. A wagon of this kind is provided with four broad and huge wheels, and is drawn by six large horses, the driver usually riding on a separate small pony. The wagons employed in



London to convey coal from the wharfs to the houses of consumers, or beer from brewers, are of the same unwieldy form, and are drawn with a needless expenditure of power. Railway traffic, however, is now rapidly diminishing the number of these ponderous vehicles; and the desire for increased speed is as rapidly substituting on all the common roads light and elegant spring-vans.

The length of time consumed in journeys by even the best kind of carriages of past times is now matter for surprise. The stage-coach which went between London and Oxford in the reign of Charles II. required two days, though the space is only fifty-eight miles. That to Exeter (168½ miles) required four days. In 1703, when Prince George of Denmark went from Windsor to Petworth to meet Charles III. of Spain, the distance being about forty miles, he required fourteen hours for the journey, the last nine miles taking six. The person who records this fact says that the long time was the more surprising, as, *except when overturned*, or when stuck fast in the mire, his royal highness made no stop during the journey.

In 1742, stage-coaches must have been more numerous in England than in Charles II.'s time; but it does not appear that they moved any faster. The journey from London to Birmingham (116 miles) then occupied nearly three days, as appears from the following advertisement:—'The Lichfield and Birmingham stage-coach set out this morning (Monday, April 12, 1742) from the Rose Inn, Holborn Bridge, London, and will be at the Angel, and the Hen and Chickens, in the High Town, Birmingham, on Wednesday next to dinner; and goes the same afternoon to Lichfield. It returns to Birmingham on Thursday morning to breakfast, and gets to London on Saturday night; and so will continue every week regularly, with a good coach and able horses.' Thus the whole week was occupied in a journey to and from Lichfield by Birmingham, an entire space of probably not more than 240 miles—that is, at an average of forty miles a day.

Of the stage-coach journey to Bath about 1740, we learn some particulars from Smollett's celebrated novel. Mr Random enters the coach before daylight. It proceeds. A highwayman attacks it before breakfast, and is repulsed by the gallantry of the hero. Strap meanwhile accompanies the coach on horseback. A night is spent on the road, and the journey is finished next day, apparently towards evening—108 miles! At that time there was no regular stage-coach from London to Edinburgh; and the newspapers of the latter city occasionally present advertisements, stating that an individual about to proceed to the metropolis by a postchaise would be glad to hear of a fellow adventurer, or more, to lessen the expenses for mutual convenience. However, before 1754, there was a stage-coach between the two British capitals. In the 'Edinburgh Courant' for that year, it is advertised that—'The Edinburgh stage-coach, for the better accommodation of passengers, will be altered to a new genteel two-end glass coach machine, hung on steel springs, exceeding light and easy, to go in ten days in summer and twelve in winter; to set out the first Tuesday in March, and continue it, from Hosea Eastgate's, the Coach and Horses in Dean Street, Soho, London, and from John Somerville's in the Canongate, Edinburgh, every other Tuesday, and meet at Burrowbridge on Saturday night, and set out from thence on Monday morning, and get to London and Edinburgh on Friday. In winter, to set out from London and Edinburgh every other [alternate] Monday morning, and to go to Burrowbridge on Saturday night; and to set out from thence on Monday morning, and get to London and Edinburgh on Saturday night. Passengers to pay as usual. Performed, if God permits, by your dutiful servant, Hosea Eastgate.' Here the distance of 200 miles requires six days in winter, being at the rate of little more than thirty-three miles a day. So lately as the end of the last century, the journey by the stage between Edinburgh and Glasgow (forty-two miles) occupied a whole day, the passengers stopping to dine on the road. It was considered a great improvement when, in 1799, a coach was started with four horses, which performed the journey in six hours. It is not unworthy of being noticed, that when the mail-coaches were started by Mr Parker in 1788, six and a half miles an hour was the utmost speed attained.

ROADS.

It will appear, from the preceding notices respecting travelling and modes of carriage for goods, that little or no improvement could be expected in either case till a great change for the better was made on the state of the roads. In no branch of art do our ancestors seem to have been more deficient or heedless than in that of making roads, and keeping them in constant repair. In this respect, indeed, they were in a condition of greater ignorance than the ancient Romans, whose roads were on the most extensive and efficient scale, suitable to the necessities of the period, and may here be shortly described.

Ancient Roman Roads.

It is, we believe, generally allowed that the Romans gained a certain degree of knowledge on the subject of road-making from Greece and Carthage, and also perhaps from Egypt; but whatever they learned, they greatly improved upon, and therefore they are entitled to be called the first and best road-makers of whom history has preserved any account. One great leading principle actuated the Roman authorities in establishing roads: it was that of maintaining their military conquests. On vanquishing a barbarous country, their first efforts consisted in penetrating it with good roads, which were maintained with jealous care, and were connected as far as possible in unbroken and direct lines with the seat of government at Rome: this indeed formed one of their grandest engines of subjugation, and affords us a striking proof of their sagacious and active character.

Speaking of the subordinate Roman capitals in Asia Minor, Syria, and Egypt, Gibbon describes as follows the manner in which they were connected by roads:—'All these cities were connected with each other and with the capital by the public highways, which, issuing from the Forum at Rome, traversed Italy, pervaded the provinces, and were terminated only by the frontiers of the empire. If we carefully trace the distance from the wall of Antoninus [in Scotland] to Rome, and from thence to Jerusalem, it will be found that the great chain of communication, from the north-west to the south-east point of the empire, was drawn out to the length of 4080 Roman [or 3740 English] miles. The public roads were accurately divided by milestones, and ran in a direct line from one city to another, with very little respect for the obstacles either of nature or private property. Mountains were perforated, and bold arches thrown over the broadest and most rapid streams. The middle part of the road was raised into a terrace which commanded the adjacent country, consisting of several strata of sand, gravel, and cement, and was paved with large stones, or in some places near the capital with granite. Such was the solid construction of the Roman highways, whose firmness has not entirely yielded to the effect of fifteen centuries. They united the subjects of the most distant provinces by an easy and familiar intercourse; but their primary object had been to facilitate the marches of the legions: nor was any country considered as completely subdued, till it had been rendered in all its parts pervious to the arms and authority of the conqueror. The advantage of receiving the earliest intelligence, and of conveying their orders with celerity, induced the emperors to establish throughout their extensive dominions the regular institution of posts. Houses were everywhere erected, at the distance of only five or six miles; each of them was constantly provided with forty horses; and by the help of these relays, it was easy to travel a hundred miles in a day along the Roman roads. The use of the posts was allowed to those who claimed it by an imperial mandate; but though originally intended for the public service, it was sometimes indulged to the business or conveniency of private citizens.'

From other accounts, we learn that the Roman roads varied in importance and uses. The great lines were called *prætorian ways*, as being under the direction of the prætors; and these formed the roads for military intercourse. Other lines were exclusively adapted for commerce or civil intercourse, and were under the direction of consuls. Both kinds were formed in a similar manner. The plan on which they were made was more calculated for durability than ease to the traveller; and for our modern wheel carriages they would be found particularly objectionable. Whatever was their entire breadth, the centre constituted the beaten track, and was made of large ill-dressed stones, laid side by side, to form a compact mass of from twelve to twenty feet broad; and therefore in their external aspect they resembled the coarse stone causeways which are still in use in the towns and highways of France. Some of the roads had double lines of this solid pavement of this nature, with a smooth brick path for foot passengers; and at intervals along the sides, there were elevated stones on which travellers could rest, or from which cavalry could easily mount their horses. One important feature in the construction of all the Roman roads was the bottoming of them with solid materials. Their first operation seems to have been the removal of all loose earth or soft matter which might work upwards to the surface, and then they laid courses of small stones, or broken tiles and earthenware, with a course of cement above, and upon that were placed the heavy stones for the causeway. Thus a most substantial and durable pavement was formed, the expense being defrayed from the public treasury. Various remains of Roman roads of this kind still exist in France, and also in different parts of Britain. One of the chief Roman thoroughfares, in an oblique direction across the country from London to the west of Scotland, was long known by the name of Watling Street, which has been perpetuated in the appellation of one of the streets in the metropolis.

Modern Macadamised Roads.

We now proceed to offer some account of the introduction of a proper kind of road in modern times. Attempts to improve the roads forming the leading thoroughfares in England were made at the beginning of the eighteenth century; and for that purpose turnpike acts for various districts were passed by parliament. It is a very remarkable fact, that some of the counties in the neighbourhood of London petitioned parliament against the extension of turnpike roads into the remoter parts of the country. These remoter counties, it was pretended, from the cheapness of labour, would be able to sell their corn at a lower rate in the London market than themselves, and would thereby reduce their rents, and ruin their cultivation. In spite of these remonstrances, turnpike roads were extended into the remoter counties, and, as ought to have been expected, so far from injuring the neighbourhood of the metropolis, they greatly increased its value—for an easy interchange of commodities is always universally beneficial.

It is of little moment to ascertain the exact period when these improvements were effected on the roads of England; for, upon the whole, they were only partial, and as yet the proper mode of road-making was not understood. The plan consisted in making the paths somewhat more level than formerly, and of filling up the ruts and holes with stones gathered from the adjacent fields. By this means the holes, ruts, and sloughs were considerably limited in both breadth and depth; but as perfect levelings was not attained, carriages were dreadfully jolted over the rougher parts, and the wheels sunk jarringly into the softer ground beyond. As also no pains were taken to lay down stones of equal bulk, but small and large mixed, it happened that the larger ones in time wrought to the surface, and so created additional jolting to vehicles and damage to the roads. The defects in this species of improved roads were so conspicuous, that various engineers of eminence, and other individuals, turned their attention to the subject; and among these is to be numbered John Loudon M'Adam—a gentleman descended of an old and respectable landed family in the Stewartry of Kirkcudbright—whose plans surpassed all others, and, as is well known, are now generally adopted. M'Adam was the first to point out and prove, in practical operation, that a bed, of a few inches in depth, formed of fragments of hard rock—granite, greenstone, or basalt—small enough to pass through a ring not larger than two and a half inches in diameter, was the best material for ordinary roads. His system, in its leading features, is so conspicuously displayed to the public eye, that any minute account of it would be superfluous. It was not till 1815, when on the verge of sixty, that he began to devote his whole mind to the business of road-making. Being then appointed surveyor-general of the Bristol roads, he had at length full opportunities of exemplifying his system, which he forthwith proceeded to do in a manner that attracted general attention, and caused it to be quickly followed throughout the whole kingdom. In 1823, Mr M'Adam was examined before a committee of the House of Commons respecting the propriety of converting the rubble granite causeway of the principal thoroughfares into a smooth pavement resembling those which he had already formed on the principal roads. He expressed himself as decidedly of opinion that such a change should be made: 'I consider,' said he, 'that the expenses would be materially reduced; the convenience of passing over the surface would be generally facilitated, particularly in the leading streets; and the same weight of stone now put upon those streets as pavement, would be obtained at infinitely less expense, in a different form, for the purpose of road-making.' The consequence was, that in London, Edinburgh, and Dublin, some of the principal lines of street, which had previously been remarkable for solidity of pavement, as well as the large sums that pavement had cost, were—to use a phrase already familiar to every ear—*Macadamised*. A counter-revolution has, however, in many instances taken place, and the old mode of causewaying with squared blocks again resorted to. Macadamising, however excellent for post-roads, is by no means well adapted for busy streets and city thoroughfares. Rough and loose when newly laid down, rapidly ground into mud in winter, and raised into clouds of dust in summer, independent of the obstruction offered by its frequent repair, it may be considered as all but exploded as a system for streets, or at least as having nothing but its pleasant smoothness to recommend it.

According to the principles of road-making, as laid down and consistently acted upon by M'Adam, a road ought to be an artificial and hard flooring, placed on a level and dry surface. To make a good road, therefore, we must in the first place level and prepare the ground. If the ground be soft—as, for instance, have a covering of turf and earthy matter beneath—the top must be pared off, and as much earth removed as will produce a hardish base. In some instances it may be necessary to excavate, and fill up the gap with compact and substantial materials; but should this be the case, the materials used must on no account include any large stones, or be otherwise unequal in their nature. The principles on which the road should be made are thus alluded to by Mr M'Adam:—'Roads can never be rendered perfectly secure until the following principles be fully understood, admitted, and acted upon: namely, that it is the natural soil which really supports the weight of travel; that while it is preserved in a dry state, it will carry any weight without sinking, and it does in fact carry the road and* carriages also; that this native soil must previously be made quite dry, and a covering as much impenetrable to rain as possible must then be placed over it, to preserve it in that dry state; that the thickness of a road should only be regulated by the quantity of material necessary to form such impervious covering, and never by any reference to its own power of carrying weight.'

To put these principles in practice: after the base of the road has been prepared, it should be laid with a layer of small stones, made by breaking larger stones into pieces weighing about three ounces. No round pebbles or channel stones must be employed; all must be angular, or irregularly-shaped pieces. The covering of this kind of material, technically called *road metal*, should be spread to a depth of from six to ten inches, as may be found necessary, and raked level on the surface. The sides of the road must possess wet ditches or gutters, into which all water may be readily conveyed and run off. For this purpose, culverts, drains, and gratings may be necessary.

In certain cases it may be expedient to carry a line of road across a bog or peat morass; and this may be done with perfect security by laying a bottom of brushwood or furze on the soft under stratum, and covering it over with gravel, and the ordinary stone material above. The road so formed may perhaps yield or bend a little when travelled by a heavily-loaded vehicle, but will sustain as much tear and wear as any other portion of the highway.

The width of the road is a matter of taste and convenience, but it should not be less than thirty-three feet, to allow a free passage of vehicles in different directions. On all the good roads in Britain near towns, a side footpath protected by a curb-stone is added to the ordinary breadth. 'With respect to the shape of the surface of the road'—we quote Scientific Tracts—'when completed, there is also some difference of opinion; but all agree that it should be convex, the only difference being in the quantity. The degree of convexity should be governed in a great degree by the locality. A road formed of soft materials should have a greater convexity than one formed of hard materials; for the obvious reason, that water will injure a soft road quicker than a hard one. A road upon uneven ground should have a greater convexity than one upon level ground, to prevent the descent of rain-water along the face of the road, which is there caught by the slightest impressions of wheels, and thus wear channels, as may too often be seen, from the top to the bottom of the hill. A wide road also requires to be more crowning than a narrower one; which more readily frees itself from rain-water, inasmuch as the distance the water has to run is less. But it must be borne in mind that the freeing a road from rain-water is not the only object to be kept in view in making a road crowning. The ease and safety of carriages, and particularly those with heavy burdens, or with high loads, must be consulted. A carriage moves most freely, or with the least resistance, when the load lies evenly upon the wheels. Just in proportion as the weight or load is thrown on one side or the other, the resistance is increased. Hence the inconveniency of a very crowning road on a steep; and hence the utility of bars or breaks in long ascents. It is plain that a road should be equally and duly convex in every part of it, otherwise it sooner becomes partially worn; the more level parts being most used.

When a road is carried round a hill instead of going directly over it, or when a road is made on a hill-side, it should not be made convex from the middle, but it should be formed like half of a common road, with the highest part on the upper side, thus giving the water a tendency to run off on the lower side. Mr Walker recommends the least possible convexity consistent with a proper drainage of the road. In most localities this will rarely exceed four inches; that is, the middle should be four inches higher than the sides. An idea of a perfect road may be formed from a frozen canal, where flatness, smoothness, and hardness are combined: in imitation of such a surface, railways were invented, and fully illustrate the principles assumed. Roads cannot be made with all of these perfections, but they should always be kept in view; for the nearer we approach to this standard, the greater will be the draught. M'Adam says roads should be made as flat as possible. 'Where a road is made flat,' he says, 'people will not follow the middle of it, as they do when it is made quite convex, which is the only place where carriages can run upright, by which means three furrows are made by the horses and the wheels, and the water continually stands there; and I think that more water actually stands upon a very convex road, than on one which is reasonably flat.'

In laying out a new road, it is of some importance that the rises and falls be not too great. The most approved angles of ascents and descents are about one inch in a foot—from this to one inch in a yard. In order to obtain ascents not exceeding these, it is necessary in our uneven country to wind up a hill instead of going directly over it. In such cases the road is to be built upon the side of a hill, and this is considered

* The latest novelty in street-laying—namely, that of paving with wooden blocks—has also been abandoned, in consequence of its dangerous slipperiness; in fact the only materials at present in repute are legitimate stone blocks, and the asphaltic concrete noticed under FICTILE MANUFACTURES, p. 336.

the most advantageous ground upon which a road can be built, provided the hill has not too great an ascent; because what is taken from the upper side serves to form the embankment on the lower side. While we are speaking of embankments, we may mention the common method of forming them:—'The natural sod, which would be covered by the base of the embankment, having been cut off and set aside, the earth is then wheeled or carted on to form the two outsides, which are raised to the required height, leaving the middle open. The sods are then placed on one another, the grassy surface at right angles to the face of the outer slopes, forming as it were a battering wall of sods against the embankment.' This method is found effectual in preventing the banks from washing away and gullying. While the outsides are forming, the lumps of earth, stone, &c. run downward to the middle; and in this way the whole is finished. When the work settles, it is found to tend towards the centre, thus preventing the outside slopes from giving way.

The following judicious observations are made by the same authority on the subject of fences and junctions of different roads:—'Fences are necessary along the sides of a road in all enclosed countries; but they should never be allowed to rise higher than four feet on common roads. It is absolutely necessary that the air and sun have free admission to a road; besides, where the fences are high, it gives a sweeping power to the wind, which is not beneficial. Mr Telford thinks that fences should never be more than four feet high, and that all trees within twenty feet of the sides of the road should be removed. He also thinks that twenty per cent. of the expense of repairing or improving roads is incurred by the improper state of the fences and trees along the sides, particularly on the sunny side: this will be manifest to any person who will take the trouble to examine the condition of that part of a road which is much shaded, compared to the other parts which are exposed to the sun and air. The junction of one road with another requires a little attention: it should always be made at right angles, and on the same level if possible. All engineers agree that plantations of trees should not be made close to roads; but what the distance should be, depends on the elevation of the country, the soil, the breadth of the road, as well as its direction, &c. &c. An elevated situation is always more exposed to winds than a level or hollow. A broad winding road has chances of the direct influence of the sun and wind, according to the obliquity of its angles; a road running north and south, though planted closely on both sides, will enjoy the sun during a part of every day in the year; one running east and west, planted on the south side with trees forty feet high or more, will enjoy no sun during the winter months. The least injurious trees are single rows trained to high stems, properly pruned.'

For some time after a road has been laid with fresh materials, it presents a rough surface, unpleasant to the feelings of those who are conveyed over it: but this roughness is gradually abated; the small stones are crushed into a compact mass; and finally, the road is smooth, hard, and level. The length of time that may elapse before any new repair is required depends on the amount and kind of traffic, as well as the weather; but a smooth surface may be speedily acquired by using a heavy roller, and by *blinding* or strewing the metal with good sharp sand, which fills up the interstices, and renders the mass more readily compact. Rain is a great enemy to macadamised roads, and particularly so when accompanied with much traffic. The water lies on the surface, and softening the material, the action of the horses' feet and of the wheels causes a certain depth of thin liquid mud. This mud should by all means be scraped off to a side, for the longer it lies, the stratum beneath is the more liable to be cut up and damaged. The scraping of the roads—which is now performed by an ingenious hand machine—therefore, becomes an essential duty of all who are interested in preserving the highways economically in repair. When the mud and refuse which is scraped aside thickens by exposure, it should be carted off, and may be employed on certain soils as a manure.

Roads exposed to much traffic require to be renewed in surface at least once a year. The first indications of decay are observable in the form of slight hollows, and ruts next make their appearance. In some cases, where the decay is only partial, a small quantity of metal may be scattered in the hollows, bringing them up to a level with all around. However, this is not usually done on well-kept roads near large towns. There the road undergoes a thorough repair once a year, which is preferable to partial mendings. The best time for repairing roads is about November, or before the winter frost and snow set in. In commencing the repair, the road should be picked across, at intervals of twelve or fifteen inches. This is done by men, each having a pick by which he indents the hard bottom, or forms scores an inch deep in the road. The use of such a preliminary process is to cause a ready union between the new and old materials. If the fresh metal were scattered over the old road, without any preparation, it would with difficulty unite to the substratum, and at best form an upper crust, which would be too easily damaged.

With respect to the keeping of roads in efficient repair, the most advantageous plan consists in assigning the entire duty to a contractor. This person, by undertaking to keep all the roads in a county or district in constant and uniform repair, is able to execute his functions much more economically than the private gentlemen who act as trustees of the highways and turnpikes. The trustees appointed by local acts of parliament to superintend highways, now generally employ contractors to keep the roads in repair at a specified price per mile, the payment being made from funds collected by the lessees of the toll-bars or turnpikes.*

Law of the Road.—For general convenience and safety, drivers of vehicles and riders, in travelling along a road, are expected to take a particular side; and this practice is now so well understood, and is in itself so proper, as to have become a part of the common law. The law of the road is, that when drivers meet from different directions, each shall keep his left hand to the wall or footpath. Secondly, when one driver overtakes another, and wishes to pass him, he must keep his left hand to the vehicle which he passes. In the case of either meeting or passing, each party is entitled to the half of the road. The same rules apply to riders. If these regulations be neglected, and an accident occur, the law is always in favour of the party who kept his own proper side, and no excuse can shelter the aggressor. The trustees of the road are liable in an action of damages for any injury that may be sustained through the carelessness of themselves or servants in leaving the road grossly out of repair.

According to a well-known rule, foot passengers on pavements or side-paths are expected to walk with their right hand to the wall—that is, they keep their left hand to those whom they are meeting and passing. This custom prevents confusion in the streets of large towns, but is not a matter of law.

CANALS.

A canal is an artificial channel of water, and is usually constructed for inland navigation. Where rivers can be resorted to for purposes of this kind, they are preferable to canals, because little expense may be required to suit them for navigation, and they may be easily kept in repair. But few rivers, generally speaking, are sufficiently level, straight, or deep, to admit of being profitably navigated by barges, and therefore artificial channels require to be cut. Canals are ex-

* Turnpikes were so called from poles or bars, swung on a pivot, having been placed on them, and turned either way when dues were paid. Gates are now substituted for these poles in Great Britain. In Germany, the pole is still used, one end being depressed to raise the other, and so permit a free passage.

tremely suitable in level countries, possessing rivers or brooks which can afford a due supply of water. In China, from a very early age, certain large rivers have formed natural canals longitudinally through the country from west to east, while artificial canals have been made to proceed in a cross direction from north to south, thus effecting a universal water communication throughout the empire. Canals existed in ancient Egypt in connection with the Nile, on a similar plan to what now prevails in China. Notwithstanding that canals were known to have existed from a remote antiquity in the East, it was long before they were introduced into western Europe. In modern times, they were first used by the inhabitants of the Netherlands, in consequence of the extreme flatness of their country, and the numerous channels of water which intersect it in all directions, in connection with the lower branches of the Rhine and other rivers. In Holland and Belgium, therefore, canals in a great measure exist as an essential requisite in the general arrangements of the country, and are, in point of fact, so many ditches or drains to receive the superfluous waters.

In countries differently constituted, canals are constructed only with reference to the profit in the form of commercial speculation. The great question, accordingly, in forming the project of a canal, is, whether the anticipated amount of traffic will raise tolls sufficient to compensate the outlay of the undertaking and subsequent charges for repair and superintendence. It simplifies such an inquiry to know the following truths in reference to cost of conveyance:—The cheapest mode of conveyance is by coasting vessels, steamboats, &c. and these will at all times be employed for heavy and bulky goods, such as coal, barrels of liquids, iron, and other cumbrous materials proceeding coastwise. The next cheapest mode of conveyance is by barges on rivers; and the next is by means of canals. After this are ranked, in point of economy, conveyance by land on railways and roads, the last being the dearest, though often the only means of transport which can be obtained. According to this view, canals can never answer as profitable speculations when they have to compete with coasting vessels of any description, or with any species of conveyance by rivers. They cannot, even in certain circumstances, compete successfully with railways, on account of the slowness of speed at which barges or boats are drawn along them; and as speed is becoming daily a matter of greater moment in traffic, canals are gradually losing the conveyance of every kind of goods for which quickness of transit is desirable. For the sake of economy in national resources, it is very desirable that these truths in statistics should be generally understood and remembered.

When the undertaking appears warrantable from a careful consideration of circumstances, the next thing to be taken into account is the obtaining of an adequate supply of water, and the fixing on the best—that is, the most level and unexpensive—line of route. In some parts of England, where an enormous traffic could be reckoned upon, canals have been projected and executed on a stupendous scale; mountains have been perforated to admit channels of water through them, valleys raised by embankments, and bridges built in the form of aqueducts across rivers; in short, no expense has been spared to render the inland navigation complete. The principal operations in an engineering point of view are the *cuttings*, which are termed level when over plane ground, and side or oblique when along the face of a declivity; the *tunnellings* through heights where open cutting would be more expensive; the *embankments* across valleys and low grounds; the *aqueducts* over rivers and ravines; the *bridges* for carrying the common roads over the canal; and the *locks* or steps by which any acclivity is ascended by the canal, instead of attempting its reduction by cutting or passing through it by tunnel.

The supply of water necessary for a canal which is level throughout its course is small in comparison with that of one pursuing an uneven line. When there is a common level of surface, the only expenditure of water is by evaporation; but when the level is various, a large loss is incurred at the locks in raising or lowering vessels. A lock is a portion of the canal enclosed by folding-doors, and must at least measure the length of a vessel. If a vessel is to be raised from one level to another, it is drawn up to the doors of the lock, and these are opened to admit it. Having sailed into the lock, the doors are closed behind it, and it is now in a kind of prison, from which there is no apparent escape. While in this situation, the doors at the opposite end of the lock, which retain the water at the higher level, are slowly opened, and admit a rush of the liquid mass, which speedily buoys up the vessel, and allows it to sail off along the higher level. The lock is not immediately emptied, but remains full of water, and is therefore ready to be employed in letting a vessel down. When the vessel approaches, and is fairly within the lock, the upper doors are shut, and then the lower doors are opened: by this means the vessel is carried into the lower level along with the rush of liquid, and is drawn on its course. A lockful of water has now evidently been shot from a higher to a lower level on the canal, and is lost, unless required for lower locks. To prevent inundation of the banks from the issuing of water from the locks, waste outlets require to be provided at certain distances, particularly at the lower termination of the line of canal. The provision of water to supply the locks is ordinarily from an artificial lake or reservoir, which is established near the highest ground in the line; and the smallest possible quantity consistent with the purposes of navigation is admitted in order to keep down the height of the sluices, banks, and dikes, all of which are affected by the pressure of an increased body of water. (See HYDROSTATICS.)

The breadth of most canals varies from twenty to thirty feet, and the depth from four to six feet. If the depth of water be sufficient to keep the vessels from touching the bottom, no greater volume is necessary, for less power is required to pull a boat upon a shallow than a deep water, there being less liquid agitated or displaced. At one side of the canal a narrow road, called the *towing-path*, is constructed, and upon this the horses which drag the vessel proceed. There is a difference in the manner in which the dragging-rope is attached to the vessel. In Holland, it is the practice to attach the rope to near the bow of the boat, and to cause it to proceed over the outer extremity of a pole or species of mast, so as to keep it considerably above the water, and prevent its friction on the banks. This is not attended to in England, where the rope proceeds direct from the bow to the horse, and, except when in a state of great tension, it trails along the bank and surface of the water. In either case, the draught of the horse is exerted with a loss of power; for instead of being a fair draught behind, it is oblique, or in the direction of the rope slanting to the vessel. The tendency of the draught is to bring the boat to the shore, which is counteracted by the helm, and this again assists in diminishing the general amount of available power.

Throughout the canals of England and Scotland, only one horse is employed to drag a boat loaded to the extent of from fifty to seventy tons; and with this weight dragging after it in a manner most disadvantageous, it will travel at the rate of two and a half or three miles an hour. That one horse should be capable of drawing fifty tons of goods in this unexpensive manner, gives an apparently favourable view of canal conveyance; but laying all charges out of the question, the slowness of the motion, and consequently the detention of goods by the way, is a drawback of the most serious nature, and in reality renders canals almost useless for the transport of any but heavy and raw materials. Latterly, on a few canals, attempts have been successfully made to run 'swift boats' for passengers, drawn by two horses, at a rate of seven or eight miles per hour; but as these vessels are run at a great expense for horse power, and at the utmost speed are not quicker in their transit than stage-coaches, it may be expected that they will utterly fail in competing with railways.

It may not be generally known that the principal obstacle to the use of steam-engines on board canal-boats, is the injury done to the banks by the action of the water from the paddles. This obstacle has to a certain degree been overcome by the use of one-paddled boats—the paddle being placed in the line of the boat's keel; and also by the application of the Archimedean screw propeller. Still, steam-dragging is by no means general; and canals, as a superseded idea, do not now much occupy the attention of engineers and inventors. It has also been proposed to lay rails along the towing-path, and employ steam-drags; a notion somewhat superfluous in these days, when it would be quite as economical to convert the path into a railway at once, or even to lay dry the canal, and apply its course to a similar purpose.

One of the largest canals in Europe is that which extends from the German Ocean to the River Ai, at Amsterdam, by which vessels are enabled to reach that city by a direct channel, instead of sailing round by the Zuyder Zee. This ship canal was begun in 1819, and finished in 1825, at an expense of £850,000. Its length is nearly 52 English miles; its breadth 125 feet at the surface, and 30 feet at the bottom; and its depth 20 feet 9 inches. Traversing a perfectly flat country, it has no locks, except at its extremities, and is of such magnitude, that two frigates, or the largest merchant vessels, can pass each other. There is a towing-path for horses on each side; and about eighteen hours are required to perform the voyage from Amsterdam to the ocean. As a commercial speculation, the canal yields no profit, but its service to the shipping of Amsterdam is incalculable, and without it the town must have sunk into comparative insignificance.

France possesses about fifty different canals, some of which are of great importance for general traffic. The chief canal is allowed to be that of Briare, called also that of the Loire and Seine. It was completed in 1642, measures 34½ miles in length, and has 40 or 42 locks. The width is 25 feet at bottom. By this canal Paris receives large supplies of inland produce. The Canal du Midi, or Languedoc Canal, makes a communication between the Mediterranean at the city of Cette and the Atlantic Ocean at the mouth of the Garonne, passing through the province of Languedoc. Altogether, there are nearly 1000 miles of canals in France.

The United States of North America posses upwards of 2500 miles of canals, the whole of which have been constructed within the last thirty years. The principal undertaking of this kind is the Erie Canal, which unites the river Hudson at Albany with Lake Erie at Buffalo, a distance of 363 miles. The Miami Canal, from Cincinnati to Lake Erie, which extends 265 miles, is another great undertaking; and there are a number of other canals, scarcely less important, for the general traffic of the country. The Rideau Canal in Canada, extending a distance of 160 miles, from the Ottawa (a tributary of the St Lawrence) to Lake Superior, is a stupendous undertaking, and will ultimately be of great service to the trade of British America.

The canals of Great Britain are believed to extend to an aggregate length of 2400 miles. The greater part are in the midland districts of England, including Lancashire, and have for their object the connection of the large seats of manufacture with the sea on both sides of the island and with the Thames at London. The Grand Trunk Canal, connecting the Mersey with the Trent and Humber, extends 93½ miles. The Birmingham and Worcester connects the Grand Trunk Canal with the Severn. The Grand Junction connects the Grand Trunk with the Thames. Thus the four great ports of the kingdom—London, Bristol, Liverpool, and Hull—are connected by canals. So generally are these and other canals spread over England, that it is supposed there is not a place south of Durham more than fifteen miles from water communication. The trade on some of the lines of canal, since the introduction of railways, has sunk in an extraordinary degree, greatly to the loss of the proprietors. Ireland has about 300 miles of canals, mostly government undertakings, and in general possessed of little trade.

Scotland has a number of canals, but they are chiefly confined to the western and mid district of the country. That which possesses the largest traffic is the Forth and Clyde Canal, reaching from the Clyde, a short way above Dumbarton, to the Forth at Grangemouth. This canal, which was opened in 1790, and affords a ready communication for small vessels between the east and west coast, extends 39 miles in length; its highest level is 160 feet, with 20 locks on the eastern acclivity and 19 on the western. The canal is connected with Glasgow by a side cut; and it is now joined by the Union Canal, which extends from near its eastern extremity to Edinburgh. This latter canal has proved a poor commercial speculation, but has been of great service to Edinburgh, by introducing coal at a cheap rate to the city, and affording an exceedingly convenient means of conveyance for goods to and from Glasgow. The Caledonian Canal is formed in a great measure by a chain of lakes, stretching across the country from Inverness on the east to Loch Eil on the west coast, a distance of 59½ miles. The canal part is 20 feet deep, 50 feet wide at bottom, and 120 feet at top, which affords a passage to frigates of 32 guns, or merchant vessels of a similar size. This great canal was undertaken as a public work by government; and after a labour of eighteen years, was opened in 1822, having then cost £900,000. It possesses 13 locks on the east, and 12 locks on the west coast, the highest level being 94 feet. By this canal the dangers of rounding the northern extremity of the island by the Pentland Firth may be avoided; but, from the prejudices of seamen, it has never been much used. As a means of allowing steam-boats to run between the Clyde and Inverness, the canal has been of considerable public service.

RAILWAYS.

Before the practice of steam navigation had attained that degree of improvement which it now possesses, a not less wonderful mode of travelling by steam power on land had come into use; wherefore, during the first thirty years of the nineteenth century, infinitely greater improvements in the means of locomotion have been discovered and brought into practical operation for the benefit of mankind than had ever previously been known. To understand and value the application of steam power to land travelling, we must advert to the subject of draught on common roads.

There exist three obstacles to the rapid motion of carriages—terrestrial attraction, the atmosphere, and friction. By no human power can the two former be removed, but the latter can be so far modified as to form little or no opposition. On all common roads, no matter how well they may be constructed, there is a certain degree of roughness which it is impossible to remove, and this causes so great a friction, that to overcome it, much of the drawing power is consumed without advancing the carriage. On some roads, the plan of laying down continuous lines or *tramways* of smooth pavement for the wheels to roll over has been resorted to, but has never been found generally answerable, not only in consequence of the great expense of construction, but because drivers will not take the trouble to keep their vehicles upon it.

The draught of a horse upon a macadamised road may be estimated at fifteen hundredweight, walking at an ordinary pace, and for several hours continuously. Particularly strong horses may habitually draw twenty or twenty-two hundredweight, but to cause them to pull to that amount is not economical. Allowing, however, that all horses can draw a ton weight, that is a small amount of draught in relation to great purposes of commerce; and the speed at which the fleetest horse can travel, when drawing a weight after it, though perhaps ten miles an hour, is unsuitable for the rapid transit of passengers on long journeys. To drag a mail coach from London to Edinburgh, a distance of about 400 miles, in 43 hours, which was reckoned a good speed, it was necessary to employ four horses, and to change these every eight miles on an average; thus 200 horses were required for the performance of the whole journey. Having attained this rate of locomotion, by improvements on roads, carriages, and in the breed of horses, nothing more could be done. Something new required to be devised.

The idea of employing steam power to drag carriages over common roads, and thus save a large outlay for horses, besides accomplishing a greater speed, was suggested by various enterprising minds, but to its practical application there were, and are, many serious objections. Independently of the ordinary and unavoidable roughness of common roads, all highways are less or more uneven; because to construct them upon a perfect level throughout, would be attended with an expense which the tolls from any traffic could not sustain. The general unevenness of roads, therefore, causes a great loss of drawing power. In these circumstances, it is evident that, for the avoidance of friction and economising of forces, an entirely new species of road required to be contrived. This important desideratum is found in the invention of *railways*. The design of a railway is to furnish a hard, smooth, and unchanging surface for wheels to roll upon. No provision, as respects smoothness, is required for any part of the path, except the narrow lines which are immediately to come under the rim of the wheels. Accordingly, it is sufficient to provide two rows or lines of strong and straight iron rails; that is, long slips of iron, about two inches in thickness, and four or six inches deep. These rails, laid in two parallel lines, to suit the width of a carriage, are raised a little above the general level of the ground, being placed neatly end to end, and secured by bolts or trenails to blocks of wood or stone at short intervals. Such is the very simple contrivance of a railway, or *chemin de fer* (road of iron), as it is called by our French neighbours. By the establishment of railways, a way was opened for the adaptation of steam power to locomotion, and now, as is well known, that has come generally into use.

The earliest railway of which there is any account was one constructed near Newcastle-upon-Tyne. In Roger North's Life of Lord Keeper North, he says that at this place, in 1676, the coals were conveyed from the mines to the banks of the river, 'by laying rails of timber exactly straight and parallel; and bulky carts were made, with four rollers fitting those rails, whereby the carriage was made so easy, that one horse could draw four or five chaldrons of coal.' One hundred years afterwards, about 1776, Mr Curr constructed an iron railway at the Sheffield colliery. The rails were supported by wooden sleepers, to which they were nailed. In 1797, Mr Barnes adopted stone supports in a railway leading from the Lawson main colliery to the Tyne, near Newcastle; and in 1800, Mr Outram made use of them in a railway at Little Eaton, in Derbyshire. Twenty-five years afterwards, this species of road was successfully adopted on a public thoroughfare for the transportation of merchandise and passengers; namely, the Stockton and Darlington Railway, which was completed in 1825, and was the first on which this experiment was made with success. From that time, accordingly, a new and wondrous era commenced in the history of inland conveyance.

It is a remarkable circumstance, that the early practisers of railway conveyance could not imagine that a carriage, moved by steam power, could proceed along the rails without the aid of toothed wheels and a rack; and to overcome this imaginary difficulty, no small degree of expense and labour was fruitlessly incurred. About the year 1815, Mr Blackett of Wylam, near Newcastle, effectually proved, by repeated experiments, that the adhesive power of the wheels on the rails was at all times sufficient to cause a progressive motion in an engine, with a train of loaded carriages, upon a railway either level or with a small acclivity. Important as was this discovery, fifteen years elapsed before steam locomotives were established. This great triumph of art occurred in connection with the opening of the Liverpool and Manchester Railway on the 15th of September 1830, since which period railways have spread to all populous parts of the country.

Simple as is the idea of a railway, a prodigious expense is necessarily incurred in bringing it into practical operation. All inequalities of surface in the ground must be removed; low parts must be filled up by embankments, high parts must be reduced, eminences, which is would be impolitic to level, must be perforated by tunnels—the whole route being brought as nearly as possible to a level. Besides, the land over which it is to proceed must be purchased frequently at an exorbitant cost; and the preliminary expense of overcoming petty opposition, and procuring an act of parliament to establish the line, sometimes amounts to as much as £2000 per mile. An entire charge of £30,000 per mile has been considered a moderate outlay in the construction of railways in Britain.

No long line of railway that has yet been formed is perfectly level throughout, but the acclivity is seldom more than one foot per mile, and this does not produce any retardation, which it would be absolutely necessary to obviate by an excess of expenditure. Every line, also, is curved, or bent from a truly straight direction, at various places in its course; and this is another evil which it is necessary to tolerate to a certain extent, rather than avoid by uneconomical outlay. For the reasons now stated, nearly all railways are neither perfectly straight nor perfectly level; and so far as such is the case, there is a loss of power in drawing vehicles along them. Yet in the most disadvantageous known circumstances, the railways are so comparatively smooth, and suitable for transit, that they allow the nearest approach to a total absence of friction. It is deserving of notice that the absence of friction in railways is advantageous not only for the saving of power, but the saving of painful sensations to the traveller. The suffering usually endured in ordinary modes of land conveyance is that which chiefly arises from *friction*. Friction is the grand evil to be overcome. Practically, in locomotion upon railways, a certain amount of friction is required between the wheels and the rails, to cause adhesion, and this is accomplished by the ordinary roughness of the iron.

Rails.—The iron trackway on which the carriages run is formed of iron rails, made in lengths neatly fitted together at the ends, and secured to the ground by contrivances about to be described. Some time ago cast-iron rails were used, but now those of wrought-iron are almost always adopted; and the old fish-bellied rail is superseded by that whose depth or profile is the same throughout. The cross section of a rail appears somewhat in the form of the letter T, the broadest surface being that on which the carriage-wheels run. 'Sleepers,' made generally of larch or oak, are laid across the line at certain intervals; and on each end of these sleepers 'iron-chairs' are fixed, into a slit or opening in which the rail is inserted, and made fast by wood or iron wedges. The chairs are fastened to the sleepers by iron bolts or trenails, and in some instances by iron screws. Instead of wooden sleepers, stone blocks are sometimes used; but these produce a jolting motion, at once disagreeable to the traveller and injurious to the mechanism of the carriage, and are consequently falling into disuse. In one or two cases, the rails have been laid upon continuous beams of wood, which are held securely in their place by cross-beams, the whole forming a compact but expensive framework. The railway between Newcastle and North Shields is laid upon this principle, and is one of the smoothest and most agreeable lines in the kingdom—being remarkably free from noise and jolting.

In Britain, two gauges have been adopted for the distance between the rails—respectively known as the broad and *narrow gauges*. The broad gauge, first followed on the Great Western line, is seven feet between the rails; the narrow, most commonly preferred, is only four feet eight inches. Frequent and somewhat angry discussions between the supporters of the different gauges have taken place. It is here needless to enter upon the merits or demerits of either: each possesses its advantages; but it is desirable that all the lines in the island were of the same breadth, so that in the event of their being joined together, one breadth of locomotive and carriage could traverse the whole. Already the difference of gauge has been felt as an inconvenience, as the two species are now in junction, requiring, both for passengers and goods, a change of carriage, with all its trouble and delay. With a view to remedy the evil, engineers are now devising methods of transfer, but as yet with very partial success.

Sidings.—As on most railways the different trains run at different degrees of speed—such as the 'express' faster than the mail, the 'mail' faster than the common passenger train, and this, again, faster than the goods or luggage wagons—provision must be made to enable all the trains to traverse the line when necessary, yet to allow the fast to pass the slow at certain points of the journey. This is effected by turn-outs, or *sidings*, which are placed at certain convenient parts of the line, and are made by means of a movable or *switch-rail* at the angle where the turn-out track branches from the main one. This rail is two or three feet, more or less, in length, and one end may be moved over that angle, and laid so as to form a part of the main track, or the turn-out track. The switch-rail is usually moved by a hand-lever, and wherever it is placed, requires the constant duty of an attendant.

Carriages—Wheels.—The principal consideration in regard to the construction of carriages, relates to their bearings on the axle and the rim of the wheel. The rule given by Mr Wood as to the bearing on the axle is, that in order to produce the least friction, the breadth of the bearing should be equal to the diameter of the axle at the place of bearing. This diameter must be determined by the weight to be carried; and the breadth of the bearing will accordingly vary with it. In order to keep the wheels fairly on the rails, they are furnished with thin edges, which dip on the outside; these *flanges* are about an inch and a half in depth. The mid wheels of locomotives are now made without flanges, but the fore and hind pair require flanges of rather more than usual depth. Wheels of large diameter move with greater ease over the rails than those which are small, because the large ones, in this as in all similar cases, have more power in overcoming obstacles. Yet there is a proper medium in the dimensions of wheels. Large wheels are inconvenient in point of height, and are apt to produce a rocking motion. It would appear that the most suitable diameter for the wagon or carriage wheels is from two and a-half to three feet, which is the usual size. The wheels of locomotives vary in diameter, but are generally from four to six feet. In an excursion on one of the English railways, when the train was at its maximum speed, the tire of one of the locomotive wheels flew off, and caused much damage; and in consequence of this, means have been taken for securing the malleable iron tire round the wheels.

Carriages are usually divided into three classes—first, second, and third. The first are covered, and resemble three coach bodies united. Each compartment is double-seated, the seats being separated by cushioned arms or supporters, thus preventing the passengers crowding one another. The whole interior is lined, cushioned, carpeted, and lighted; presents as much elegance, and affords as much luxurious ease, as any nobleman's carriage. The second-class carriages—originally very uncomfortable concerns—are now covered, and provided with windows, and on some lines are furnished, like the first-class, with lamps, and soft cushions for seats. These are not divided into compartments, but are calculated to hold, without crowding, from four to six passengers on each side. The third-class carriages were originally quite open, and in some cases entirely unprovided with seats; but now the parliamentary third-class—so called from companies being obliged to run them by act of parliament—are very comfortable conveyances, infinitely superior to the outside seat of a mail or stage-coach. They are covered, and furnished with seats and windows.

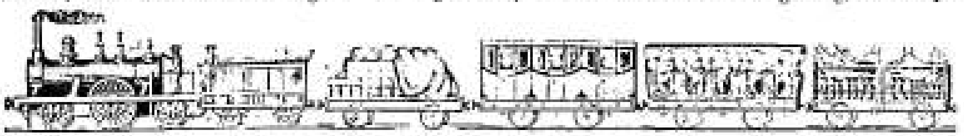
To lessen the amount of concussion between the carriages, each is provided at back and front with 'buffers'—that is, cushioned steel-rods which act upon springs, the springs in each case being made to resist a high degree of pressure. To diminish the noise arising from the wheels, it has been proposed to enclose them in cases of zinc, and fill the spaces between the spokes with sawdust: a mode which is said to be effectual, but seldom if ever adopted in practice. To prevent oscillation during high rates of speed, various plans have been proposed; but none, we believe, so efficient as well-balanced and well-constructed wheels and carriages. Another recent improvement is the sheltering of the guards from the inclemency of the weather, thereby enabling them to do their duty with greater efficiency; but means are still wanted by which the guards or the passengers may communicate readily with the engineer in cases of accident. There is great room, indeed, for improvement in the 'passenger transit department;' and we are happy to observe, from the introduction of 'pleasure,' 'invalid,' and other carriages, that some of the first-class lines seem alive to this subject.

Curvatures.—The curvatures in the line of railway present some obstructions, since the axles of the car and wagons being usually fixed firmly to the frames, every bend of the tracks must evidently cause some lateral rubbing or pressure of the wheels upon the rails, which will occasion an increased friction. If the wheels are fixed to the axles, so that both must revolve together, according to the mode of construction hitherto most usually adopted in passing a curve, the wheel that moves on the outside or longest rail must be slided over whatever distance it exceeds the length of the other rail, in case both wheels roll on rims of the same diameter. This is an obstruction presented by almost every railway, since it is rarely practicable to make such a road straight. The smallest curvature that is allowable should not be less than a radius of 300 feet. In going round a height, the radius should on no account be so small as this, in order that the engine-drivers may have a clear look-out a-head, and so prevent collisions and overtakings on the road. Another point to be observed is the proper elevating of the outer rail at any sudden curvature, in order to prevent as much as possible the centrifugal or tangential tendency of the train to escape from the line.

Inclined Planes.—Where the inclination of the road is greater than that for which the ordinary power is calculated, the ascent must be effected by means of an additional power, the amount of which can be readily computed, since in those parts no additional friction of the cars or wheels is to be provided for, and only the additional resistance arising from gravity is to be overcome. If, for instance, the additional inclination is one in ninety-six, or fifty-five feet in a mile, the additional power must be to the weight as one to ninety-six, or as fifty-five to the number of feet in a mile—namely, 5280. In descending planes so much inclined that the gravity would move the carriages too rapidly for safety, the velocity is checked by means of a break, which consists of a piece of wood of the same curvature as the rim of a set of the wheels, upon which the break is pressed by means of a lever, so adjusted, as to be within reach of the conductor in his position on the carriage. Very powerful breaks are occasionally applied (by wheel and screw) to separate trucks—these trucks being made of iron, very heavily loaded, and placed by way of drag in the rear of the train.

In some tunnels the incline is so great, that stationary engines are employed to drag up the trains, either by means of an endless chain, or by wire ropes of a peculiar formation. An invention, however, has recently been patented by an American engineer for enabling locomotives to ascend steep inclines with their usual load, and which bids fair to be of extensive utility. On the inclined plane *within* the usual line of rails a second line is laid down, and at regular distances in this enclosed line are laid small cross rollers. Beneath the locomotive employed to drag the train is placed a contrivance of a peculiar nature. This consists of what may be termed an 'Archimedean screw,' which is worked by the engine. On arriving at the incline, by a very ingenious arrangement, the wheels of the locomotive are completely lifted up from the outside rails, and at the same time the 'screw' is placed in contact with the line of rollers—the whole weight of the engine resting on this line. By putting the engine in motion, the screw revolves, and by working between these rollers, drags the train to the summit, on arriving at which, the screw is 'taken out of gear.' The engine rests on the outside rails, and once more proceeds on its journey. The whole operation is done in a remarkably short space of time, and is so efficient, that inclines so steep as to prevent the ascent of the most powerful engines by the ordinary way, are surmounted with apparent ease and facility.

Locomotives.—Within the last few years, very considerable improvements have been made in the construction of the locomotive engines by which the draught of the trains of carriages is effected. Originally, the locomotive was placed upon four wheels, the two front ones being smaller than those behind. Now six wheels are usually employed, the front and hind pair being smaller than those in the middle, these middle ones being the wheels upon which, by the action of cranks from the engine, the whole mass is propelled. As may be seen in the annexed engraving, which repre-



sents a railway train, the locomotive consists of a long iron barrel or cylinder supported by six wheels, with a chimney rising in front, and affording standing space behind for the engineer, who conducts and regulates the machine. It is unnecessary to give a minute account of this wonderful apparatus, which has been already explained under THE STEAM-ENGINE: suffice it to say, that the end of the barrel-like object next the engineer consists of a furnace or fire-box, and the heat generated in it by the consumption of coke is conducted thence through a great number of tubes in the cylinder, and finally escapes at the chimney. The cylinder, in which the water is boiled, and steam generated, is sheltered from the external air by a case; and by receiving the action of heat from so many tubes passing through it, the steam is rapidly generated for the use of the engine. The engine lies horizontally beneath the chimney, and in such a position, as to permit the working of the piston upon the crank of the axle of the middle set of wheels. By means of lever handles affecting the mechanism, the engineer can at pleasure produce or stop the motion as effectually, and much more readily, than a coach-driver could set off or arrest the progress of his horses.

Immediately behind the locomotive is a carriage called the *tender*, which is loaded with a supply of fuel, and a tank round its sides containing water. The weight of a locomotive, supplied with its proper quantity of water and fuel, is about twelve tons. The tender, when filled with water and fuel, weighs seven tons; it can carry 700 gallons of water, and eight hundredweight of coke forms a sufficient supply for a trip of from thirty to forty miles with an ordinary load. The average cost of a locomotive is about £1700 (though, during the late railway mania, it rose so high as £2100), and it seldom wears longer than two years without undergoing a very extensive repair. On the Great Western Railway, which is of unusual breadth of track (the broad gauge), the locomotives are much larger and more powerful. Ordinary locomotives evaporate seventy-seven cubic feet of water per hour, but those on the Great Western evaporate about 200 cubic feet. It is calculated that the evaporation of one cubic foot per hour, produces a gross mechanical force of nearly two horse power; consequently, to ascertain the power of a locomotive, we must multiply by two the number of cubic feet which it evaporates per hour. In common circumstances, an ordinary-sized locomotive exerts a power of 150 horses, and a larger one exerts a power of 400 horses. To estimate this degree of force, it is necessary to recollect that a horse upon a common road cannot draw for any length of time more than fifteen hundredweight, while on a railway it will pull with equal ease ten tons, being thirteen times the amount. We may now, therefore, compute that the power of a locomotive such as is usually employed, is equal to a draught of 1500 tons. With this weight to drag, however, only a slow motion is obtainable; and to procure the necessary speed of from twenty to twenty-five miles per hour, the load must be proportionally diminished. Something must also be allowed for the difficulty of ascending inclined planes. A weight of from 100 to 150 tons is considered a fair load for a locomotive to draw; but it is seldom more than sixty to seventy tons. The following experiments on the power of draught were made on the Liverpool and Manchester Railway in 1832:—

'On Saturday the 5th of May, the engine called the Victory took 20 wagons of merchandise, weighing gross 92 tons 19 cwt. 1 qr., together with the tender containing fuel and water, of the weight of which there is no account, from Liverpool to Manchester (30 miles), in 1 hour 34 minutes 45 seconds. The train stopped to take in water half-way for 10 minutes, not included in the above-mentioned time. On the inclined plane rising 1 in 96, and extending 1½ mile, the engine was assisted by another engine called the Samson, and the ascent was performed in 9 minutes. At starting, the fireplace was well filled with coke, and the coke supplied to the tender accurately weighed. On arriving at Manchester, the fireplace was again filled, and the coke remaining in the tender weighed. The consumption was found to amount to 929 lbs. net weight, being at the rate of one-third of a pound per ton per mile. Speed on the level was 18 miles an hour; on a fall of 4 feet in a mile, 21¼ miles an hour; fall of 6 feet in a mile, 25½ miles an hour; on the rise over Chatmoss, 8 feet in a mile, 17½ miles an hour; on level ground sheltered from the wind, 20 miles an hour. The wind was moderate, but direct ahead. The working wheels slipped three times on Chatmoss, and the train was retarded from two to three minutes.

On the 29th of May, the engine called the Samson (weighing 10 tons 2 cwt., with 14-inch cylinders and 16-inch stroke; wheels 4 feet 6 inches diameter, both pairs being worked by the engine; steam 50 lbs. pressure, 130 tubes) was attached to 50 wagons laden with merchandise; net weight about 150 tons; gross weight, including wagons, 223 tons 6 cwt. The tender weighed 7 tons, making a gross load (including the engine) of 240 tons 8 cwt. The engine with this load travelled from Liverpool to Manchester (30 miles) in 2 hours and 40 minutes, exclusive of delays upon the road for watering, &c.; being at the rate of nearly 12 miles an hour. The speed varied according to the inclinations of the road. Upon a level, it was 12 miles an hour; upon a descent of 6 feet in a mile, it was 16 miles an hour; upon a rise of 8 feet in a mile, it was about 9 miles an hour. The weather was calm, the rails very wet; but the wheels did not slip, even in the slowest speed, except at starting, the rails being at that place soiled and greasy with the slime and dirt to which they are always exposed at the stations. The coke consumed in this journey, exclusive of what was raised in getting up the steam, was 1762 lbs., being at the rate of a quarter of a pound per ton per mile.'

General Appearance and Management.—In America and Belgium, most lines consist of but one track; in Great Britain all possess two tracks, suitable for trains going in opposite directions, besides which there are turn-offs or sidings, at which quick-going trains may pass those of slower motion. At certain convenient points along the line there are station-houses, at which the trains stop to take up and set down passengers, and there is no stoppage at any other place. On most of the lines there are slow trains, taking goods and second-class, or an inferior kind of carriages; and fast trains, taking only first and second-class carriages: some lines also have mail trains, which proceed at more than usual speed, and taking only first-class carriages, stop at fewer places by the way. 'Express' trains are now daily seen on most of the lines: they carry only a limited number of passengers, and stop only for water—seldom taking up or setting down a passenger except at very important stations. These express trains run at a most astonishing speed, usually from fifty to sixty miles an hour. Generally, the fares charged for transmission are higher than they need be: a common charge is at the rate of 3d. per mile for each passenger in a first-class carriage; but it is understood that lower rates would create more than a compensatory amount of traffic. In the parliamentary carriage trains, the highest rate allowed is one penny per mile—a great boon indeed to the poorer classes of society.

There are certain excellences in the arrangements of all the railways which deserve to be mentioned. Each line, being the property of a private association, is secluded from one end to the other from the intrusion of the public; and therefore no jostling or confusion takes place either upon entering or leaving the carriages. The rails of one line, likewise, join those of another, by which means carriages generally proceed onwards, without changing passengers or luggage. A carriage in which passengers take their seats at London can go straight on to Edinburgh; and very shortly even to Aberdeen. The extraordinary magnitude of the railway undertakings has enabled the directors to organise rules which could never be enforced in the irregular scramble of stage-coaching. It is customary to dress the subordinate functionaries on all the lines in a uniform resembling that of the London police—each man having his number inscribed in figures on some part of his dress; so that if any one be guilty of incivility or inattention, he can be easily reported to his superiors. There is one pleasing peculiarity in the arrangements which is entitled to the highest commendation: it is the rule that no officer shall on any account take a fee from passengers, on pain of instant dismissal. Those who imagine that fees to guards, coachmen, or waiters, are requisite to insure civility, will be surprised to find that railway attendants are infinitely more polite and attentive than their brethren of the coach conveyances. This in itself gives travelling by railway a great superiority over all other modes of public conveyance. On all the lines there are waiting-rooms both for ladies and gentlemen at the different stations; and on some there are large and commodious houses of entertainment at the termini, where meals stand ready prepared for the passengers.

Passengers who make the journey for the first time by the mail train on the great lines of England, will be amused by observing a travelling post-office in the string of carriages. This 'Grand Northern Railway Post-office,' as the inscription on its side denotes, is a carriage consisting of two small apartments, one of which is appropriated to the guard, whose duty is to exchange the bags, and the other is fitted up with a table for sorting letters, and holes round the walls for their reception. The manner in which the duties of the clerk and guard are performed in this flying post-office, is strikingly significant of the new order of things introduced by the railway system. Outside the vehicle a species of net is extended by a hoop, and into this the letter bags are dropped as the train sweeps onward in its course, the bags which are to be left being at the same time tossed from the window by the guard. The fresh bag of letters being received, it is speedily opened, its contents rearranged, and a new bag for next town being made up, it is projected as before at the place of its destination. By this means a letter may be written, sent through the post-office, and delivered at the distance of twenty miles, in the space of a single hour.

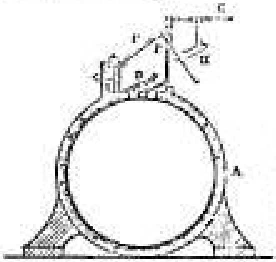
The speed at which railway trains usually proceed is from twenty to twenty-five miles per hour, though sometimes it is much more. At the ordinary rate of speed, a journey from London to Liverpool by the mail train is performed in about nine hours. Now that a continuous line of railway is made from London to Edinburgh, *via* Carlisle, journeys between these cities will soon be made by 'express' trains in eleven or twelve hours. Already an express train has traversed the distance (427 miles) between London and Edinburgh, *via* Berwick and Newcastle, in little more than ten hours, and this with the interruptions caused by the yet incompleted bridges over the Tweed and Tyne. Contrary to early predictions, travelling by railway at any of the common rates of speed is attended with less personal danger than stage-coaching, because the locomotives are perfectly under control. Any deaths or personal injuries which have occurred on railways are, with scarcely an exception, attributable to the carelessness of the engine-drivers; and by the employment of a superior class of men to direct the motions of the trains, this fruitful cause of mischief is in the course of being obviated. With this improvement, conveyance by railways will be ranked among the most useful and stupendous inventions of art.

Atmospheric Railways.

If a smooth and straight metal tube be provided at one end with an air-tight piston, and the contained air be extracted, the piston, on being let go, will traverse the tube from end to end, being, as it were, forcibly driven by some unseen agency. This agency is the weight or pressure of the atmosphere. It is well known that the atmosphere presses upon all substances exposed to its influence with a certain force; this, when the barometer stands at thirty inches, being about 15 lbs. on the square inch. Now, in the case supposed above, before the air is extracted from the tube, the same pressure exists on each side of the piston, consequently it remains at rest; but as a vacuum is formed, the atmosphere, pressing on each square inch of the piston with a force of 15 lbs., drives it along the tube, there being no atmospheric pressure on the other side to prevent its movement. This, then, is the principle of the atmospheric railway.

If the reader will suppose a small carriage to be fitted to the tube, and attached to the piston, he will have a good idea of the atmospheric railway, as first proposed to be established between London and Brighton. This mode of travelling not possessing many charms to ordinary travellers, excepting that of novelty, the scheme, as might be supposed, did not succeed; but the idea being a good one, many engineers and men of science directed their attention to the subject. The first evident improvement to be made was having the carriages *external*, and connected with the piston by some contrivance sliding along a slit or opening made in the upper side of the tube. Messrs Clegg and Samuda patented improvements, which were first tried experimentally at Wormwood Scrubbs, on a portion of the West London Railway; and these proving successful, were adopted by the Dublin and Kingstown Railway on that part of their line between Kingstown and Dalkey, a distance of about one mile and three-quarters. This line is much inclined; the carriages descend by their own gravity, and are propelled up the incline by the atmospheric agency. This first application of the atmospheric principle proving eminently successful, the example has been followed by the London and Croydon, and South Devon Companies. There are many conflicting opinions relative to the merits of the system; but some of the engineers of first celebrity having, within these last three years, directed their attention to its improvement, we doubt not that in a short time the difficulties which have beset the plan will be overcome by their ingenuity, and that in a few years it will meet with more extensive adoption. Numerous patents have been taken out for improvements in connection with it, but our space will not permit any detail; we must content ourselves with giving a brief account of the plan adopted on the Kingstown and Dalkey line.

The vacuum pipe (the distinguishing feature of the system) is fifteen inches diameter, and is laid in the ground between two lines of rail on which the carriages run. In the upper side of the tube is a slit or opening, closed with a valve, to render the tube air-tight when required. This valve is made of leather, on the sides of which are rivetted pieces of iron—the inner plate assuming the same curve as the pipe, so that when the valve is closed, the bottom side of the valve forms part of the pipe. The upper side of the plate and leather is longer than the lower, and extends a little over the edge of the opening. The valve is attached to one side of the pipe by a projecting rib, and the other edge lies in a groove among wax and tallow, which, when melted, forms an air-tight joint or seam. A piston, having a rod fourteen or fifteen feet in length, to which are attached rollers for opening the valve in the rear of the piston, is placed within the tube or vacuum pipe. This piston is connected with the first carriage, called the *driving-car*, by a contrivance called a *coulter;* to the driving-car is attached a copper vessel heated with coke, used for melting the wax lying in the hollow previously mentioned. The annexed sketch will show the operation; it is a transverse section of the vacuum tube: A, the tube; B, the air-tight valve; C, the weather valve, which prevents rain, snow, &c. from getting into the air-tight valve; F, the coulter; G, part of the driving-car; H, roller to open the weather valve. The rollers to open the air-tight valve are not shown, as it would confuse the sketch.



The operation is as follows:—The steam-engine placed at the extreme end of the line exhausts the air from the tube before the piston, and when the barometer shows a vacuum of proper degree, the driving-car moves forward, dragged by the piston; the sealed valve is opened behind the piston, and the air is thus admitted to the tube. The valve is now pressed into its seat again, the heated copper follows, melts the wax, and makes the joint air-tight. Meanwhile the engine works to maintain the partial vacuum, and on the train arriving at its destination, the pipe is ready sealed for another trip. As the tractent power of the atmospheric railway depends upon the sectional area of the vacuum tube, and the degree of rarefaction of the air before the piston, the larger the tube, and the faster the air can be withdrawn from it, the greater the power and velocity of the train. A speed of sixty miles an hour has been realised on the Dalkey line. It will be evident that no collision can possibly take place—indeed one train running into another in the atmospheric line is a physical impossibility; there is little or no danger of the train being turned off the rails, the connection with the piston preventing this; and there is little or no oscillation. A gentleman placed a half-crown on the step of a carriage on starting from London, and on his arrival at Croydon, the half-crown was still there; an ample proof of the smoothness of this mode of transit. Steep gradients, or inclines, can be ascended with ease by the atmospheric line, which are impracticable to locomotive engines. Much trouble has been encountered by the changing of the composition in extreme hot or cold weather. We believe this difficulty has now been obviated by the discovery of a very ingenious valve.

Such is the atmospheric principle. The most important objections yet given by the opponents of the system are in the words of Mr Barlow; namely, 'that the traffic is dependent upon keeping air-tight a great length of pipe, and upon the perfect order of a great number of engines. In fact it depends upon the perfect order of an extensive, delicate, and complicated machine, composed of an infinite number of parts, the failure of any one of which would render the whole machine useless; and it must be evident to any person practically connected with the maintenance of a railway, that the machinery of such an engine will be liable to frequent interruption from causes which it is impossible to control.'

Electric Telegraph.

Astonishing as the rapidity of railway transit may appear, it is not for an instant to be compared with that of the Electric Telegraph. This wonderful apparatus is now appended to every railway of importance, both for the purpose of conveying messages in connection with the working of the line, and as a means of correspondence for the public. Telegraphs so set in motion were invented by Cooke and Wheatstone about the year 1837, but have since undergone numerous modifications and improvements by Bain, Brett, Little, and others. As explained under ELECTRO-MAGNETISM, p. 272, the invention depends upon the principle, that an electric current can pass along a conducting wire to any distance, and be made to move magnetic needles at any part of its course—these needles indicating or signalling according to some predetermined arrangement. The essential features of the operation are the *conducting wire* or wires, the *battery* which generates the electric current, the *signalling apparatus*, and the *mechanism for making and breaking the metallic contact* that completes the circle. As the passage of the current is almost instantaneous, no matter what the distance, the chief endeavour has been to discover a mode of signalling a message with as great rapidity as it can be spoken or written. At present, there are two great modes—the *mechanical*, by which needles will signal at the rate of fifty or sixty letters per minute; and the *chemical* (involving the action of the voltaic current on chemically-prepared paper), by which a thousand symbolic characters or letters may be transmitted in the same space of time. These symbolic characters are in fact a species of electric printing; and though the trouble of transcribing them in ordinary writing is at present requisite, there is little doubt but we shall shortly have the electric telegraph printing correspondence in the common character as fast as the human voice can dictate, or at all events as rapidly as the hand can indicate the original. Thus the message-sender at London will scarcely have withdrawn his hand from the wires, when his friend at Edinburgh will have spread before him every word and letter of the intelligence! With such an extraordinary instrument as this, it is impossible to conjecture what may yet be accomplished in the way of rapid communication between the most distant and remote places. There is, indeed, no necessary limit, but the matter of expense, to its application; for the wires, under certain precautions, are equally fitted to convey the electric current through water as through the medium of the atmosphere. At present, this telegraphic network is being spread over the country under the superintendence of a Company, to whom the exclusive right has been patented for a period of fourteen years.

MARITIME CONVEYANCE.

The instruments of maritime conveyance are *ships*—a term which, though commonly applied to decked vessels only, may be made to include every species of craft, from the rude canoe of the savage to the three-decked man-of-war. Their construction and equipment, their navigation and management when afloat, the building of docks and harbours for their reception, the erection of lighthouses and beacons for their guidance; in fact, the whole science by which man is enabled to traverse the ocean, and bring the most distant regions as it were into local proximity, is one of superlative interest, and especially so to the inhabitants of an insular country like Britain. To a brief exposition of its leading features, as above indicated, we intend to devote the following pages.

SHIPS.

Of the early history of ship architecture little can be said of any importance. The buoyant property of water, particularly that of the sea, must have been soon observed by mankind; and therefore, beginning with rude skiffs and canoes, they would in time acquire sufficient experience and skill to form vessels of a larger size, and to guide them in the required direction by means of a rudder and sails. The cultivated nations of antiquity—Egyptians, Phœnicians, Carthaginians, and others—possessed ships for commerce and war, some of which were of large dimensions, and were moved either by oars or by the action of the wind on sails. But of these early vessels, as well as of those now employed by half-civilised nations, it is unnecessary here to speak; and we proceed to notice the construction and character of ships formed according to the principles of modern and improved science.

The nicest and most difficult operation in ship-building consists in first forming a draught or model of the proposed vessel, or, as we may call it, the *plan* which the mechanics are to adopt and follow out. In forming this plan, the designer is governed by a consideration of the precise object to be attained. There are two classes of vessels—ships of war and merchantmen—and each must possess certain qualifications. In a ship of war the great object is speed, with ease of movements, and capacity to accommodate her crew, and carry a sufficient weight of guns, stores, and provisions. One point, moreover, is especially to be looked to; this is, that the ship float high enough above water to run no risk of receiving waves or seas in her lower ports during action, when these holes must be necessarily open. In order to be secure of this, the constructor makes an estimate of the whole weight of the ship, including body, spars, armament, men, and munitions, and must so model the bottom that it will have displaced an equal weight of water when arrived at the desired depth. In the case of merchantmen, the primary consideration is to attain the greatest capacity to carry cargo, combined, as far as possible, with safe and easy movements and rapid sailing.

The English excel in ship-building, but in some respects they are outdone by the Americans, whose packet ships carry enormous weights, while they are noted for their speed. Among the admitted and well-established principles of construction is the leading one, that the greatest breadth must always be before the centre, and consequently the *bow* or front be more blunt than the *stern* or hinder part. Abstractly, it would seem most important that the bow should be the sharpest, so as to cleave the water with the least possible resistance; but experience has proved that it is far more essential to facilitate the escape of the displaced water along the side of the vessel; for when once a passage is opened for the ship, the fluid tends to reunite behind the point of greatest breadth, where, instead of offering resistance, it presses the ship forward, and fills up the space constantly opening behind her. The principle is evident in the form of the duck and other aquatic animals, which are uniformly broadest in front, and gradually diminish to the tail. As it is, then, less essential that a ship should be sharp forward than aft, there is a further advantage in having the bow full towards the edge, that it may check her in descending into the waves, not abruptly, but gently—pitching, or rising and falling endwise, being the most dangerous to hull and spars of all a vessel's movements. Though sharpness towards the stern-post is vitally essential to fast sailing, yet care must be taken to leave the buttock full towards the surface, in order to check the stern gently in descending, and when scudding before a gale, to lift it in timely season on the arrival of a sea. To hit the exact mean in these respects, so as not to retard the sailing on the one hand, nor to endanger the ship on the other, requires all the skill of the architect.

There must likewise be a due correspondence between the general bulk of the vessel and its length and breadth; the whole must be properly proportioned. If unduly long, speed may be gained, but there is a difficulty of turning, and also of rising to escape the breakings of the sea; long ships, therefore, are apt to roll and to cut through waves instead of breasting them, by which their safety is perilled. When a ship is unduly short for its general bulk, it is apt to pitch, which is equally dangerous; hence the greatest care is required to proportion the various dimensions.

All essential preliminaries being settled, the ship is begun to be constructed; and this is always done in the yard of a ship-builder, close by the water's edge. The wood considered to be best adapted for ship-building is oak, pine, teak, elm, or beech; and whichever is employed, it requires to be strong, well seasoned, and dry: the greater part, likewise, should be bent or crooked, to suit the curves and angularities in the structure; and for this end growing timber is often constrained to assume particular forms. The *keel*, which is the lowest part of the vessel, and corresponds to the backbone of an animal, from which the ribs or *timbers* spring, is formed and laid first on a slip and blocks set for the purpose. As the framework proceeds, all parts are firmly bolted and rivetted together, and the whole is finally covered with the planking in even lines from bow to stern. When it is necessary to bend a plank for either the bow or stern, it is heated by steam, and then forced into its place by screws and levers. The planks are fastened to the ribs by *treenails* or wooden pins, and the plan is followed of allowing a seam or space between each plank, which is filled up or *caulked* with oakum, and the whole is smeared with pitch. In some instances the bottom is further secured by sheathing it in sheets of copper. Meanwhile the interior beams and partitions have been placed; and when duly prepared, the vessel is *launched*, or shot, by an easy movement, down the inclined plane on which it rests into the water. After launching, the rudder or *helm* is shipped. The rudder is a wooden apparatus placed at the stern of the ship, a large portion being in the water; and by means of it the vessel is steered and turned about at pleasure. The steering part is on deck, and consists either of a simple lever, called the *tiller*, or of a wheel placed perpendicularly, and connected with the tiller by chains and pulleys. The principle on which the rudder acts is very simple: the object is to turn the vessel; and to whatever side the inclination is to be made, the rudder is caused to present an obstacle to the water in that direction.

The masts of the vessel are now set; and the *spars*, comprehending the bowsprit and yards, and also the rigging, are attached. The spars of a ship are not abandoned to their own unsupported strength, but are sustained by what is called the *standing rigging*, which consists of strong well-spun ropes, or in some recent instances, of iron wire twisted into strands of the requisite thickness. Besides this there is the *running rigging*, which consists of the tacks and sheets that serve to spread the sails, the halliards, traces, lifts, clewlines, and all other ropes used in making, taking in, or manœuvring the sails. In the construction of both hull and rigging there is a vast amount of bolting, nailing, splicing, and so forth, much of which is likely to be now superseded by the use of Jeffrey's marine glue—a substance of such tenacity that planks joined by it have been found to give way invariably in the solid wood, and not at the junction. Masts marine-glued, and without hoop or bolt, have been tried, and after the exposure of a tropical voyage, have returned sound and strong as on the day they were constructed. Indeed so invincible is the tenacity of this compound, that the possibility of constructing a hull without bolt or treenail has been soberly asserted.

The sails of a ship are sheets of canvas bent to the yards, and fore-and-aft sails traversing on stays or bent to gaffs. Let us proceed to describe an entire suite, beginning forward, and referring to the subsequent figures:—On the extremity of the bowsprit is the *flying-jib*, a three-cornered sail, which goes from the end of its boom upward along its stay, leading to the foretop-gallant-mast-head, and confined to the stay by rings of wood or iron, called the *hanks*. It is hoisted by means of the halliard; hauled down by a downhaul; and when up, is trimmed to hold the wind by a sheet or rope leading to the forecastle. The *jib*, which leads from its boom to the foretop-mast-head, is of similar form, and so is the *foretop-mast-stay-sail*, running from the bowsprit end towards the mast-head. On the foremast we have the *fore-sail*, bent to the fore-yard, and spread at the foot by means of tacks and sheets; above it, the *foretop-sail*, bent to the top-sail-yard, by means of which it is hoisted aloft, while its lower corners are spread to the extremities of the fore-yard; next the *top-gallant-sail*, bent to its yard, and sheeting home to the top-sail-yard; and so with the *royal* and *sky-sail*. All these sails are turned at pleasure, to be presented to the wind, by means of braces attached to their yard-arm, and leading to the mainmast. The mainmast is furnished with a similar suite of sails, somewhat larger; the mizen-mast also, though smaller than either, instead of a square-sail on the lower part of the mast, has a *gaff-sail*, hoisting up or down abaft the mast. Some ships have similar gaff-sails on the fore and mainmasts, which are found of great use in gales of wind, as a substitute for storm stay-sails. Most carry, also, light stay-sails between the masts; but they are very troublesome. *Studding-sails*, spread beyond the square-sails like wings, are found useful when going before the wind. The perfection of equipping a ship with spars, rigging, and sails, consists in so disposing them, that in a whole or full sail breeze the centre of effort of all the sails will be in the same line with the ship's centre of rotation; or that the effects of the forward and after-sails to turn the ship will be exactly balanced, as not to require any continued assistance from the rudder in either direction.

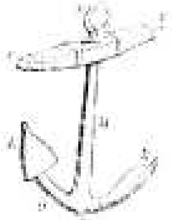
Such is a brief outline of the construction of a common decked vessel as regards hull and rigging. It must be remembered, however, that different modes are adopted according to the kind of service for which the craft is intended, and that general improvements are occasionally being made in naval architecture. Thus independently of a difference in material, some arrange the timbers or framework in such a manner that they shall form the main strength of the vessel; while others, following a cheaper and less scientific course, plant the timbers perpendicularly and sparsely, thereby throwing a great, if not the greater, portion of the strain on the outer planking. Again, much depends on the securing of the masts, which, when under press of canvas, act as powerful levers on the parts of the hull to which they are attached. Instead of resting these only upon steps, strong platforms, which diffuse the pressure on all sides, are now generally used, and by this means a fertile source of leakage extinguished. Round sterns, which can be constructed with all the strength of the bow, are now also preferred to the old square and massive but weak stern; and further, the breadth of beam, which adds stability to the whole fabric, has of late been considerably increased.

The principal ship-building ports in Britain—laying aside consideration of the government dock-yards—are London, Sunderland, Newcastle, Liverpool, Hull, Yarmouth, &c. 'The business'—we quote M'Culloch's Statistics—'has increased with extraordinary rapidity at Sunderland; so much so, that while only 60 ships, of the burden of 7560 tons, were built in that port in 1820, no fewer than 302 ships, of the burden of 87,023 tons, were built in it in 1840. Ships built at London, Liverpool, Bristol, and other western ports, are, however, in higher estimation than those built in the Tyne and the Wear, at least for those branches of trade in which the best ships are required. Within the last few years, a great many steam vessels have been built in the Clyde.' With respect to the classification of British vessels, the same authority remarks: 'Until very recently, ships, how much soever they might differ in other respects, were classified at Lloyd's (the office of the Society of Underwriters, and great centre of shipping affairs) with reference solely to their age and the place where they were built. Thus, supposing two ships were launched about the same time in the Thames, the Wear, or anywhere else, they were enrolled together in the *highest* class in Lloyd's Register, and stood there for a certain number of years, how different soever they might have originally been, or how different soever they might afterwards become! And underwriters thus seeing them standing together, and having no other test of goodness to which to refer, insured and employed the one on the same terms as the other! It is unnecessary to dwell on the preposterous absurdity of such a system. Practically it operated as a high bounty on the building of defective, or what is called *slop-built* ships; and there can be no doubt that it tended materially to depreciate the character of our mercantile marine, and to multiply shipwrecks to a frightful extent. We are therefore glad to state that a new system of classification has been adopted, by which the place of vessels on the register will be made to depend, not on their age, or the port where they were built, but upon their actual condition.' The several classes are marked by the letters A, Æ, E, and I, which have reference to the state of the hull; and by figures which indicate the condition of the stores and equipment. Thus 10A1 denotes a ten-years ship of the first description of the first-class, with stores well and sufficiently found. Steam-ships are similarly classified, but require to be surveyed *twice a year*.

Anchors—Buoys.

The retarding apparatus of the vessel consists of heavy iron instruments called anchors, of which each vessel has usually more than one. Large ships carry the following suite of anchors:—1. The *sheet* anchor, which is the largest, and only used in the case of violent storms; 2. Two bower anchors—namely, the *best bower* and *small bower*, so called from their situation at the bows; 3. The *stream* anchor, the *kedge*, and *grappling* or *grapnel*. The three last are often used for moving the ship from place to place in a harbour or river. Each anchor is let down by a strong cable of iron or rope, and is lifted by means of the windlass placed on deck. To the cable, when in the water, a *buoy* or floating object may be attached, to show where the anchor has been let down; and to save time, or in an emergency, the anchor and cable are sometimes left, while the vessel proceeds, the buoy serving to point out where the anchor may be recovered. The anchor is said to be *a-peak* when the cable is perpendicular between the hawse and the anchor; it is said to come *home* when it does not hold the ship; it is said to be *foul* when the cable gets hitched about the flukes. *Riding at anchor* is the state of the vessel when moored or fixed by the anchor. *Dropping* or *casting anchor* is letting it down into the sea. *Weighing anchor* is raising it from the bottom.

An anchor—whatever be its form—should be of sufficient weight to fix itself to the bottom; and for this purpose it is customary to allow one hundredweight of anchor for every fifteen or twenty tons of ship-burden or tonnage. In men-of-war, the weight is sometimes roughly estimated at one hundredweight for every gun. The weight of the anchor is not strictly proportional, however, to the size of the vessel, as large vessels are less affected by sudden or violent motions than smaller ones. The shape and proportion of the different parts must be also carefully attended to; so as at once to yield the greatest hold or gripe, and withstand the greatest amount of strain. Large anchors are made thicker in proportion to their length than smaller ones; and as the greatest strain takes place during the operation of weighing, the diameters of the shank are unequal—the longest being in the direction of the arms. The several parts of a common anchor, here represented, are technically designated as follows:—The straight bar B, to which the cable is attached, is called the



shank; r the *ring*; the cross bar s s, fixed at the free extremity of the shank, the *stock*; the upper end of the shank the *small round*; the extremity c, where the shank and arms unite, is called the *crown*; the angle formed by the arms and the shank is termed the *throat*, and generally stands about 50°. The arms consist of three parts—the *blade*, g; the *palm*, h; and the *bill*, k. The palm or fluke is made of a flat triangular shape, the apex of which is prolonged so as to form the bill or peak. However large and ponderous, anchors are all formed of bar-iron, welded and wrought together by hand-hammering. Their fabrication, which is extensively carried on in Britain, requires great skill and care.

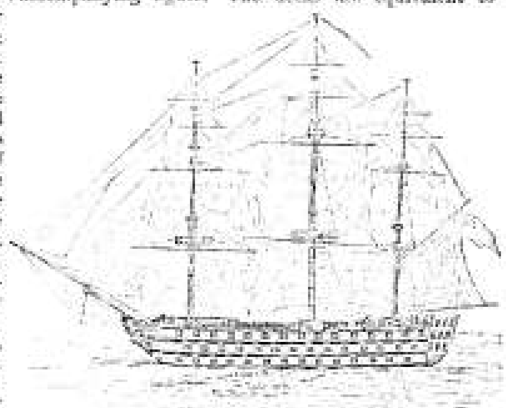
In addition to the common anchor represented above, there are various other forms in use, each laying claim to some peculiar superiority. Thus the grapnel has three or four arms instead of two; the mushroom anchor (so called from its shape), much used in the East Indies, has an entire holding edge, being shaped like a mushroom or bowl; and in the patent anchor of Lieutenant Rodger, R.N., the old broad flukes are entirely dispensed with, and the arms placed at an angle of 45° with the shank. Several forms of *floating anchor* have been proposed, for the purpose of retarding the progress of vessels during heavy gales in the open sea, where anchoring is not practicable. The principle of this species of anchor is simple:—A structure or framework is passed over the stern into the sea, so as to present a large amount of perpendicular or resisting surface to the forward motion of the vessel. Dr Franklin's device consisted of lashing two cross-bars firmly together, and stretching over these strong sailcloth—a simple apparatus, by which he thought sufficient retardation could in most cases be produced.

Buoys are vessels either formed of wood, cork, or some light substance, moored or anchored so as to float over a certain spot, in order to indicate the situation of a shoal or sandbank, and thus mark out the course which the ship ought to follow; or they may be constructed of large blocks of wood, clamped with iron, and furnished with rings, to which vessels may moor themselves in rivers or in harbours. When used for the former purpose, they are usually hollow vessels, barrel-built, in the form of a cone, of large dimensions, so that they may be seen at a distance; and generally painted of some particular colour, that they may be more readily distinguished from one another. Mooring buoys, on the other hand, are generally solid blocks, kept in their places by heavy anchors or sunken weights. As these are liable to be dragged, various methods of secure fixing have been proposed, but none with the same likelihood of success as the 'screw pile' of Mr Mitchell, to be hereafter described. Buoys for the above purposes are designated *public*, and are placed under the control of the Trinity House, who charge, as in the case of lighthouses, a small tonnage-due for their maintenance. *Private* buoys are those used by individual vessels for indicating the situation of their anchor, with a view both to prevent their running foul of the anchor, and also that the anchor and cable may be recovered when the latter may happen to be broken or cut.

Having thus treated of the general construction and outfit of ships, we shall now briefly advert to the peculiar characteristics which distinguish vessels of war from those of mercantile burden.

War Vessels.

At the head of the list stands the ship-proper, a vessel with three masts, called the fore, the main, and mizzen-masts, and which is square-rigged, or carrying large square sails. The largest ships are vessels of war, named line-of-battle ships, having three complete decks, and carrying 120 guns. A representation is given of such a magnificent floating apparatus in the accompanying figure. The decks are equivalent to



First-rate War Vessel.

different floors. On the first or uppermost, extending on each side of the foremast, is the *forecastle*, and next to it, between the foremast and the mainmast, are the *waist* and *gangway*; between the main and mizzen-masts is the *quarter-deck*; and next to it, towards the stern, is an elevated part called the *poop*. A narrow passage on each side of the vessel, communicating from the quarter-deck to the forecastle, are called *gangways*, and in nettings above these the seamen's hammocks are stowed as a protection during action.

The forecastle is appropriated to the best or able-bodied seamen, the quarter-deck is the proper situation for the officers, and in the poop are stationed the marines. The quarter-deck is a privileged spot, and as, by a fiction, the sovereign is supposed to be present, every one who enters this deck must salute it by touching his hat, and all present return the compliment by touching their hats likewise. Beneath the poop are the apartments of the captain, and some others. Descending from the upper range of decks, we arrive at the *main-deck*, at the fore-part of which is the sick-ward, and next to it the *galley* or cook's room; at the after-part, beneath the captain's cabin, is the admiral's cabin. The next, or third range of deck, is the *middle-deck*; at the fore-part of which is the ward-room, or general apartment for the officers. The fourth range is the *lower-deck*, where the sailors sleep and mess, and on which also is the *gun-room*, for inferior officers. On all the decks mentioned, cannon or large guns are ranged, each having its appropriate port-hole; and by these holes, on which temporary windows are fastened, light is admitted to the interior. We now descend to a floor beneath the surface of the water, which is called the *orlop-deck*, on which, between the main and mizen-masts, is the cockpit, or surgeon's room; the purser's, boatswain's, and carpenter's berths, and midshipman's messroom. Beneath the orlop-deck is the *hold*, a species of cellar in divisions, containing the boatswain's and carpenter's stores, the powder-magazine, shot, the water-casks, and provision stores.

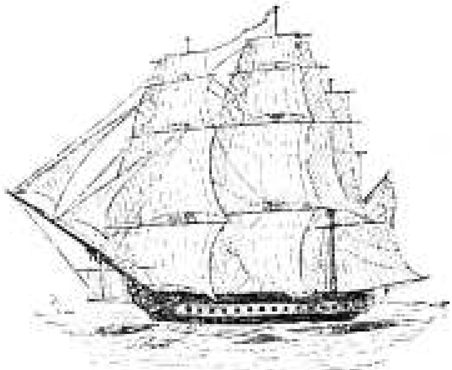
War vessels receive their designations from the number of their decks, or of the guns which they carry. Line-of-battle ships are of various *rates*. The *first*-rates include all carrying 100 guns and upwards, with a company of 850 men and upwards; *second*-rates carry 90 to 100 guns, and from 650 to 750 men; and *third*-rates carry from 60 to 80 guns, and from 600 to 650 men. The rates thus diminish in bulk and complement of men down to sixth-rates. A common rate is a 74 gun-ship, which carries 600 men. The following is a list of the titles and number of the crew of a first-rate war vessel, classed in the order of their amount of pay:—

Captain,	1	Brought forward,	106
Lieutenants,	8	Coxswain of Pinnace,	1
Master,	1	Sailmaker's Mate,	1
Chaplain,	1	Caulker's Mate,	1
Surgeon,	1	Armourer's Mates,	2
Purser,	1	Cooper,	1
Second Master,	1	Volunteers,	12
Assistant Surgeons,	3	Gunner's Crew,	25
Gunner,	1	Carpenter's ditto,	18
Boatswain,	1	Sailmaker's ditto,	2
Carpenter,	1	Cooper's ditto,	2
Mate,	1	Yeoman of Storeroom,	1
Midshipmen,	23	Able Seamen, } Ordinary ditto, }	470
Master's Assistants,	6		
Schoolmaster,	1	Cook's Mate,	1
Clerk,	1	Barber,	1
Master-at-Arms,	1	Purser's Steward,	1
Ship's Corporals,	2	Captain's ditto,	1
Captain's Coxswain,	1	Captain's Cook,	1
Launch ditto,	1	Wardroom ditto,	1
Quartermasters,	12	Wardroom Steward,	1
Gunner's Mates,	5	Steward's Mate,	1
Boatswain's Mates,	8	Lamleman,	1
Captains of Forecastle,	3	Boys,	32
Captain of Hold,	1		
Ship's Cook,	1	Total Seamen,	690
Sailmaker,	1		
Ropemaker,	1	Captain of Marines,	1
Carpenter's Mates,	2	Lieutenants,	3
Caulker,	1	Sergeants,	4
Armourer,	1	Corporals,	4
Captains of Maintop,	3	Drummers,	2
Captains of Foretop,	3	Privates,	146
Captains of Mast,	3		
Captains of After-Guard,	3	Total war complement of officers, seamen, and marines,	850
Yeoman of Signals,	1		
	106		

A number of the above officers and subalterns are not appointed to third or inferior rates. Latterly, engineers have been added to the list of men in the royal navy, intended for service in the steam marine; they take rank below carpenters.

The burden of a first-rate is from 2700 to 2800 tons; the length of the lower gun-deck is 205 feet 6 inches, and length of keel for tonnage 170 feet 6 inches, the upper decks being longer in proportion; the height from keel to midships from 50 to 60 feet. The guns are generally distributed as follows:—Forecastle, two 18-pounders and two 34 carronades; quarter-deck, two 18-pounders and fourteen 32 carronades; main-deck, thirty-four 32-pounders; middle-deck, thirty-four 32-pounders; and lower-deck, thirty 32-pounders and two 68 carronades. Total, 120 guns.

Ships of less than 44 guns are termed *frigates*. A frigate, of which the following engraving is a sketch, has only one gun-deck beneath the quarter-deck; and beneath that, lighted and ventilated partly by skylights, and partly by small holes in the sides, is a deck appropriated to the men, officers, &c.



Frigate.

The following account of the organisation and arrangements on board of war vessels is abridged from a work entitled 'Two Years and a Half in the American Navy,' by E. C. Wyne; 1833. Though strictly applying to an American frigate, it is generally applicable to a similar vessel in the British navy. 'Time on shipboard is divided into watches, and reckoned by bells. Hence you never hear the question, "What's o'clock?" but "How many bells is it?" The twenty-four hours are divided into six equal portions, called watches. At the end of the first half hour of one of these portions the bell is struck one; at the end of the second, two; and so on, till the series reaches eight, when it commences again. In the ship's journals, the dates are put down according to the common mode of reckoning time. The division of time into watches differs somewhat at sea and in port.

Order is the first great rule on board a man-of-war, and that to which all others must bend. From day to day, from week to week, from month to month, and from year to year, the same stroke of the bell is followed by the same whistle, the same call, and the recurrence of the same duties. Everything has its place, too, and must be kept in it. So true is this, that a person acquainted with the details of a ship, can lay his hand on a given object in any part of her as well in the dark as if a thousand suns were shining on it. To the same grand principle—ORDER—are to be attributed the numerous divisions and subdivisions of the officers and seamen.

At the head of the list of officers stands the captain, whose will is supreme; and from his decisions, for the time being, there is no appeal. He has a general superintendence over the affairs of the ship, and every order of a general nature must originate in him. No important alteration can be made without his knowledge and consent. It is his duty to take a general oversight of the officers' conduct; to see that they are guilty of no improprieties, and to punish such as are. He is responsible for the safety of the ship both at sea and in port. If any business of a public nature is to be transacted with a foreign power, it falls of course into his hands. These are his duties in time of peace; in war he has still higher responsibilities.

Next in rank come the wardroom officers, consisting, on board of a frigate, of six lieutenants, a purser, surgeon, chaplain, sailing-master, and lieutenant of marines. The first lieutenant is next in power to the captain; and though his station is less responsible, his duties are more laborious. He has a general supervision over the ship, and is to see that she is kept clean and in proper order. To this end he is obliged to inspect every part of her at least once a day, and report her condition to the captain. When the ship is put in commission, it devolves chiefly upon him to station the men;

a business of the most laborious and difficult nature, requiring great patience, a discriminating judgment, and deep insight into the human heart. It is his duty to have the men frequently exercised at the guns; to regulate the expenditures of certain public stores; to take care that the men keep themselves clean and decently clad; to superintend the watering and victualling of the ship; and, in short, to see that all her multifarious and complicated concerns move on regularly and harmoniously. In coming to an anchor, and getting under weigh, and when all hands are called to reef topsails, or for other purposes, he takes the trumpet. On him, more than on the captain himself, depends the comfort of the officers. In port, it belongs to him to grant or withhold permission to go ashore; and there are a thousand other ways in which, if he is a man of capricious or malignant disposition, he can gratify his whims or his spleen at the expense of the comfort and feelings of his fellow-officers.

The other lieutenants are divided into watches, and take turns in performing the duties belonging to their station. The lieutenant on duty is styled in writing the officer of the watch, but is familiarly called the officer of the deck. Some of his duties are common at sea and in port, and others are peculiar to each of these situations. In both he is responsible for the deck while he has charge of it, and has also to take a general oversight of the ship. He must see that the men's rations are properly cooked, and that they have their meals at proper hours. The serving of the grog is also under his control. At sea, his duty is to sail the ship, keeping her on the course given her by the captain, and reporting to him any change in the wind, the discovery of land or strange sails, and any extraordinary occurrences. At night he has the captain waked at stated periods, and the state of the weather reported to him. On receiving the trumpet, the first thing the officer of the deck does is to glance at the compass, the sails, the dog-vane, the sky, and the water, to discover the state of the ship, the wind, and the weather; and at the end of the watch, he must have a general account of the weather, and other matters which he may deem proper, inserted in the ship's log-book. The duty of the officer of the deck in port is to receive any supplies of water or provisions which may come alongside, to regulate the sending away of boats, to keep a look-out as to what is going on in the harbour, to report the arrival of ships and any important occurrences to the captain, &c. The lieutenants are also officers of divisions, and frequently have to exercise the men at the guns, besides superintending the monthly issues of slops to their respective divisions.

Next in rank to the lieutenants comes the sailing-master, whose duties are more comprehensive and arduous than those of any other officer. His supervision and responsibility extend to almost all the public stores in the ship, but particularly to the water, spirits, cables, and anchors. He reports the daily expenditures of water to the captain. It is his business to keep the ship's place, and report it at least twice a day to the commander, together with the bearings and distance of the port to which she is bound, or the nearest land desired to be made. Some commanders leave this entirely to their sailing-masters.

There is no berth on board a man-of-war more cozy than that of purser. He holds the keys of the strong-box; and though his regular salary is not much, his emoluments arising from other sources are considerable. All the provisions on board are committed to his charge, and the ship's accounts are all kept by him. His responsibilities are very great, and heavy bonds are therefore justly exacted from him.

The surgeon and his two assistants form the medical staff of a frigate. The assistant-surgeons form a distinct class of officers, ranking between the wardroom officers and midshipmen. In frigates and ships of the line they mess in the cockpit, but in all other public vessels in the steerage. The business of the staff is of course to take care of the sick, and perform such surgical operations as may be necessary. A daily journal is kept of the names, rank, diseases, and constitutional habits of all the sick on board, and also of the medicines administered to them. From the journal a report is made out and signed by the surgeon every morning, stating the names, rank, and diseases of the sick, and the number added to and taken from the list. This is handed to the captain. Another list, containing only the names, is placed in the binnacle for the use of the officer of the deck. Nothing will excuse either an officer or a man from duty, but the fact of his being registered on the sick list. A general review of the sick takes place every morning after breakfast. One of the assistant-surgeons inspects the ship's coppers every day, to see that no verdigris is allowed to collect upon them. It is the duty of the surgeon not only to attend to the sick, but also to recommend and enforce such precautionary measures as will have a tendency to prevent disease, and thus secure the general health of the officers and crew. On board of every war vessel there is a chaplain, who conducts the Sunday services, and administers spiritual consolation to the dying. Of late, a schoolmaster has been added to the list of functionaries.

The midshipmen may be called apprentice officers, and they require to learn certain duties of seamen. They are also useful by carrying messages from the officer of the deck to the captain, and in port one of them takes charge of every boat that leaves the ship. Towards noon, while at sea, they are obliged to go on deck with their quadrants, and take an observation. They have to work out the last day's run, and report the course, distance made good, and ship's place at noon each day, to the captain. They muster the crew when the watch is called at night. They are also required to keep a journal of the cruise, which is, however, only a copy of the ship's log. This is examined every few weeks by the commanding officer; and if it happens not to be written up when called for, the delinquent is generally punished by a curtailment of some of his indulgences. Five of the oldest midshipmen are master's mates; and their duties are more important and responsible than those of the others.

The boatswain, gunner, carpenter, and sailmaker, form a distinct class of officers, called warrant-officers. The boatswain is charged with the rigging of the ship, and in port attends to squaring the yards. You may know him by his silver whistle, rattan cane, and above all, by the ruddy hues of his countenance, and the odious vapours that issue from his mouth. The gunner has charge of the military stores, and when all hands are called, of the main rigging. The carpenter is responsible for the stores belonging to his department, and superintends the corking of the ship, and other work performed by his subalterns. The sailmaker is charged with the sails, hammocks, and generally all the canvas in the ship. At sea, he is obliged to go aloft on each of the three masts, examine the condition of the sails, and report it to the first lieutenant every morning before breakfast.

The grand divisions of the crew are into petty officers, seamen, ordinary seamen, landsmen, and boys. This division has reference to rank; but there are others into which considerations of this kind do not enter. Such are the military divisions, and the divisions into larboard and starboard watches, into forecastlemen, fore, main, and mizentopmen, afterguard, waisters, &c.

The petty or warrant-officers are appointed by the commander, and may be degraded by him without the formalities of a court-martial. They are selected from among the most experienced and trustworthy of the seamen. They consist, on board of a frigate, of a master-at-arms, eight quartermasters, four boatswain's mates, eight quarter-gunners, a boatswain's and gunner's yeomen, a carpenter and sailmaker's mate, an armourer, a cooper, cook, and cockswain.

The highest and most responsible of the petty officers is the master-at-arms, who may be called the principal police-officer of the ship. He has charge of all the prisoners, and every morning makes out and hands to the commander a list of their names, with a specification of the crime for which each is confined, and the time when he was put in confinement. He has charge also of the berth-deck, and it is his duty to see that it is kept in good order. All property that falls in his way for which he cannot find an owner, is thrown into the "lucky-bag," the contents of which, if not finally claimed, are sold at auction.

The office of quartermaster is one of some dignity and considerable importance. It is his duty to keep a look-out with his spyglass for signals from other ships, and to report them to the officer of the deck; and also to report to him all boats that come alongside, and all other movements and occurrences in the harbour, which he may deem of sufficient importance. One quartermaster is stationed at the wheel to steer the ship, and the others keep a look-out, as in port. When the log is thrown, they hold the minute-glass. All the colours and signals are under their charge.

Boatswain's mates are an indispensable class of men on board of a man-of-war, but their office is the most invidious and least desirable of all. They have to perform all the flogging, and the men accordingly hold them in some degree of detestation. Each of the boatswain's mates has a silver whistle suspended from his neck, with which he echoes the orders of his superiors. The armourer is the ship's blacksmith. The cooper opens the provision barrels when their contents are wanted, and performs other matters in his line of business when necessary. The duties of the cook are somewhat arduous, and it requires a good deal of patience and care to perform them acceptably to the crew. The meals must always be reported "ready" morning, noon, and night. At noon, when dinner is reported ready, the cook takes a specimen to the officer of the deck, who inspects it, to see that it is properly prepared.

The above are the principal petty officers; and we now come to the rest of the crew, or seamen, who are of different classes. The first class consist of seamen, or able-bodied men, who are expected to be finished sailors; the next class are ordinary seamen; and after these are boys, who perform various useful offices, but chiefly as servants. The boys, and all others on shipboard who do not keep watch, are called *idlers*.

On board of a frigate there are six military divisions; one on the quarter-deck, one on the forecastle, three on the gun-deck, and one on the berth-deck. The last is commanded by the purser, and each of the others by a lieutenant. It is the business of those who compose the purser's division to pass up powder to the combatants. Every officer and man is included in one or the other of these divisions, and is stationed in a particular part of the ship. These are the stations for action, and are called general quarters. The crew is mustered and inspected at quarters always once, and on board many of our ships twice a day. There are ten or twelve men to each of the guns in a broadside, called first and second captains, spungers, loaders, powder-boys, &c. On the intimation being given, the boarders run for their caps, and every man seizes a cutlass. At the first tap of the drum, there is a general rush throughout the ship, and before the music has ceased, you may hear the midshipmen of the divisions calling over the names, George Bell—first captain, sir; James Anderson—second captain, sir; William Stokes—powder-boy, sir; and so on. Having called the names, the midshipmen report to the officers of their divisions, the officers of the divisions to the first lieutenant, and he again to the captain. Should the order be given to retire, another rush takes place, the cutlasses and boarding-caps are returned to their places, and the men, as the case may be, proceed to their daily labours or their evening diversions. All this is but the work of a moment. Sometimes the call to quarters is beaten in the dead of night, and then the men are obliged to get up, lash their hammocks, take them on deck, and stow them in the nettings, and be ready to answer to their names in the space of about eight or ten minutes. The midshipmen have to do the same.

In addition to their general quarters, the men are also stationed for getting under weigh, and coming to an anchor for tacking and veering, and for other general evolutions. I have sometimes been astonished to see how quick, in the darkest night, it is discovered that a man is missing from his post, and how speedily he is searched out and brought to it. But not only does every man know his station; he has a specific duty to perform at every order, and a failure on his part might disconcert the whole operation. Thus it will be seen, that notwithstanding the complicated nature of naval evolutions, and the apparent confusion which must necessarily prevail when all hands are called, there is, in fact, the greatest possible order, efficiency, and harmony of action.'

The marines act as a body of soldiers, and do duty both as sentries at different parts of the vessel, and as marksmen, both below and aloft, during action. Being in some respects an armed police over the sailors, there is often, if not a feeling of jealousy between the marines and other members of the crew, at least a tendency to depreciate and jeer at each other.

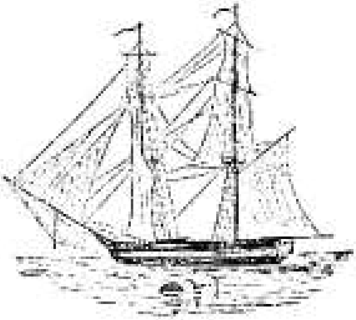
The following is the gradation of officers in connection with the royal navy:—Midshipman; lieutenant; master and commander (usually called captain); post-captain; rear-admiral (of which there are several gradations, styled red, white, and blue); and admiral. The senior captain of a squadron, which consists of a few vessels sent upon an expedition, is styled commodore, and he is the general commander for the time being. A fleet is a large number of vessels commanded by an admiral. The affairs of the royal navy are managed by a department of government called the Admiralty, whence the commissions of the officers are issued. Latterly, the condition of both officers and men in the royal navy has been greatly improved, and rendered much more comfortable than formerly.

Merchant Vessels.

Vessels employed in trade, or merchantmen, are of numerous sizes, shapes, and modes of rigging—these depending not merely on the peculiar trade for which they are destined, but on the taste and whims of the owners. The largest is of the ship-proper, as represented in the subjoined figure, with three masts

Merchant Ship.

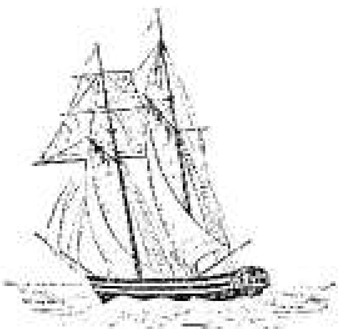
and square sails, but having only an upper deck, the sides of which are usually pierced to carry guns. Vessels of this kind possess holds of very large dimensions for stowing goods, and their burden is from 1000 to 1500 tons. When destined for long voyages, and in good service, as they generally are, order and discipline is maintained on board with almost as much severity as in the regular navy. The ships employed in the China and East India trade are the largest belonging to this country; those in the West India trade rank next; then the whale ships, those in the Baltic and Canada trade, the Mediterranean trade, the coal and general coasting trade, and so on in descending gradation.



Brig.

Next beneath the class of ships is that of *brigs*. A brig, of which we here present a sketch, has only two masts, but it possesses square rigging, like a ship. Brigs are handsome and roomy vessels, carrying from 400 to 800 tons burden.

With brigs, square rigging terminates, and we now come to classes of vessels in which the rigging is of a



Schooner.

different character. At the head of these stands the *schooner*, a vessel with two masts, and capable of carrying a large press of canvas. A schooner is in general sharp-built, with masts of considerable height and *rake* (that is, slant sternwards), and with small topmasts and fore-and-aft sails. The rigging, however, is various, though normally as above represented.

Vessels possessing only one mast are either *sloops* or *cutters*, both distinguished by their tall mast and extremely large main-sail, which projects towards the stern. Sloops are chiefly engaged as coasting traders, and are of all burdens, from 100 to 500 tons. The class of sloops employed to carry goods and passengers between distant ports are ordinarily styled *smacks*. There are schooners and sloops of war carrying from ten to twenty guns; they are generally employed in the custom-house service, and adapted for quick sailing.

Sloop.

A *lugger* is a small kind of vessel, but carrying three masts and a running bowsprit, with sails of the form called lug-sails. A *brigantine* is a brig which can be either sailed or rowed. A *xebec* is a light swift-sailing vessel, of three masts, and a long prow, peculiar to the ports of the Mediterranean. A *galley* is another vessel peculiar to the ports of the Mediterranean; it is low built, and carries two masts, but depends chiefly on being rowed with oars; condemned criminals are often sent as a punishment to row these galleys. A *yacht* is a small vessel designed either for state or pleasure. All the preceding classes of vessels possess decks. Small open vessels, not possessing the accommodation of a deck, are of the class of *boats*, of which there are many varieties—as the long-boat, pinnace, wherry, gig, barge; and so forth. Boats are mostly built with the side planks lapping over one another; and this, which is called being *clinker-built*, gives them greater buoyancy and strength than if built in the manner of ships.

In every class of merchant vessels the prime object is to accommodate as large a quantity of goods as possible, and therefore comparatively little space is occupied with accommodation for either the captain or his crew. If the cargo be light, such as cotton, *ballast* is required to be put on board; this consists of sand, shingle, or any other heavy material, which is placed lowest in the hold, in order to balance the vessel, and give it due hold of the water. In the royal navy iron ballast alone is used, in pigs of nearly three hundredweight. This has the advantage of lying in small compass; but in consequence of its great weight, it tends to give excess of stability, which renders the vessel uneasy from the suddenness of the motion. This defect is remedied by *winging* the ballast, whereby its centre of gravity is raised. For the like reason, in stowing the ballast, it is tapered to a point at the fore and after extremities. Iron ballast, from its greater cleanliness, is more healthy for the crew than that of other materials." When a ship has no other loading, she is said to be *in ballast*. In stowing cargo, care is taken to preserve the *trim* of the vessel—that is, to keep it upright, and also equally balanced fore and aft. The connection between the motions of a ship and her stowage (whether of ballast or cargo) has not, however, been sufficiently analysed to lead to the discovery of any direct rule on this very important point.

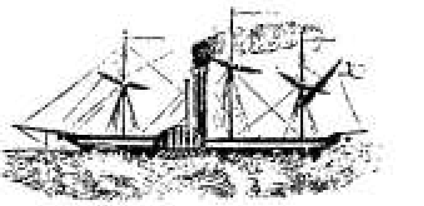
Within the present century, vessels propelled by steam power have been introduced and largely employed both in the commercial marine and in the royal navy; and to these we shall now advert.

Steam Ships.

Referring the reader for an account of the *mécanique* of steam power, as applicable to propulsion, to the article STEAM-ENGINE, p. 397, we shall here merely allude to the progress of the discovery, and to the extraordinary changes which have been effected upon maritime conveyance since its general adoption. For this purpose we transcribe, with some slight modifications, from the Cyclopædia of Commerce the following brief and perspicuous account:—

'Steam navigation was attempted by various individuals in the course of the eighteenth century; but the experiments which tended more than any other to develop this application of steam were the joint labours of three Scotsmen—Patrick Miller of Dalswinton, Dumfriesshire; James Taylor, his son's tutor; and William Symington, a mining engineer—Miller preparing the proper vessel and propelling apparatus, Taylor recommending the steam-engine as the moving power, and Symington effecting the modifications necessary in its structure. This took place between 1786 and 1789; and in 1802, a steam-tug made by Symington, with a single paddle-wheel in the stern, was placed on the Forth and Clyde Canal; but the project was abandoned, through fear that the undulation produced by it would prove injurious to the banks. Symington's apparatus, though then neglected in this country, had been seen and examined by many, and especially by Robert Fulton, an American, then studying under West, and who, with less merit as an inventor than Symington, but with more ample resources and greater energy, succeeded, in conjunction with Chancellor Livingstone, in introducing steam navigation into the United States in 1807, when the "Clermont" of 160 tons was launched at New York. Four years afterwards it was successfully established in this country by Mr Henry Bell, an enterprising house-carpenter of Glasgow, who in 1811 started the "Comet" of twenty-five tons burden and three horse-power, to ply to a bath hotel which he had set up at Helensburgh.

The progress of steam navigation was afterwards rapid, particularly in the United States, owing to the extent and number of its rivers, for which alone steamers were at first considered to be adapted. As improvement advanced, however, and confidence increased, they came gradually into use as marine vessels, for which purpose they were first fitted, in 1818, by David Napier, engineer, Glasgow, who, from that year till 1830, effected more for the improvement of steam navigation than any other man. He established regular steam communication between Britain and France and Ireland; by degrees, almost all parts of the shores of Europe were traversed in like manner; and in 1838, a line of steamers of gigantic size commenced running between England and the United States—a distance now generally performed in ten or twelve days. Steam vessels have since been adopted for many other parts of the ocean; and their increasing use in every civilised country has produced, and is daily producing, results which it is impossible fully to estimate.'



We refrain from entering into any details respecting the formation of steam vessels; but we may notice that, of late years, many have been wholly constructed of iron, and that the old paddle has been superseded in some instances by the Archimedean screw, and other kinds of propeller. By many iron is preferred, on account of its superior buoyancy, the facility of working it, its greater tenacity, and in the long-run, its greater cheapness. Vessels constructed of iron, either wholly or in part, are now divided into water-tight compartments, so that any one of these might be stove in and filled with water without destroying the buoyancy of the ship. As a proof of the value of the compartment system, we may instance the case of the Nemesis, which struck some time ago on the English Stones in the Bristol Channel, going nine or ten knots an hour: she slid off, after making such a slit as filled the forward compartment. She steamed several hours with the compartment full, until she obtained additional pumps in Mount's Bay, with which the space was pumped out, and the leak stopped. At Portsmouth she was examined, and drawings of the damage were made by an employé of the Great Western Company: she was repaired in a few hours, at an expense of about £30, and then started for China. An instance of the time a complete wreck takes to go down, so as to enable the crew to escape, was afforded by the Brigand, a large iron steamer, which had been trading between Liverpool and Bristol. She struck on sunken rocks off the Scilly Islands, filled a forward compartment, and had some part of her paddle-wheel forced so far into the engine-room as to damage the plates, and fill that part also. She remained afloat, in consequence of the remaining compartments, long enough to enable the crew to save themselves and their kits comfortably, and then went down in deep water.

We have already stated that steamers, at first timorously confined to rivers and estuaries, are now found traversing the whole line of coast, and holding communication with ports in the most distant parts of the globe. Many of these voyages, both coasting and by open sea, are performed with the utmost regularity and precision, without reference to wind or tide, or to the season of the year. For this purpose lines of large steamers are got up by companies as a speculation, and by the carriage of passengers, goods, and the government mails, have been enabled in most instances to realise very profitable returns. The vessels are despatched to an hour, a regular succession is maintained; and thus the public can calculate with certainty, almost to a day, when they shall receive news from China, India, the West Indies, the United States, Canada, or any other country between which such lines have been established. Several of the vessels so employed are of vast dimensions and substantial construction, and are fitted up with promenade saloons, state-rooms, dining-rooms, bedrooms, and other apartments, in a style of elegance not surpassed by the first-class hotels on land. Besides the ordinary transit vessels here spoken of, steam ships have been adopted in the royal navy to a considerable extent, and from their speed and certainty of passage, are likely to prove highly advantageous, should their services unhappily be ever required. There are no means at present of arriving at accurate statistics respecting the steam navy of Britain, war and mercantile; but excluding the small unregistered craft which ply on rivers, the number of steam vessels, home and colonial, must exceed 1000, with a horse-power of nearly 100,000, and a burden of about 200,000 tons.

Large as this force may appear, on the coasts and rivers of North America steam navigation has been carried on to a much greater extent than in Great Britain or any other country. Some of the American steam vessels are equally powerful with those of Britain, and are still more splendid in decoration; but they are much more liable to accidents, from the employment of steam at a very high pressure, and a general carelessness in the mode of management. Very few war steamers have as yet been constructed in the United States. France also possesses a respectable steam navy; but that of other countries is comparatively inconsiderable.

NAVIGATION.

Navigation is the art of conducting vessels at sea in the direction in which they are designed to proceed; the term is derived from the Latin word *navis*, a ship, and *ago*, to manage or govern. From *navis* also is derived the term *navy*, which signifies a collection of ships. The terms *marine*, *maritime*, and *mariner*, are likewise from a Latin root—namely, *mare*, the sea.

Laying aside the consideration of steam as a moving power, vessels may be said to advance in their course by means of tides, currents, and winds; the winds are in most instances the principal agent, and the art of the mariner consists in rendering almost every breath of wind which blows subservient to the purpose of the intended voyage. The winds most favourable for impelling the vessel are those which blow on the *quarter*, or slantingly on the ship's course. The reason for this is very obvious: when the wind blows directly astern, it can affect one, or perhaps two sails with commensurate force; but when it comes obliquely, every sail may be trimmed to meet it, and receive a share of the impulsive power. The variety in the rigging of vessels causes much difference in sailing powers: some will sail close to the wind, as it is called, or with a very small angle to the direction of the breeze, while others require winds much more fair. When the wind becomes too powerful, certain sails are taken in, and others are *reefed*, a portion being bound to their respective yards, so as to reduce the surface of canvas. Reefing and bracing the yards are among the nicest points of seamanship.

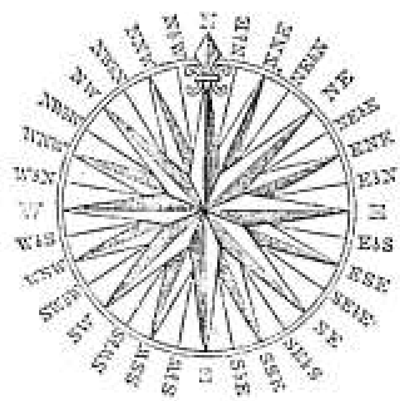
Ships are navigated, as nearly as possible, by the path which is the shortest distance between the port whence they depart and that for which they are destined; but from contrary winds and intervening land, it is generally necessary to sail in a track of a zig-zag form. When a vessel is obliged to sail to the right or left of the direction of the intended port, it is said to *tack*; when the ship is tacking towards the left, and the wind consequently on the right, it is said to be on the *starboard* tack; and when it is tacking towards the right, it is said to be on the *larboard* tack. A ship does not sail exactly in the direction of her keel, but deviates towards the side that is opposite to the wind; and the angle contained between the apparent and real direction is called *leeway*.

The tacking or changing of directions, in order to present the sails at a proper angle to the wind, is a process requiring considerable seamanship. The ship being already close to the wind, the helm is gradually eased down, so that the rudder may not exert its full force until she begins to turn, nor act suddenly to check the headway, so essential to the success of the evolution; at the same time the head sheets are flown, so as to cause the sails before the centre of rotation to shake, and lose their power of balancing the after ones. As the ship approaches the wind, the spanker is drawn gradually from the lee side towards the centre, that it may keep full, and by its action so near the stern, continue promoting the rotation. As soon as the sails reach the direction of the wind, and cease to draw, the corners of the courses are drawn up, and the tacks and sheets overhauled, ready to swing the yards. After a while the sails catch aback, and the foresails, soon masking the after ones, act with a powerful leverage in turning the bow. At length, having come head to wind, without loss of headway, and the evolution being certain, the after-yards are swung round, ready to receive the wind on the opposite side; which operation is then more easily performed, from the sails being becalmed by the fore ones. Lastly, when the after-sails are filled by the wind, the head-yards are also braced round to receive its impulse, and the ship at once recovers headway, and proceeds on her new tack.

Thus easily is a ship manœuvred in fine weather. Not unfrequently, however, a gale comes to disturb the peaceful course of the mariner, and call forth all his exertions. Let us suppose that, whilst our ship is contending against the head wind, the misfortune is augmented by its gradual increase. Shortening sail becomes necessary, and is determined by two leading considerations—the stability of the ship, and the strength of her masts: it is to diminish the careening of the one, and avoid endangering the other, that the surface spread to the wind is reduced. In shortening sail, we always begin with the highest and lightest sails, descending gradually, and keeping pace, in an inverse ratio, with the increase of wind. The sails do not, however, come in uniformly in the direction of the length; but the after-sails most rapidly; because, as the wind increases, the energy which it exerts in a forward direction upon the masts, tends, with a powerful lever, to depress the bow and raise the stern. Hence the latter drifts more easily to leeward, thereby bringing the bow towards the wind; this effort is also promoted by the action of the sails passing farther to leeward, and by the ship ceasing to sail on an even keel. From all those reasons, the more the wind increases, the more she tends to come to; so, to avoid a constant recurrence to the action of the rudder, it becomes necessary to shorten sail faster aft than forward, taking in the mizen-top-gallant-sail, and even the spanker, before the fore and maintop-gallant-sails: for the same reason, when it becomes necessary to reef, it is not unusual to begin with the mizen-top-sail. In the case of a heavy gale, it is sometimes necessary to reef or take in the whole from stem to stern; the helm being at the same time kept constantly hard down, the vessel is said to *lie to*. Should the gale abate, the reefs are shaken out, sail is added, and the vessel bounds actively on its course.

The Compass.

The most important instrument for the guidance of the mariner is the compass. There are different kinds of compasses to suit peculiar purposes; but that which is commonly in use on shipboard is of the following construction:—The most essential part is a magnetised bar of steel, called the needle, which is supported horizontally on a central pivot, round which it is free to move and to point in any direction. The pivot of the needle rises from a circular *card*, resembling the dial-plate of a timepiece, and round the circumference of which are marked thirty-two points. The following figure represents the card of a compass. North, South, East, and West, are the main or cardinal points, and are indicated by their initial letters respectively, while the subordinate points are also marked by letters, as N&E for north-by-east, NNE north-north-east; and so on. To be able to recite the various points is said to 'box the compass.' The north is usually indicated by an ornamented figure, or arrow head, as in the sketch here presented.



The card and needle are fixed in a round box, enclosed by a sheet of glass, to secure it both from the agitation of the atmosphere, as well as to exclude dust, moisture, and other things which might interfere with the correctness of the indications. The whole is enclosed in another box, suspended by two concentric brass circles or *gimbals*, as they are technically called, and in such a manner that the compass hangs as it were on points like a swivel, by which, during the lurching, or heaving up and down, or motion from side to side of the ship, the needle and its card remain in a horizontal position, and under all circumstances indicate the various points correctly. The compass, thus encased, is placed upon deck in a covered stand called the *binnacle*, in front of the man at the helm, so that the direction in which the needle points can be constantly seen in guiding the vessel. The point of the needle, which, for distinction, is some way ornamented, is understood to point towards the north, but properly it points a little to the west of due north; and this, as well as other variations to which it is subject in certain latitudes, must be thoroughly understood by the navigator. In the whole of the northern hemisphere of the globe, the point or northern pole of the needle is the active agent in pointing the direction of the compass. In the southern hemisphere, the southern pole of the needle assumes the active management of the instrument; and by pointing towards the south pole of the earth, keeps the point of the needle pointing towards the north as before. Practically, it is of no consequence to the mariner which point of the needle is most affected by the polarity of the earth, for in all places and conditions (slight variations excepted) the needle keeps its northern ornamented point towards the north pole of the globe.

The needle being liable to be affected by the proximity of iron, no piece of that metal is used in the construction of the binnacle, or is allowed to be near it. In the case of iron ships, or ships having much iron on board, means are adopted to counteract the tendency which the needle has to point in a wrong direction. From want of attention to this important point, serious disasters at sea have ensued.

The Log—Sextant.

Provided with a compass, the next object of importance is the *log*, an instrument for measuring the rate at which the vessel proceeds through the water in a given space of time. The log is a very simple contrivance. It consists of a long cord, having a piece of wood attached to one end, and called the *chip*. This is of a quadrantal form, and being slung at the corners with line, and loaded at the circumference, when thrown overboard it remains erect and stationary, and drags the line off as fast as the ship passes through the water. The line is divided into knots and half knots, representing miles and half miles, or minutes of a degree, to which they bear the same proportion as the log-glass does to an hour. Thus the log-glass being filled with sand to run through in 30", the length of a knot must be 51 feet, the first being the same proportion of an hour that the last is of a mile. As, however, the log is found to come home a little in the effort to draw the line out, it is customary to mark the knot a foot or two less than the true length. The mode of heaving the log to measure a ship's rate is as follows:—The log-reel, upon which the line is wound, being held by one of the sailors, the officer places himself on the rail to leeward, and a third person holding the glass, he proceeds to prepare the chip, so that the peg of one of the lines holding the chip in a perpendicular direction will draw out, by the force of the water, when the reel is stopped, and allow it to haul in easily. Then having gathered a sufficient quantity of line into his hand, he throws it far to leeward, that it may not be affected by the eddies which follow in the wake. The stray line, which allows the chip to get astern, now runs off, and the instant that the white rag, which marks its termination, passes through the hand of the officer, he cries 'Turn!' and continues to veer out line until the glass runs out, and the person holding it cries 'Stop!' Then the line is grasped, and the number of knots that have passed off mark the speed of the ship. When this exceeds five miles, it is usual to use a glass of 15" instead of 30", counting the knots double. The rate of sailing per hour multiplied by the hours sailed, thus gives the mariner the measure of his run.

In addition to these essential instruments for directing the course and ascertaining the distance, the navigator must be provided with *octants* of double reflection, to measure the altitude of the heavenly bodies, and a circle, or *sextant*, more nicely graduated, to measure distances between the moon and stars. He should also have with him a book containing the logarithms of numbers, sines, tangents, and secants, to facilitate trigonometrical calculations; tables for correcting altitudes for dip, parallax, and refraction; also lists of latitudes and longitudes for every part of the world; and of time of high water at every port, at the period of full and change of the moon, from which at all times to be able to find the tide; and a variety of tables to facilitate the various problems of navigation. He should also have with him the 'Nautical Almanac,' containing the places and declinations of the fixed stars and planets, and especially the distances of the moon from the sun and other stars, and all that relates to that body, with a view to calculate the longitude by observation. Finally, he must be provided with the general and local charts applicable to his contemplated voyage.

Thus furnished, the mariner may set sail with confidence; many do so with no other aids than their compass, log, quadrant, a single chart, and book of navigation, and arrive in safety. But it is less our business to show with how little care a ship may be navigated, than to show how she may be carried from port to port with the greatest possible certainty. Having taken leave of the port, and when the last land is about to disappear from view, either from the growing distance or the intervention of night, the mariner selects some conspicuous headland, of which the latitude and longitude are noted in his tables, and placing a compass in some elevated position, remote from any iron object to disturb its polarity, proceeds to determine its bearing, and estimate his distance from it, either by the progress made from it, or by the ready estimate of a practised eye. Or taking the simultaneous bearings of two distinct points of coast, he has still surer data for deducing his position. This is called *taking the departure*, and is carefully noted on the log-slate, with the time of making the observation. Thenceforth the log is thrown every hour, and the course and distance are entered upon the slate, to be copied into the log-book at the end of the day.

Working a Reckoning.

At the first noon succeeding the time of taking his departure, the mariner works up his reckoning. Noon is an epoch fixed by nature, being determined by the passage of the sun over the meridian, and is therefore well chosen as the beginning of the day. The log-slate being marked, he copies the courses and distances, if from head-winds or other causes they have been various; the departure from the land is also converted into a course; as is also the current, if there be any known one. He next proceeds to find the difference of latitude and departure from the meridian corresponding to each course, either by geometrical calculation, or, more expeditiously, by reference to tables; then he adds the several differences of latitude and departure, and if they be of different names, as some north and some south, some east and others west, deducts the less from the greater. With the remaining difference of latitude and departure, he not only finds the course and distance made good, but also the latitude and longitude in which he is; the difference of latitude being applied to the latitude left, by adding or subtracting, in sailing from or towards the equator, at once gives the latitude of the ship. But before the departure can be thus applied to find the longitude, it is necessary to reduce it for the converging of the meridians towards the poles; for though all degrees of longitude are divided, like those of latitude, into 60 minutes or miles, yet they decrease in length from being equal to a degree of latitude at the equator, until they become nothing at the poles. There are many ways, more or less accurate, of deducing the difference of longitude from the departure, the latitude being known; they are founded upon this principle: the circumference of the earth at the equator is to its circumference at any given parallel of latitude as the departure is to the difference of longitude. The most easy and correct way of obtaining the difference of longitude on an oblique course, is by the aid of a table of meridional parts; for having taken out the meridional difference of latitude, the mariner has this simple proportion: the proper difference of latitude is to the meridional difference of latitude as the departure to the difference of longitude. The difference of longitude thus obtained is applied to the longitude left, adding or subtracting, in sailing to or from the first meridian, and the result will be the ship's longitude; which, with the latitude previously ascertained, determines her position on the chart. The method of navigating thus described is called *dead reckoning*. It is far from infallible, and leaves much to desire. It will indeed do pretty well in short runs; but as errors daily creep in from many causes escaping calculation, such as bad steerage, leeway, heave of the sea, unknown currents; and as these accumulate, and become considerable at the end of a long voyage, it becomes necessary for the mariner, removed from all reference to terrestrial objects, to resort to the immovable guides in the heavens. All the heavenly bodies are, by the revolution of the earth, daily brought to the meridian, at which time, if their altitude is measured, their declination or distance from the equinox being known, the latitude is readily deduced; it may also be deduced from single or double altitudes of bodies not in the meridian, the times being accurately known. But the meridian altitude of the sun is what furnishes at once the easiest and most correct method of finding the latitude. So great, indeed, are the advantages offered by the meridian altitude of the sun, that no other means of finding the latitude are used, except when these have failed from a clouded atmosphere, or when the momentary expectation of making the land quickens the mariner's anxiety. We shall therefore now explain the method of deducing the latitude from the sun's meridian altitude.

Taking an Observation.

Furnished with a sextant, circle, or octant of reflection, the observer goes upon deck, and having examined the adjustment of his instrument, proceeds to bring down the image of the sun reflected by its mirror, until the lower limb just sweeps the horizon. He continues to follow and measure its ascent, until it ceases to rise; the moment that it begins to fall, and the lower limb dips in the horizon, the sun has passed the meridian. The altitude marked by the index being read off, it is next corrected. And first, the observer adds the semi-diameter, in order to make the altitude apply to the centre of the object; next he subtracts the dip, to meet the error caused by the extension of the horizon, in consequence of the rotundity of the earth, and the elevation of his eye above its surface; also the refraction of the atmosphere by which the object, when not vertical, is made to appear higher than its true place; lastly, he adds the parallax (a small correction, inconsiderable from the sun's distance), in order to reduce the calculation for the centre of the earth; from which point all calculations are made, and which is ever supposed to be the station of an observer. (See Astronomy.)

Having made all these corrections, which many mariners despatch summarily, by an addition of 12 minutes, he has the true meridian altitude of the sun. Taking this from a quadrant, or 90 degrees, gives its zenith distance, or distance from that point in the heavens which is immediately over the observer, and would be met by a straight line passing from the centre of the earth through his position. Now, if the sun were for ever on the equinoctial, the zenith distance would always be the latitude; for whilst the zenith is the observer's position, referred to the heavens, the equator is there, in like manner, represented by the equinoctial; and we have already seen that latitude is the distance from the equator. But as the sun is only twice a year upon the equinoctial, and as his distance from it at times increases to more than 23 degrees, it becomes necessary to take this distance (called his *declination*) into the estimate. The sun's declination is given in the Almanac for the noon of each day; by correcting it for the time anticipated or elapsed, according as the sun comes first to him or to the first meridian, by his position east or west of east of it, the observer obtains the declination for noon at his own position. This declination applied to the zenith distance, by adding when the sun is on the same side of the equator, by subtracting when on the opposite side, gives the true latitude.

A daily and accurate knowledge of his latitude is, then, to the mariner of modern times, a desideratum of comparatively easy attainment. By its aid nothing is easier than to sail clear of any rock or shoal that crosses his track, either by a watchful look-out at the moment of passing its latitude, or else by avoiding its parallel entirely, until it be surely passed. Moreover, this is his best and surest guide in aiming at his destined port; for he has but to attain the exact latitude it lies in, and then sail directly upon it, east or west, to be sure of success. And here nature is again his friend: by a singular coincidence, discoverable in glancing at the map of the world, most coasts and continents lie in a northern and southern direction. Hence the value attached by seamen to an accurate knowledge of the latitude; and hence the familiar saying of 'Latitude, lead, and look-out.'

To find the Longitude.

Various ways have been devised to find the longitude, in all of which the great element is time. The earth performs her diurnal revolution in 24 hours, or, in other words, each part of the circumference of the globe, which is divided into 360 degrees, is brought under the sun once a day. Hence each part of the circumference (reckoning from east to west) has its own peculiar time of day. When it is noon at one place, it is one o'clock afternoon at another place, two at another, and so on; the time differs all round the globe. Dividing the 360 degrees by 24, we find that 15 is the result; for every 15 degrees, therefore, along the circumference, going westwards, there is an hour of difference, in advance; and going eastwards, an hour behind. If it be noon at Greenwich, it will be one o'clock at a point 15 degrees east from it (that is, the sun has passed over it an hour ago), and eleven o'clock forenoon at a point 15 degrees west from it (that is, the sun will be an hour in getting up to it). Dividing the 60 minutes of an hour by 15, the result is 4; the earth, therefore, moves under the sun at the rate of a degree, or 60 geographical miles, in four minutes, or 15 miles in the minute, or one mile in the four seconds, or a quarter of a mile in the second. Here, then, the element of time is brought at once, and in the most satisfactory manner, to bear upon the distance of any given place, east or west from any other given place. The measuring of such a distance is called finding the longitude.

Different places on the globe have been established as starting points in making these measurements. The French reckon from Paris, and the English from Greenwich, near London, where an astronomical observatory has been long established, and supported at the public expense. In all English works of geography, the longitude is reckoned from Greenwich, although not expressly mentioned. Navigators determine their longitude by watches or chronometers, whose movements are as exact as can possibly be obtained from mechanism. (See Horology.) In setting out on a voyage, the chronometer is set to London time, and kept going at that time. At the hour of noon of each day, as determined by an observation with the sextant, the difference is estimated between that hour and the hour indicated by the chronometer, and that difference is the longitude east or west of Greenwich, as the case may be. Some mariners, for security, take several chronometers to sea with them, as one only is by no means a safe guide. In general, however, the masters of coasting traders, or those who pursue short voyages by regular lines of route, depend on books containing lists of longitudes as well as of latitudes.

Marine Barometers—Log-Book.

The last great requisite in navigation is a good barometer, to indicate the approach of foul weather. The most delicate instrument of this kind is the sympiesometer of Adie, by which the earliest and most certain indications are presented of coming storms. In treating of the nature and value of instruments of this nature, Dr Arnott makes the following observations:—'The watchful captain of the present day, trusting to this extraordinary monitor, is frequently enabled to take in sail, and to make ready for the storm, when in former times the dreadful visitation would have fallen upon him unprepared. The marine barometer has not been in general use for many years, and the author was one of a numerous crew who probably owed their preservation to its almost miraculous warning. It was in a southern latitude. The sun had just set with placid appearance, closing a beautiful afternoon; and the usual mirth of the evening watch was proceeding, when the captain's order came to prepare with all haste for a storm. The barometer had begun to fall with appalling rapidity. As yet, the oldest sailors had not perceived even a threatening in the sky, and were surprised at the extent and hurry of the preparations: but the required measures were not completed, when a more awful hurricane burst upon them than the most experienced had ever braved. Nothing could withstand it; the sails, already furled and closely bound to the yards, were riven away in tatters; even the bare yards and masts were in great part disabled; and at one time the whole rigging had nearly fallen by the board. Such, for a few hours, was the mingled roar of the hurricane above, of the waves around, and of the incessant peals of thunder, that no human voice could be heard, and amidst the general consternation even the trumpet sounded in vain. In that awful night, but for the little tube of mercury which had given the warning, neither the strength of the noble ship nor the skill of the commander could have saved one man to tell the tale.'

A journal of events and observations on board ship is usually kept in what is called the log-board, and transferred thence into the log-book. The log-board consists of two boards shutting together like a book, and divided into several columns, containing the hours of the day and night, the direction of the winds, and the course of the ship, with all the material occurrences that happen during the twenty-four hours, or from noon to noon, together with the latitude of observation. From this table, which is written in chalk, and daily effaced, the officers work the ship's way, and compile their journals. From it, also, entries are carried to the log-book, in an expanded form, with any observations and additional particulars supposed to be necessary. The log-book is thus the journal of the ship, and is preserved with great care for exhibition, if required, at the termination of the voyage.

Thus, then, by the use of various instruments and practical experience in navigation, a ship is conducted from port to port, dangers avoided, and difficulties overcome. Though they who traverse the vast ocean leave no track for the guidance of those who follow, it is thus converted into a plain and convenient highway, extending to the extremities of the earth.

LIGHTHOUSES—BEACONS.

Beacons, warning-bells, lighthouses, and the like, are among the most indispensable adjuncts of maritime conveyance; without them, indeed, it would be utterly impossible to conduct it with anything like regularity or safety. The most ancient structure of this description which we read of was the Tower of Pharos—regarded by our ancestors as one of the seven wonders. It was commenced by Ptolemy the Elder, and finished some years after by himself and his son Ptolemy Philadelphus, in the year of the world 3670, on the island of Pharos, in the Bay of Alexandria. 'It was built,' says an ancient authority, 'on the east end of this island, upon a rock of white marble, of a large square structure, on the top of which fires were kept constantly burning for the direction of vessels. It was a most magnificent tower, 450 feet high, consisting of several storeys and galleries, with a lantern at top, which could be seen many leagues at sea.' This wonderful work has been demolished for ages; as also the Colossus of Rhodes, another ancient erection of a similar nature. The Light-Tower of Corduan in France, situated upon a low rock about three miles from land, at the mouth of the Garonne, was for a long time regarded as one of the chief wonders of modern Europe. It was founded in 1584, and completed in 1610. Its lower part consists of a solid platform of masonry, 135 feet in diameter, above which, in succession, are a number of apartments, all narrowing in circumference till the upper storey is reached—being in all 145 feet high.

In our own day, the most celebrated lighthouse is that built on the Eddystone rocks—a low reef situated south-south-west from the middle of Plymouth Sound, nearly fourteen miles distant from that port, and about ten from the promontory of Ramhead. The reef, which stretches across the channel for upwards of 200 yards, slopes gradually towards the south to the distance of a mile, so that the swell sweeps up, as it were, an incline, till within a few fathoms of the exposed rock, where, striking against a sudden ledge, it breaks and dashes upwards to a height of forty or fifty feet. On this dangerous reef the necessity of a lighthouse was early felt; and accordingly, in 1696, a gentleman of the name of Winstanley was furnished with the necessary powers to carry such a design into execution. He entered upon his task in 1696, and completed it in four years. So certain was Winstanley of the stability of his wooden structure, that he declared it to be his wish to be in it 'during the greatest storm that ever blew under the face of heaven;' a wish that was but too soon and fatally gratified, for in November 1703, while there with some workmen and the light-keepers, a storm of unparalleled violence arose, and in one night the whole fabric was swept away. In 1709 another lighthouse was built of wood by a Mr Rudyerd; and this structure, after braving the elements for forty-six years, was burned down in 1755. On the destruction of this lighthouse, Mr Smeaton, the celebrated engineer, was next applied to, who at once fixed upon the more durable material, stone, and chose for his model the natural figure of the trunk or bole of a large spreading oak. With these views as to the proper form of the superstructure, Mr Smeaton began the work on the 2d of April 1757, and finished it on the 4th of August 1759. The rock, which slopes toward the south-west, is cut into horizontal steps, into which are dovetailed and united by a strong cement Portland stone and granite. The whole, to the height of thirty-five feet from the foundation, is a solid of stones, ingrafted into each other, and united by every means of additional strength. The building has four rooms, one over the other, and at the top a gallery and lantern. It is nearly 80 feet high; and since its completion, has been assaulted by the fury of the elements without suffering any appreciable injury.

Equally remarkable with the lighthouse of the Eddystone is that of the Bell-Rock—a sunken reef, lying at the distance of eleven miles from the promontory called the Red Head, in Forfarshire, and on the highway to the firths of Forth and Tay, two of the most frequented estuaries in the kingdom. The ledge is said to be about 850 yards in length, and 110 in breadth; at low water, some of its summits appear from four to eight feet above the level of the sea; but at high water, they are always covered to the depth of ten or twelve feet. Tradition says that the abbots of the monastery of Aberbrothock succeeded in fixing a bell, which was rung by the swell of the sea, so as to warn the mariner of his situation; but that this benevolent erection was destroyed by a Dutch pirate, who, to complete the story, was afterwards lost upon the rock with his vessel and crew. However this may have been, it was not till the beginning of the present century that a solid substantial lighthouse, after the model of the Eddystone, was determined upon and erected. This work was intrusted to Mr Stevenson, the Scottish engineer; was begun in 1808, and completed in 1810. Being lower in the water than any rock on which a similar building has been raised, the difficulties of the architect were greatly increased; but by preparing all the stones on shore, and conveying them in lighters to the reef, where a tender and other accommodation were provided for the workmen, his success was complete, and the revolv-

ing ruddy light of the Bell-Rock now ranks among the chief achievements of British engineering. 'The lighthouse,' we quote the Edinburgh Encyclopedia, 'is a circular building, measuring forty-two feet in diameter at the base, and thirteen feet in diameter at the top. The masonry is 100 feet in height, and including the light-room, it is 115 feet. The ascent from the rock to the top of the solid, or lowest thirty feet, is by means of a kind of trap ladder; the ascent from the level of the entrance door is by means of a circular stair to the first apartment, containing the water, fuel, &c.; and from thence to the several apartments the communication is by wooden steps. The windows have all double sash-frames, glazed with plate-glass, besides a storm-shutter of timber for the defence of the glass against the sprays of the sea; for although the light-room is about eighty-eight feet above the medium level of the tide, and is defended by a projecting cornice or balcony, with a cast-iron rail, formed like the meshes in network, yet the sprays of the sea occasionally lash or fall upon the glass of the light-room, so that it becomes necessary in gales of wind to shut the whole of the dead-lights to the windward.'

Not less bold and hazardous in point of erection is the recent structure on the Skerryvore—a cluster of rocks just appearing above high-water in the Atlantic, between the north of Ireland and the Hebrides, from the nearest point of which it is twelve miles distant. This lighthouse, commenced in 1835, and finished in 1844, by Mr Alan Stevenson, son of Mr Stevenson above-mentioned, consists of a tower 138 feet high, curving inwards from a basis of forty-two feet, and contains nine apartments over each other, for the accommodation of the establishment by which the light is to be maintained. The lantern consists of an apparatus of eight annular lenses revolving round a lamp of four concentric wicks, and producing a bright blaze every minute, visible to the distance of eighteen miles. The cost of the entire structure amounted, we understand, to £89,000. We particularise this and the preceding cases as illustrations of the magnitude of some of our lighthouses, and of the hazard and expense encountered in their erection—difficulties which could be surmounted only at a period of great material wealth and scientific skill, and when the importance of maritime conveyance is so vast as to compel such protection.

A number of improvements have recently been made and promulgated in the construction of lighthouses, chiefly with a view to the saving of time and expense in their erection. The first deserving of notice is the iron lighthouse of Captain Brown. This structure is composed solely of rings of cast-iron, joined or cased one upon another till the requisite height be attained. The advantages of this plan are cheapness, facility of erection, strength, and durability. Metal lighthouses —that is, composed either of cast-iron, wrought iron, or gun-metal—have been strenuously advocated by Mr Gordon, who, from pretty obvious data, maintains that the Skerryvore, for example, could have been erected on this principle with equal efficiency at little more than one-third of its actual cost. The 'screw-pile' of Mr Mitchell is another invention likely to come into use in the erection of lighthouses on shoals and sandbanks. As the name implies, the basis consists of a framework of piles screwed, instead of driven home, and on this an open fabric is erected for the support of the lighting apparatus—the open structure offering no resistance to the waves. Another set of inventors have directed their attention to the improvement of the lighting apparatus—its lamps, lenses, and reflectors. As this department involves mathematical and optical principles of high consideration, we shall merely remark, that at present the lights on our coasts generally consist of Argand burners, placed on the foci of parabolic reflectors made of silver strengthened with copper. The reflectors are arranged, and the lights exhibited, in such a manner that those on the same line of coast should have some essential distinction: thus some of them are revolving or intermittent, many are fixed, others are placed one above another, some flash every five seconds, and not a few alternately red and white. These movements are in general effected by clockwork of a very ingenious description.

The lighthouses on and about the British coasts are upwards of 200 in number, and are classed as 'harbour lights' and 'general lights.' Almost all of them are now vested in public boards, as are also the marine beacons and buoys of the kingdom. The chief board of supervision and control is the Trinity House, Deptford, incorporated so early as 1515 by Henry VIII. In Scotland, the lights are under the immediate management of the 'Commissioners for Northern Lights;' those of Ireland are under a similar trust; but both Scotch and Irish are subject to the control of the Trinity corporation, who regulate all new erections and alterations, and give notice to the public of any change which may be effected. For the erection and maintenance of lights, beacons, and buoys, a rate is levied on all vessels passing them within certain limits—this rate varying from one farthing to one penny per ton for each light so passed.

Beacons are generally placed on sandbanks, rocks, and shoals, and are either floating or stationary. When floating, they are termed buoys (already noticed); when fixed, they are either of solid masonry, or of an open framework of wood or iron. Of late, their number has been much increased along the British coasts; many of them being composed of cast-iron pillars, screwed and rivetted together into a substantial framework, which stands thirty or forty feet above water-level, and which no storm can possibly destroy. The most remarkable of our beacons are those erected by the Trinity House (under the superintendence of Captain Bullock) on the fatal and shifting sands of Goodwin. From the number of shipwrecks constantly occurring on these shoals, these beacons are intended to serve also as a place of refuge for shipwrecked sailors. The first and largest consists of a strong framework, sunk to a considerable depth in the sands, from which rises a vertical column; and on this, at a height of eighteen feet above high water, is placed an octagonal platform, capable of holding forty persons. The platform always contains a barrel of water, a flag ready to be hoisted, and is inscribed in eight different languages with the words 'Hoist the flag.' The second, which was erected in 1847, is of a different construction. The centre column is a tube of cast-iron two feet six inches in diameter, put together in ten and twenty-feet lengths; it is inserted thirty-two feet into the sand by means of Dr Potts's newly-invented process of atmospheric pressure (see No. 28); the four surrounding tubes are of fifteen inches diameter; the whole is bolted together, and surmounted by a cage of seven feet diameter, the top of which is fifty-six feet above sand-level. At present the mariner is warned off these fatal sands at night by a floating light; but means are about to be adopted for the erection of a fixed and permanent structure.

SHIPWRECK—LIFE-PRESERVERS.

Notwithstanding every precaution of lighthouse and beacon, shipwrecks are continually occurring at different parts of our coasts, and to save the lives of the seamen in such cases—without reference to the fate of the vessel—has ever been a subject of earnest consideration with the humane and ingenious. During last century, several *life-boats* were invented; among others, one by Mr Lukin in 1785. But an accident which occurred on the Herd Sands of South Shields in September 1789, led to material improvements in the art of constructing these vessels. The 'Adventure,' a merchant-ship of considerable bulk, was wrecked within three hundred yards of the shore, in presence of an immense number of spectators; and almost every man of the unhappy crew perished, without the possibility of receiving assistance from the shore. The consequence was, that the people of South Shields met soon afterwards and offered a reward to any one who should invent a boat capable of being launched from the shore to the aid of ships in distress. Mr Greathead gained the premium; and in 1790, a life-boat constructed upon the plan proposed by him was effectually used in saving the crew of a vessel stranded under circumstances similar to those of the Adventure. Several other trials of the life-boat proved its utility so fully, that in 1802 the Society of Arts presented the inventor with their gold medal and fifty guineas; and parliament also decreed to Mr Greathead a reward of £1200. The Trinity House followed the example; and the Committee of Lloyd's devoted £2000 to the purpose of building boats on the same principle.

The form of Mr Greathead's life-boat is one well adapted to give it buoyancy, and keep it afloat in any sea. It is usually 'made about thirty feet in length, ten in breadth, and three feet three inches deep at midships; both extremities are made precisely of the same form, so that it goes through the water with either end foremost; and its shape lengthwise is a curve, so formed that a line drawn from the top of one stem to that of the other would be two feet and a-half above the gunwale at midships. In this boat there are five thwarts, or seats for *rowers*, double-banked, so that it must be manned with ten oars. It is cased and lined with cork, which gives it such buoyancy, that it will float and be serviceable though so damaged by hard knocks as to be almost in pieces; and this the softness and elasticity of the cork is well calculated to prevent. The cork on the outside is four inches thick, and it reaches the whole length of the shear, or side of the boat; on the inside it is thicker; and the whole quantity is about seven hundredweight. It is firmly secured with slips or plates of copper, and fastened with copper nails. The advantages of this boat are stated to be, that its curvature gives it great facility in turning, a single stroke of the steering oars, of which there is one at each end, moving it as though on a centre; that the covering of cork, being immediately under the gunwale, gives great liveliness, or disposition to recover its balance, after being suddenly canted aside by a heavy wave; and that its capability of being propelled with either end forwards increases its manageability.'

The life-boat is kept in a boat-house, and placed on a frame furnished with wheels, in order that it may be moved at an instant's notice. Where the road to the sea is smooth, this simple mode of moving the boat does well enough; but it has been found better in many cases to suspend the boat under the axis of the wheels, so that the shaking may be less injurious. At most of the life-boat stations the boat is under the charge of a committee; and twenty or twenty-four men, composing two crews, are alternately employed in its navigation. A reward is given to these men in cases of shipwreck, and the vessel receiving aid is expected to contribute to this end. Of course the life-boat men are picked persons, of steady habits and active frames; and the individual in command requires to possess peculiar skill and knowledge of the coasts and currents. It has been observed that the occupation of the life-boat men gives a sort of dignity to their character, and elevates their tone of thought. Many noble actions have been performed by them, which no mere pecuniary reward could compensate.

Mr Greathead recommends the life-boat to be painted white on the outside, as a colour that most readily catches the eye. He also advises the steersman to keep the head of the boat to the sea, and to give her an accelerated velocity to meet the wave. The strong reflux of the waves renders it necessary to approach a wreck with great caution, and the lee-side is usually the safest of access. Of course the first object is to convey the wrecked crews on shore, which, if they are numerous, must be done by degrees.

Since Greathead's time, several improvements have been effected on his life-boat, chiefly with the view of increasing its buoyancy and strength. One of the latest is the application of vulcanised caoutchouc, a substance possessing at once lightness, strength, and elasticity, and which may be used either in sheets or tubes. We believe, indeed, that in one or two instances life-boats have been constructed wholly of caoutchouc and cork-planking upon a frame of hollow iron. A boat of this kind is only about half the weight of the common life-boat, and will consequently be rowed with greater swiftness; at the same time that, under ordinary circumstances, it will be impossible to sink it.

Captain Manby's Apparatus.—Next to the life-boat, the most important inventions for the humane end of saving lives at sea have been those of Captain Manby. This philanthropic gentleman was in the corps of engineers, and held the situation of barrack-master at Yarmouth, on the Norfolk coast, in the year 1807. That coast, it is well known, is full of shoals, and many vessels have gone to pieces within a hundred yards of the shore, in sight of multitudes of people, without any chance of giving relief. Life-boats could not be stationed at all points of an extensive coast, and perhaps could not be always used if they were present. The lamentable case of the 'Snipe,' where sixty persons lost their lives near Yarmouth, made so deep an impression on Captain Manby, that he resolved to devote his mind and his life to the discovery of some means of relieving similar cases of distress. It appeared to him that the desired end was the discovery *of some means of throwing a rope from the shore to the ship, or from the ship to the shore.* Boats with the crews could obviously be thus drawn ashore in almost any circumstances. A cannon shot affixed to a rope, and projected from a piece of ordnance over a stranded vessel, seemed a practicable mode of establishing the communication. But to reduce it to practice, was found to be attended with much greater difficulty than the simplicity of the object appeared at first sight to promise. In the first place, the folding or manner of laying the rope, so as to unfold itself with the rapidity equal to the flight of a shell from a mortar, without breaking by sudden jerks at each returning fold, and without entanglement from the effect of uneven ground and boisterous winds, was no easy task. But it was at length attained by adopting what is called a French faking, in folds of the length of two yards; and by laying the rope in a flat basket always kept ready, with the rope in order in a secure place, so that it could be transported at a moment's notice to the situation required, and laid upon rocks and uneven ground, even in the most boisterous weather, without fear of disarrangement.

The next difficulty consisted in the means of connecting the rope with a shot, so as to resist the inflammation of gunpowder in that part of it which must necessarily occupy the interior of the mortar. Chains in every variety of form and strength universally broke, from the sudden jerks or play to which they were liable, which proved that not only an elastic, but a more connected body was necessary. 'At length,' says Captain Manby, 'some stout plaited hide, woven extremely close to the eye of the shot, to prevent the slightest play, extending about two feet beyond the muzzle of the piece, and with a loop at the end to receive the rope, happily effected it.' This apparatus, projected from a small howitzer over a vessel stranded on a lee-shore, so light as to be easily conveyed from one part of the coast to another, affords a certain means of saving the lives of the crew in the daytime, and when, from cold and fatigue, they are not disabled from seizing the rope, and in other respects joining their own exertions to those of their friends on shore.

Such is the simple but efficacious nature of Captain Manby's first invention; and a few practical experiments soon ascertained the allowance to be made in pointing the mortar to windward of the object over which the rope is to fall, in order to obviate the effect of a strong wind, which would of course carry it considerably to leeward. Experience also proved that the mortar should be laid at a low elevation, to insure the certainty of the rope's falling on the weathermost part of the rigging.

This original invention, however, was obviously capable of many improvements. The first of these was to afford assistance to vessels whose crews, either from their being lashed to the rigging, or from extreme cold and fatigue, are incapable of assisting to secure the rope to the wreck when projected over it from the mortar. This was attained by adding a quadruple barb to the shot—that is, making four hooks project from the ball—by means of which, when the rope is hauled tight by the people on shore, one end is firmly secured on some part of the rigging or wreck, and a boat can of course be hauled to the relief of the crew without any assistance on their part.'

But in order to make this invention effective in the darkest night, as well as by the light of day, the ingenious philanthropist had yet much to do and discover. He attained his end, difficult as the task was. 'The requisite objects were—*First*, to devise the means of discovering precisely where the distressed vessel lies, when the crew are not able to make their exact situation known by luminous signals. *Secondly*, to discover a method of laying the mortar for the object with as much accuracy as in the light. *Thirdly*, to render the flight of the rope distinguishable to those who project it, and to the crew on board the vessel, so that they cannot fail of seeing on what part of the rigging it lodges.

To attain the first object a fire-ball is used, such as is often thrown up in the attack and defence of fortified places to discover the situation of an enemy by night. It consists of a hollow ball of pasteboard, having a hole at top containing a fusee, and filled with about fifty luminous balls of star composition, and a sufficient quantity of gunpowder to burst the ball and inflame the stars. The fusee is graduated so as to set fire to the bursting powder at the height of 300 yards. On the stars being released, they continue their splendour, while falling, for nearly one minute, and strongly illumine every surrounding object: ample time is therefore allowed to discover the situation of the vessel. During the period of the light, a board, with two upright sticks at each end (painted white, to render them more discernible in the dark), is pointed towards the vessel, so that the two white sticks shall meet in a direct line with it, the wreck being a fixed object. This will obviously afford an undeviating rule by which to lay the mortar, making an allowance for wind, &c. Thus the second object is attained. For the third, a shell (instead of a shot) is affixed to the rope, having four holes in it to receive fusees, and the body of the shell is filled with the fiercest and most glaring composition, which, when inflamed, displays so splendid an illumination of the rope, that its flight cannot be mistaken.'

Such are the most prominent features in the scheme of Captain Manby for the relief of ships in distress. The number of persons saved by these inventions has been very great. Almost immediately after turning his mind to the subject, Captain Manby had the gratification of rescuing ninety persons from a grave in the deep. The whole expense of his apparatus did not exceed £10. Captain Manby was deemed worthy of a parliamentary reward.

Floats and Buoys.—In addition to such a flat boat as that recommended by Captain Manby, with rods and ropes furnished with hooks for grappling, Humane Societies usually possess floaters, consisting of circular cork buoys, or of short bars of wood, with masses of cork at each end. One of these being thrown out with a rope, a party in danger may grasp the bar, and be readily borne up till pulled ashore. Another provision of late invention consists of hollow girdles of cloth, air and water-proof, which, being sustained by straps from the shoulders, can be filled with air from the mouth, and when the pipe is closed, will sustain the wearer perfectly in water. One of the best and most convenient of these is the safety-cape, which combines an article of dress with its principle of life-preservation. It is the invention of a member of the Skating Club of Edinburgh, and is furnished by the Albion Cloth Company of that city. The cape, which is suited to lie easily round the neck and shoulders, and hang as low as the elbows, is formed of Macintosh cloth, which may be partially inflated with air at pleasure, by means of a small mouth-piece hid from external observation. A tape from the inner part of the back, to be tied round the body, keeps the cape down, in the event of immersion in water. When blown up, the cape swells to about an inch in thickness, which presents nothing unsightly; however, it need not be inflated till the wearer goes into a condition of danger.

HARBOURS—BREAKWATERS—DOCKS.

These are essential adjuncts of navigation—affording shelter and protection to ships during stress of weather, accommodation for loading and unloading, and facilities for repair and equipment. *Harbours* may be classed as natural, artificial, and composite—that is, partly formed by nature, and partly by art. Any creek, sound, or estuary sufficiently deep and land-locked, constitutes a natural harbour for shelter; but for the purposes of commerce, quays, wharfs, and landings must be erected by man. When harbours wholly artificial are to be constructed, surveys and soundings are taken, plans drawn, and various modes of execution adopted. Excavations have sometimes to be made, but more frequently piers and jetties are built forward into deep water, a certain amount of space enclosed, and breakwaters erected for its protection. Occasionally, foundations have to be piled, diving-bells, caissons, and cofferdams employed in submarine building, and all the resources of the civil-engineer and architect called into action. (See 'Practice of Architecture,' No. 28.) Stone piers and quays form the most substantial structures; they consist in general of rough rubble, faced seaward with dressed blocks placed on edge, and built slopingly, so as to present a gradual resistance to the impact of the waves; and finished harbourwards with stone coursings, so as to offer a concave or bevelled wall to the convex sides of the vessels. Wooden piers are constructed of squared beams, mortised and jointed together, and so arranged as to endure the greatest amount of strain and pressure. They are built either upon a stone or pile foundation, present an open framework to the sea, and are finished above with a strong planking. A really good harbour—no matter how formed—should possess sufficient depth of water at all states of the tide, should have a fairway of easy entrance, and be so protected as thoroughly to exclude the influence of the waves and currents.

The prime objection to harbours enclosed by solid walls and breakwaters, is their liability to be obstructed by deposits of sand, shingle, and other marine silt. Rivers and sewers entering the harbour, the drifting action of the tides and waves, all tend to collect débris; and unless these natural forces be made to counteract each other, or extraneous sluicing and dredging operations be resorted to, both fairway and basin of the finest harbours will in time be rendered useless. The contrivance adopted by Smeaton at Ramsgate is efficient, and might be applied with advantage elsewhere. He constructed a dock which was filled at high tide; at low tide the sluice gates were opened, and the rush of water was found to be so great, as to scour away the deposit. The chief objection to this plan is, that the water always taking the same channel, is not so extensive in its operation as to clear away the silt from all parts of the harbour; for instance, at the sides and angles of the quays, where the deposit goes on accumulating till it prevents vessels from being drawn closely up for loading and discharging. In such cases the *dredging machine* is now generally had recourse to. This machine consists of a boat of peculiar construction, provided with a steam-engine, which works machinery so contrived, that an endless chain or series of iron buckets, continually revolving near the stern, scoop up the deposit, and deliver it into barges. The bottoms of these barges are provided with trap-doors or sluices, and when they are taken to sea, the traps are struck out, and the slimy burden dropped into the deep. These dredging machines are very efficient, but are expensive in construction and operation. A more scientific remedy than either of the above has been proposed—namely, to convert the action of the tides and waves into a sluicing power. This is to be effected by leaving arched openings at frequent intervals in the piers and quays, through which the waters would pass with a force sufficient to scour away every vestige of deposit. Whatever may be the result of this proposal, there is no doubt that it is within the scope of hydraulic engineering so to construct piers, breakwaters, and jetties, and so to give them a direction and arrangement, that tidal and other currents shall be made to carry off, rather than lay down, the materials which they hold in suspension.

In addition to the ordinary harbours of commerce, an efficient system of maritime conveyance requires *harbours of refuge*, to which vessels can run for safety in cases of emergency. Britain, as becomes a great maritime country, is about to adopt such a system, and one of large dimensions is already begun at Dover. The chief point to be attended to in the construction of harbours of refuge, is the placing of the fairway or entrance so that vessels may 'make' the passage from almost any point, and without risk of being driven against the extremities of the piers.

Breakwaters are contrivances by which the force of the waves rolling into a harbour or roadstead may be broken, and the water within rendered comparatively smooth and easy. As now constructed, they are formed either of wooden or stone piers projecting from the land into the sea, of isolated mounds thrown across the opening of the roadstead or harbour, or of floating structures of timber. The celebrated breakwater at Plymouth may be given as an example *par excellence*. This erection consists of an immense mole, stretching for a full mile across the middle of the Sound or opening, which forms the entrance to the harbours of Plymouth and Devonport. This Sound has been for many years the principal place of rendezvous for the fleets of the royal navy; but though possessing numerous advantages over every port in the south-west of England, it had one great fault—that of being open to the fury of gales from the south and west, to which this part of the country is much exposed. Some defence from the inroads of these gales had long been a subject of public discussion; and in 1812, the suggestion of Messrs Rennie and Whidbey, that an 'insulated pier should be constructed, extending 1700 yards across the middle of the Sound,' was adopted, and the work commenced. Twenty-five acres of limestone rock, on the east bank of Catwater, were purchased from the Duke of Bedford for its construction; and on the 12th of August, the foundation stone—a huge block of marble raised for the purpose—was laid, or rather thrown into the sea, with great ceremony. In March 1813, the first stone was observed above the surface of low water; and by the end of 1816, the work was considered as half completed, at an expense of £364,000. The blocks, weighing from one to eight tons each, were carried to the spot in vessels constructed for the purpose. In 1822, about two millions of tons of stones had been laid; and the principal object of the breakwater being attained, there was a great reduction in the number of men and vessels employed, and a consequent slowness in bringing the work to a conclusion. In February 1841, a lighthouse was begun at the western extremity, the western entrance to the Sound being the safest, and the only one used by large vessels at night. The height of this tower is about 60 feet, or more than 120 feet from the bottom of the sea. It is wholly built of granite, and is divided into five storeys—respectively serving for oil-room, store-room, dwelling-room, sleeping-room, and one above, over which is placed the lantern. The lighthouse, which may be said to have completed the breakwater, was finished in 1843; the whole structure having required upwards of four millions of tons of rough stones, besides more than eighty thousand tons of cut granite.

What are termed *floating breakwaters* have been proposed at different times; but as yet, we know of no instance of adoption on a large scale. The late Sir J. Bentham drew out a plan of such a breakwater for Plymouth, the distinguishing feature of which was, the construction of prismatic floats of timber, securely moored across the entrance to the Sound. The floating breakwater of Captain Taylor consists of timber caissons or frameworks, fastened together by chains of a peculiar construction; and is recommended by the inventor on grounds of economy, quickness of erection, and, from its open character, preventing the deposition of silt, which a solid erection is likely to assist.

Docks are excavations formed in connection with harbours for the reception of vessels, and are generally lined with stone, and provided with appropriate gates or sluices. They are usually distinguished as 'wet' and 'dry.' Wet docks are used for the purpose of loading and unloading; and as they can be completely isolated from other parts of the harbour, every facility is given for warehousing and for conducting the business of the Excise. The level of the water in the docks corresponds with high water in the harbour or roadstead with which they communicate; consequently, at high water ships can enter and leave them, and if necessary, at low water they can be sluiced out and cleaned. In tidal rivers, it would be impossible to conduct a shipping business to any extent without wet docks; and thus on the Mersey, for example, upwards of a hundred acres of dock, of unparalleled magnificence, have been constructed for the commerce of Liverpool and Birkenhead. Dry docks are intended for the building, repairing, or examination of vessels which are admitted into them at flood-tide, and are so called because they are either left *dry* by the ebbing of the sea, or are rendered so by using gates, and pumping out the water. After the vessel has been repaired, the gates are opened, the tide admitted, and the vessel floated out. What are termed *naval docks* are depôts fitted with all sorts of naval stores, and all the requisite machinery for ship-building. The principal naval docks of Great Britain are Portsmouth, Plymouth, Chatham, Sheerness, Woolwich, and Deptford. It is in these docks, and particularly in the three first, that ships of war are laid up in time of peace. Vessels can also be conveniently laid dry for repairs by Morton's patent slip, which consists of a cradle first floated or slipped under the vessel, and then dragged up an inclined plane by steam power.

MARITIME LAW.

It is a common law of nations that the ocean is a free and universal highway, which no state can appropriate to its own especial use. While this exists as a principle generally recognised by all civilised powers, Great Britain has for a considerable period of time claimed *the dominion of the seas*, as a right acquired by its extensive conquests, and the skill and valour of its seamen. By this claim it is not assumed that Great Britain possesses a legal right of property in the waters of the ocean, or the lands which they may cover: the claim resolves itself into what is termed in law 'a military sovereignty,' which it would be exceedingly difficult to define, and is practically an empty and vainglorious boast. Within the last thirty years, during which a large maritime force has grown up in France, Russia, and the United States of America, the claim of the British to the dominion of the seas has been little heard of, and is perhaps now a dead letter in maritime law, as it is in fact. Each nation retains a judicial control over its vessels and their crews, in whatever part of the ocean they may be: all crimes and misdemeanours committed on board of a ship are punishable by law as soon as the vessel reaches the country to which it belongs. The other points of maritime law are of a civil or commercial nature, and refer to chartering, lading, pilotage, signalling, insurance, quarantine, and the like—subjects of too special and professional a character to be of interest to the general reader.

ARCHITECTURE.

ARCHITECTURE, or the art of planning and raising edifices, appears to have been among the earliest of human inventions. The first habitations of men were such as nature afforded, with but little labour on the part of the occupant, yet sufficient to supply his simple wants—grottos, huts, and tents. In early times, the country of Judea, which is mountainous and rocky, offered cavernous retreats to the inhabitants, who accordingly used them instead of artificial places of shelter. From various passages in Scripture, it appears that these caves were often of great extent, for in the sides of the mountain of Engedi, David and 600 men concealed themselves. In the course of time art was employed to fashion the rude cavernous retreats, and to excavate blocks by which rude buildings were composed in more convenient situations. The progress of architecture, however, from its first dawn, differed in almost every different locality. Whatever rude structure the climate and materials of any country obliged its early inhabitants to adopt for their temporary shelter, the same structure, with all its prominent features, was afterwards kept up by their refined and opulent posterity.

From the cause now mentioned, the Egyptian style of building had its origin in the cavern and mound; the Chinese architecture, with its pavilion roofs and pointed minaret, is moulded from the Tartar tent; the Grecian is derived from the wooden cabin; and the Gothic from the bower of trees. It is evident that necessity as much as choice or chance led to the adoption of the different kinds of edifices. Among a roving and pastoral people, the tent, which could be easily struck and removed, was obviously more suitable than an immovable and laboriously erected structure; it is equally clear that lofty and substantial edifices would be out of place in a country subject to earthquakes, or low buildings in situations liable to periodic inundation. Thus local circumstances everywhere produced local styles of architecture, and these distinctions are now almost as observable as they were thousands of years ago.

After mankind had learned to build houses, they commenced the erection of temples to their gods, and these they made still more splendid than private dwellings. Thus architecture became a fine art, which was first displayed on the temples, afterwards on the habitations of princes and public buildings, and at last became a universal want in society.

Traces of these eras of advancement in the art of erecting buildings are found in various quarters of the globe, especially in eastern countries, where the remains of edifices are discovered of which fable and poetry can alone give any account. The most remarkable of these vestiges of a primitive architecture are certain pieces of masonry found in Greece, Asia Minor, and in the island of Sicily, called the works of the Cyclops, an ancient and fabulous race of giants, mentioned by Homer in his 'Odyssey.' By whom these gigantic walls were actually erected is unknown, though it is most probable that they were raised by the Pelasgians—the predecessors or ancestors of the later Greeks. A gradual progress, indeed, may be traced in them, from the extreme of rudeness, to a degree of symmetry that indicates an approach to the elegance of Grecian architecture. Mr Hamilton divides these so-called Cyclopean structures into four eras:—1. Those such as the walls at Tyrins and Mycenæ, in which the blocks are of various sizes, having smaller stones in their interstices. 2. Those at Julis and Delphi, formed of irregular stones, without courses, their sides fitting to each other. 3. Where the stones are in courses of the same height, but of unequal length, as in Bœotia, Argolis, and Phocis. 4. Where the blocks are of various heights, and always rectangular, as in Attica.

Of the progressive steps from comparative rudeness to elegance of design, history affords no certain account, and we are often left to gather facts from merely casual notices. The most ancient nations known to us, among whom architecture had made some progress, were the Babylonians, whose most celebrated buildings were the temple of Belus, the palace and the hanging gardens of Semiramis; the Assyrians, whose capital, Nineveh, was rich in splendid buildings; the Phœnicians, whose cities, Sidon, Tyre, Aradus, and Sarepta, were adorned with equal magnificence; the Israelites, whose temple was considered as a wonder of architecture; the Syrians; and the Philistines. No architectural monument of these nations has, however, been transmitted to us; but we find subterraneous temples of the Hindoos, hewn out of the solid rock, upon the islands of Elephanta and Salsette, and in the mountains of Eloru. These temples may be reckoned among the most stupendous ever executed by man. The circuit of the excavations is about six miles. The temples are 100 feet high, 145 feet long, and 62 feet wide. They contain thousands of figures, appearing, from the style of their sculpture, to be of ancient Hindoo origin. Everything about them, in fact, indicates the most persevering industry in executing one of the boldest plans. In the chief temple, the vault is supported by several rows of columns, which form three galleries, one above the other. Twenty-four colossal monoliths, representing Indian gods, are placed in separate divisions, the sculpture of which, though on the whole rude, shows in some parts an advanced period of art, and a certain development of taste. In many respects Hindoo architecture bears a striking resemblance to the Egyptian (hereafter described), more especially in the pyramidal character of its masses, in its excavations and cavern temples, as well as those which, though presenting the forms of constructed buildings, are yet hollowed out of the rock. The Egyptian, however, is more simple and severe, and less loaded with incongruous and often grotesque ornament.

Of late years, travellers have made known the remains of an architecture and sculpture not very dissimilar to that of the ancient Hindoos in certain districts of Central America, believed to be the execution of a people anterior to those Mexicans who existed at the period of the invasion of Cortes. Our limited space precludes any detail of these curious structures, which consist of temples, palaces, triumphal and religious monuments—all of which are covered with rude but elaborate sculptures, and mark the existence of a luxurious and wealthy, but semi-barbarous people.*

EGYPTIAN STYLE.

All the architectural remains of ancient times sink into insignificance when compared with those of Egypt. The pyramids, obelisks, temples, palaces, and other structures of this country, are on the grandest scale, and such as could only have been perfected by a people considerably advanced in refinement. The elementary features of Egyptian architecture were chiefly as follow:—1. Their walls were of great thickness, and sloping on the outside. This feature is supposed to have been derived from the mud walls, mounds, and caverns of their ancestors. 2. The roofs and covered ways were flat, or without pediments, and composed of blocks of stone, reaching from one wall or column to another. 3. Their columns were numerous, close, short, and very large, being sometimes ten or twelve feet in diameter. They were generally without bases, and had a great variety of

* Of these new-world antiquities, the reader will find an ample and most interesting account (accompanied by illustrations) in Stephen's 'Yucatan' and 'Central America'—published at New York respectively in 1841 and 1843.

capitals, from a simple square block, ornamented with hieroglyphics or faces, to an elaborate composition of palm-leaves, not unlike the Corinthian capital. 4. They used a sort of concave entablature or cornice, composed of vertical flutings or leaves, and a winged globe in the centre. 5. Pyramids well known for their prodigious size, and obelisks composed of a single stone often exceeding seventy feet in height, are structures peculiarly Egyptian. 6. Statues of enormous size, sphinxes carved in stone, and sculptures in outline of fabulous deities and animals, with innumerable hieroglyphics, are the decorative objects which belong to this style of architecture.

The main character of Egyptian architecture is that of great strength with irregularity of taste. This is observable in the pillars of the temples, the parts on which the greatest share of skill has been lavished. The following are examples:—

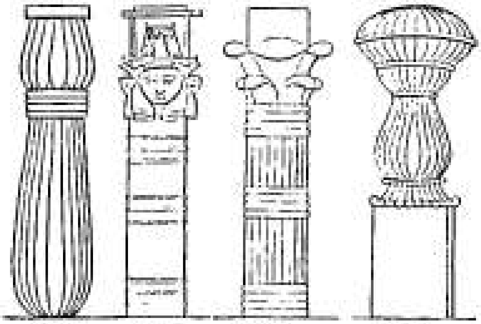


Fig. 1. Fig. 2. Fig. 3. Fig. 4.

In these columns we may notice that sturdiness is the prevailing characteristic. The design has been the support of a great weight, and that without any particular regard to proportion or elegance either as a whole or in parts. When assembled in rows or groups, the columns had an imposing effect, because, from their height and thickness, they filled the eye and induced the idea of placid and easy endurance. 'Compared with Greek architecture, the Egyptian,' says a recent writer, 'is deficient in beauty, grace, variety, and unity. Powerful and imposing as must have been its effect, combined with its sculptural and pictorial decorations, its avenues of sphinxes, obelisks, and gigantic statues, yet is there something so fixed, monotonous, and conventional, as to impress the mind with a conviction that it was unchangeable and incapable of improvement.' In fig. 5, which represents the exterior of a

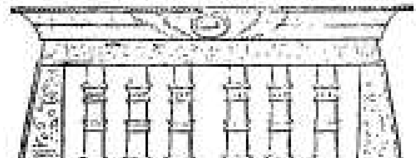

Fig. 5.

temple, this simple and imposing character is conspicuous. But while the Egyptians thus raised temples and monuments which in strength, solidity, and vastness of dimensions far outstrip those of all other nations; yet in street and domestic architecture they were all but utterly deficient. Their streets, if so worthy to be called, were narrow and irregular; the generality of their dwellings were mere huts built of sun-dried bricks formed of mud and chopped straw; and only among the higher classes was there anything like the enjoyment of a house possessing the elements of elegance or comfort. According to the delineations of Mr Wilkinson, their ordinary houses occupied three sides of a courtyard, which was separated from the street by a wall; while large mansions were detached, having entrances in their several sides, with doors very similar to those of their temples.

GRECIAN STYLE.

From Egypt the architectural art spread to Greece, where it passed from the gigantic to the chaste and elegant. The period during which it flourished in the greatest perfection was that of Pericles, about 440 years before Christ, when some of the finest temples at Athens were erected. After this it declined with other arts, and was carried to Rome, where, however, it never attained the same high character. The Grecian temples were built chiefly of marble, and surrounded or decorated with columns, and had a pleasing effect when situated amidst groves of trees or other kinds of natural scenery; and as they were lighted from the roof, the beauty of the structures was not deformed by formal rows of windows, such as are now common in modern edifices. Before describing the various orders of Grecian and Roman architecture, it will be advantageous to explain the terms ordinarily employed in reference to the component parts of buildings:—

Explanation of Terms.

The *front* or façade of a building, made after the ancient models, or any portion of it, may present three parts, occupying different heights (see fig. 7):—The *pedestal* is the lower part, usually supporting a column; the single pedestal is wanting in most antique structures, and its place supplied by a *stylobate;* the stylobate is either a platform with steps, or a continuous pedestal supporting a row of columns. The lower part of a finished pedestal is called the *plinth*, the middle part is the *die*, and the upper part the *cornice* of the pedestal or *surbase*. The *column* is the middle part, situated upon the pedestal or stylobate. It is commonly detached from the wall, but is sometimes buried in for one quarter of its diameter, and is then said to be 'engaged.' *Pilasters* are square or flat columns attached to walls. The lower part of a column, when distinct, is called the *base;* the middle or longest part is the *shaft;* and the upper or ornamented part is the *capital*. The swell of the column is called the *entasis*. The height of columns is measured in diameters of the column itself, taken always at the base. The *entablature* is the horizontal continuous portion which rests upon the top of a row of columns. The lower part of the entablature is called the *architrave* or *epistylium*. The middle part is the *frieze*, which, from its usually containing sculpture, was called *zophorus* by the ancients. The upper or projecting part is the *cornice*. A *pediment* is the triangular face produced by the extremity of a roof. The middle or flat portion enclosed by the cornice of the pediment is called the *tympanum*. Pedestals for statues, erected on the summit and extremities of a pediment, are called *acroteria*. An *attic* is an upper part of a building, terminated at top by a horizontal line instead of a pediment. The different mouldings in architecture are described from their sections, or from the profile which they present when cut across. Of these the *torus* is a convex moulding, the section of which is a semicircle, or nearly so; the *astragal* is like the torus, but smaller; the *ovolo* or *echinus* is convex, but its outline is only the quarter of a circle; the *scotia* is a deep concave moulding; the *cavetto* is also a concave, and occupying but a quarter of a circle; the *cymatium* is an undulated moulding, of which the upper part is concave and the lower convex; the *ogee* or *talon* is an inverted cymatium; the *fillet* is a small square or flat moulding. In architectural measurement, a diameter means the width of a column taken at the base; a module is half a diameter; and a minute the sixtieth part of a diameter.

In representing edifices by drawings, architects make use of the plan, elevation, section, and perspective. The plan is a map or design of a horizontal surface, showing the ichnographic projection or groundwork, with the relative position of walls, columns, doors,

&c. The elevation is the orthographic projection of a front, or vertical surface; this being represented, not as it is actually seen in perspective, but as it would appear if seen from an infinite distance (fig. 7). The section shows the interior of a building, supposing the part in front of an intersecting plane to be removed (fig. 17). The perspective shows the building as it actually appears to the eye, subject to the laws of scenographic perspective (fig. 23). The three former are used by architects for purposes of admeasurement; the latter is used also by painters, and is capable of bringing more than one side into the same view, as the eye actually perceives them. As the most approved features in modern architecture are derived from buildings which are more or less ancient, and as many of these buildings are now in too dilapidated a state to be easily copied, recourse is had to such imitative restorations, in drawings and models, as can be made out from the fragments and ruins which remain. In consequence of the known simplicity and regularity of most antique edifices, the task of restoration is less difficult than might be supposed. The groundwork, which is commonly extant, shows the length and breadth of the building, with the position of its walls, doors, and columns. A single column, whether standing or fallen, and a fragment of the entablature, furnish data from which the remainder of the colonnade and the height of the main body can be made out and restored.

Grecian temples are well known to have been constructed in the form of an oblong square, or parallelogram, having a *colonnade* or row of columns without, and a walled *cell* within. The part of the colonnade which formed the front portion was called the *pronaos*, and that which formed the back part the *posticus*. There were, however, various kinds of temples, the styles of which differed; thus the *prostyle* had a row of columns at one end only; the *amphiprostyle* had a row at each end; the *peripteral* had a row all round, with two inner ones at each end; and the *dipteral* had a double row all round, with two inner ones at each end, making the front three columns deep.

The theatre of the Greeks, which was afterwards copied by the Romans, was built in the form of a horse-shoe, being semicircular on one side and square on the other. The semicircular part, which contained the audience, was filled with concentric seats, ascending from the centre to the outside. In the middle or bottom was a semicircular floor, called the *orchestra*. The opposite or square part contained the actors. Within this was erected, in front of the audience, a wall, ornamented with columns and sculpture, called the *scena*. The stage or floor between this part and the orchestra was called the *proscenium*. Upon this floor was often erected a movable wooden stage, called by the Romans *pulpitum*. The ancient theatre was open to the sky, but a temporary awning was erected to shelter the audience from the sun and rain.

Orders.

Aided, doubtless, by the examples of Egyptian art, the Greeks gradually improved the style of architecture, and originated those distinctions which are now called the 'Orders of Architecture.' By this phrase is understood certain modes of proportioning and decorating the column and its entablature. They were in use during the best days of Greece and Rome for a period of six or seven centuries. They were lost sight of in the dark ages, and again revived by the Italians at the time of the restoration of letters. The Greeks had three orders—called the Doric, Ionic, and Corinthian. These were adopted and modified by the Romans, who added two others—the Tuscan and Composite.

Doric.—This is the earliest of the Greek orders, and we see in it a noble simplicity on which subsequent orders were founded. Compared with the best of the Egyptian models, it exhibits a great advance in purity of taste. From the remains of ancient art, it is found that the Doric varied in its proportions. The column, in its examples at Athens, is about six diameters in height; but in those of older date, as those at Pæstum, it is only four or five. One of the most correct examples is that given in fig. 6. The shaft of the Doric column had no base, ornamental or otherwise, but rose directly from the smooth pavement or stylobate. It had twenty flutings, which were superficial, and separated by angular edges. The perpendicular outline was nearly straight. The Doric capital was plain, being formed of a few annulets or rings, a large echinus, and a flat stone at top called the *abacus*. The architrave was plain; the frieze was intersected by oblong projections called triglyphs, divided into three parts by vertical furrows, and ornamented beneath by *guttæ* or drops. The spaces between the triglyphs were called *metopes*, and commonly contained sculptures. The sculptures, representing Centaurs and Lapithæ, carried by Lord Elgin to London, were metopes of the Parthenon, or temple of Minerva, at Athens. The cornice of the Doric order consisted of a few large mouldings, having on their under side a series of square sloping projections, resembling the ends of rafters, and called *mutules*. These were placed over both triglyphs and metopes, and were ornamented on their under side with circular guttæ. The Romans, in adopting the Doric, greatly spoiled its simplicity and grandeur by unduly lengthening the shaft, and making other tasteless alterations. To have a just idea of the Doric, therefore, we must go back to the pure Grecian era. The finest examples are those of the temple of Theseus, and the Parthenon (fig. 7) at Athens. The Parthenon, which is now a complete ruin, has formed a model in modern

Fig. 6.

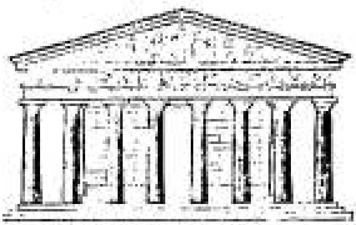

Fig. 7.—Façade of the Parthenon.

architecture. It was built by the architect Ictinus, during the administration of Pericles, and its decorative sculptures are supposed to have been executed under the direction of Phidias. The platform or stylobate consists of three steps, the uppermost of which is 227 feet in length and 101 in breadth. The number of columns is eight in the portico of each front, and seventeen in each flank, besides which there is an inner row of six columns at each end of the cell. The proportional height of the columns is five diameters and thirty-three minutes, and they diminish thirteen minutes in diameter from bottom to top. The sculpture of the frieze represented the combats of the Centaurs and Lapithæ; those of the eastern pediment represented the fabulous birth of Minerva; and those on the western the contests between the goddess and Neptune for the right of presiding over the city. The building was destroyed by the explosion of a bomb-shell during the siege by the Venetians in 1687.

Speaking of these splendid objects of art, a modern authority observes—'Of their effect it is impossible to form a competent idea without seeing one. And whence, it may be asked, does this interest arise? From their simplicity and harmony: simplicity, in the long unbroken lines which bound their forms, and the breadth and boldness of every part—such as the lines of the entablature and stylobate, the breadth of the corona, of the architrave, of the abaci, of the capitals, and of their ovalos also; in the defined form of the columns, and the breadth of the members of the stylobate: harmony, in the evident fitness of every part to all the rest. The entablature, though massive, is fully upborne by the columns, whose spreading abaci receive it, and transmit the weight downwards by the shafts, which rest on a horizontal and spreading basement; the magnitude of every part being determined by the capacity of the sustaining power. Besides graceful and elegant outline, and simple and harmonious forms, these structures possess a bewitching variety of light and shade, arising from the judicious contour and arrangement of mouldings, every one of which is rendered effective by the fluting of the columns, and the peculiar form of the columnar capital, whose broad square abacus projects a deep shadow on the bold ovalo, which mingles it with reflections, and produces on itself almost every variety. The play of light and shade, again, about the insulated columns, is strongly relieved and corrected by the deep shadows on the walls behind them; and in the fronts, where the inner columns appear, the effect is enchanting. For all the highest effects which architecture is capable of producing, a Greek peripteral temple of the Doric order is perhaps unrivalled.'

Ionic.—In this order the shaft begins to lengthen, and to possess a degree of ornament, but still preserving a great degree of simplicity of outline. In the best examples, as represented in fig. 8, the column was eight or nine diameters in height. It had a base often composed of a torus, a scotia, and a second torus, with intervening fillets. This is called the Attic base. Others were used in different parts of Greece. The capital of this order consisted of two parallel double scrolls, called *volutes*, occupying opposite sides, and supporting an abacus, which was nearly square, but moulded at its edges. These volutes have been considered as copied from ringlets of hair, or perhaps from the horns of Jupiter Ammon. When a column made the angle of an edifice, its volutes were placed, not upon opposite, but on contiguous sides, each fronting outwards. In this case the volutes interfered with each other at the corner, and were obliged to assume a diagonal direction. The Ionic entablature consisted of an architrave and frieze, which were continuous or unbroken, and a cornice of various successive mouldings, at the lower part of which was often a row of dentels, or square teeth. The examples at Athens of the Ionic order were the temple of Erectheus, and the temple on the Ilissus, both now destroyed. Modern imitations are common in public edifices.

Fig. 8.

Corinthian.—This was the lightest and most highly decorated of the Grecian orders (fig. 9). The base of the column resembled that of the Ionic, but was more complicated. The shaft was often ten diameters in height, and was fluted like the Ionic. The capital was shaped like an inverted bell, and covered on the outside with two rows of leaves of the plant acanthus, above which were eight pairs of small volutes. Its abacus was moulded and concave on its sides, and truncated at the corners, with a flower on the centre of each side. The entablature of the Corinthian order resembled that of the Ionic, but was more complicated and ornamented, and had, under the cornice, a row of large oblong projections, bearing a leaf or scroll on their under side, and called *modillions.* No vestiges of this order are now found in the remains of Corinth, and the most legitimate example at Athens is in the choragic monument of Lysicrates. The Corinthian order was much employed in the subsequent structures of Rome and its colonies. The finest Roman example of this order is that of three columns in the Campo Vaccino at Rome, which are commonly considered as the remains of the temple of Jupiter Stator. This example has received the commendation of all modern artists, yet has seldom been executed in its original form. This is probably owing to its excessive richness and delicacy, which renders its adoption very expensive; and perhaps the modification of it by Vignola is preferable to the original, possessing a sufficient enrichment without the excessive refinement of the other. In this order the base is one module in height; the shaft sixteen modules twenty minutes; and the capital two modules ten minutes; thus giving ten diameters to the whole column. The architrave and frieze are each one module fifteen minutes in height, and the cornice two modules. The cornice is distinguished by modillions interposing between the bead-mouldings and corona; the latter is formed by a square member surmounted by a cymatium, supported by a small ogee: the former is composed of dentels, supported by a cyma reversa, and covered by the ovalo. When the order is enriched, which is usually the case, these mouldings, excepting the cymatium and square of the corona, are all sculptured: the column is also fluted, and the channels are sometimes filled to about a third of their height with cablings, which are cylindrical pieces let into the channels. When the column is large, and near the eye, these are recommended as strengthening them, and rendering the fillets less liable to fracture; but when they are not approached, it is better to leave the flutes plain. They are sometimes sculptured, but this should only be in highly-enriched orders.

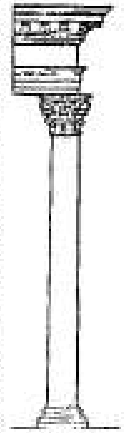

Fig. 9.

The flutes are twenty-four in number, and commonly semicircular in their plan. The Corinthian base is similar to that of the Composite order, excepting that two astragals are employed between the scotiæ instead of one; but the Attic is usually employed for the reasons before assigned.

'The Corinthian order,' says Sir William Chambers, 'is proper for all buildings where elegance, gaiety, and magnificence are required. The ancients employed it in temples dedicated to Venus, to Flora, Proserpine, and the nymphs of fountains, because the flowers, foliage, and volutes with which it is adorned, seemed well adapted to the delicacy and elegance of such deities. Being the most splendid of all the orders, it is extremely proper for the decoration of palaces, public squares, or galleries and arcades surrounding them; and on account of its rich, gay, and graceful appearance, it may with propriety be used in theatres, in ball or banqueting rooms, and in all places consecrated to festive mirth or convivial recreation.' 'The taste and perfect composition of the Corinthian capital,' says a more recent authority, 'sufficiently demonstrate that it could not have been of Egyptian origin, but the legitimate offspring of Grecian genius and Grecian art. Whatever hints the Greeks may have borrowed from Egyptian or Phœnician architecture, as regards the three orders of their decorative features, their superior taste, science, original genius, and fertile imagination so improved and remodelled, as to make them entirely their own. They breathed into them new grace and beauty, new life and vigour; in a word, they stamped them with the highest perfection of which they seem susceptible.'

Caryatides.—The Greeks sometimes departed so far from the strict use of the orders, as to introduce statues in the place of columns, to support the entablature. Statues of slaves, heroes, and gods appear to have been employed occasionally for this purpose. The principal specimen of this kind of architecture which remains is in a portico called Pandroseum, attached to the temple of Erectheus at Athens, in which statues of Carian females, called Caryatides, are substituted for columns. One of these statues has been carried to London.

ROMAN STYLE.

Strictly speaking, Roman architecture possessed little originality; it was founded on copies of the Greek models, and these were modified to suit circumstances and tastes. The number of orders was augmented by the addition of the Tuscan and Composite; the former being the Doric stripped of its distinctive ornaments; the latter, a combination of the Ionic and Corinthian. The distinguishing feature of the Roman style is boldness of execution and elaborate profusion of ornament—as by their adaptation of the principles of the arch, they were enabled to rear structures of greater extent and complexity of design. In the Colosseum, for example, columns and arches are piled upon columns and arches in the interior, and must have struck the beholder with wonder and astonishment; yet in the external plan the building has been pronounced 'a gigantic illustration of architectural blunders.'

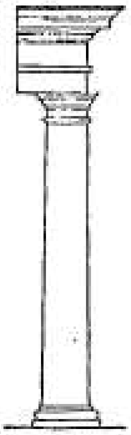

Fig. 10.

Tuscan.—This order is not unlike the Doric, and is chaste and elegant. As represented in fig. 10, the shaft had a simple base, ornamented with one torus, and an astragal below the capital. The proportions were seven diameters in height. Its entablature, somewhat like the Ionic, consisted of plain running surfaces. There is no vestige of this order among ancient ruins, and the modern examples of it are taken from the descriptions of Vitruvius.* The general effect is strength with simplicity, and the order is considered to be well adapted for such buildings as prisons, public halls, and inferior parts of edifices.

Composite.—This order, as the name imports, is a compound of other orders—namely, the Corinthian and Ionic (fig. 11). The proportion and distribution of its parts do not differ much from those of the Roman-Corinthian. It would appear from these efforts, as well as from all subsequent attempts, that the Greeks attained the highest state of improvement of which their style was susceptible, and that, consequently, all schemes to execute something better must prove abortive. The higher class of Roman architects were convinced of this fact, and very judiciously held to the Corinthian order in all their finest buildings, both in Rome and in the provinces. Thus the Corinthian prevails among the celebrated ruins of Palmyra and Balbec, and other great cities founded by Roman provincials.

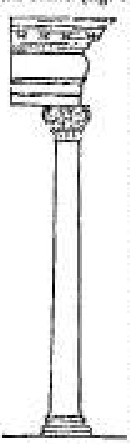

Fig. 11.

The temples of the Romans sometimes resembled those of the Greeks, but often differed from them. The Pantheon, which is the most perfectly preserved temple of the Augustan age, is a circular building, lighted only from an aperture in the dome, and having a Corinthian portico in front. Though stripped of its external ornaments, to furnish materials to decorate the modern cathedral of St Peter's, it is still incomparably the finest. It is a perfect circle, of 180 feet in diameter. 'Its beauty,' says Forsyth, 'consists in its admirable proportions; and its portico, 110 feet in length by 44 in depth, supported by sixteen Corinthian columns of white marble, has a most majestic appearance. Its portal is more than faultless: it is positively the most sublime result that was ever produced by so little architecture.'

The amphitheatre differed from the theatre, in being a completely circular or rather elliptical building, filled on all sides with ascending seats for spectators, and leaving only the central space, called the *arena*, for the combatants and public shows. The Colosseum is a stupendous structure of this kind. It consists of a vast ellipse, the length of the longest diameter being 620, and that of the shortest 513 feet, so that it covers about five and a quarter acres of ground! The longest diameter of the arena has been variously given at from 287 to 300, and the shortest at from 180 to 190 feet; the space between the arena and the outer wall (from 160 to 167 feet) being occupied by the walls, corridors, and seats, that rose, tier above tier, from the wall round the arena nearly to the top of the outer wall. The latter, which is about 179 feet in height, consists of three rows of vaulted arches, rising one above another, exclusive of which it had, when perfect, upper works of wood. This colossal amphitheatre is said to have had seats for 87,000 spectators, and standing room for 20,000 more! Belonging to the same class of buildings were the circuses, of which Rome had at one time no fewer than fifteen. Of these the chief was the Circus Maximus, of which there are now no remains; but of whose dimensions we may judge from the statement of Pliny, that it was capable of accommodating 200,000 spectators.

The aqueducts of Rome, both at home and in her provinces, were erections often of the boldest designs and most stupendous dimensions. They were essentially stone canals for conveying large streams of water for the supply of cities, and had frequently in their course to be supported on massive arcades, to which the largest of our modern railway viaducts are tame in comparison. Many of these arcades consisted of double and triple tiers of arches, and as they stretched their light and lofty structures across valleys of great width, must have had a sublime and imposing effect. For details as to their history and dimensions, the reader is referred to No. 30, in which he will find an account both of the ancient and modern methods of conducting supplies of water.

The triumphal arches were commonly solid oblong structures, ornamented with sculptures, and open with lofty arches for passengers below. The edifice of this kind most entire in the present day is the triumphal arch of Constantine at Rome, represented in fig. 12. This structure is ornamental, and far from inelegant, but it contains much that is tasteless, inasmuch as being without meaning; and there is also an undue overloading of embellishment, or at least frittering away in details. Carrying the eye up the columns, and dissecting their individual bearings,

Fig. 12.

we perceive that each may be resolved into the shafting represented on a larger scale in fig. 13, which is evidently anomalous in design, and inconsistent with the dignified simplicity of the pure Grecian models. The arch of Constantine has been copied at Paris, in the structure erected by Napoleon in front of the Tuileries.

The *basilica* of the Romans was a hall of justice, used also as an Exchange or place of meeting for merchants. It was lined on the inside with colonnades

* Vitruvius was a celebrated writer on architecture, who is supposed to have flourished in the time of Julius Cæsar and Augustus. His treatise on architecture was first printed at Venice in 1497. An English translation appeared in 1771. A new translation by Wilkins was published in 1812.

of two storeys, or with two tiers of columns, one over the other. The earliest Christian churches at Rome were sometimes called *basilicæ*, from their possessing an internal colonnade. The monumental pillars were towers in the shape of a column on a pedestal, bearing a statue on the summit, which was approached by a spiral staircase within. Sometimes, however, the column was solid. The *thermæ*, or baths, were vast structures, in which multitudes of people could bathe at once. As they now exist, they are an assemblage of naked, half-dilapidated brick walls, which surprise by their huge size and the extent of ground they cover—those of Caracalla, for example, occupying not less than twenty-eight acres! In the palmy days of Rome, these were fitted not only as hot and cold-water baths, but as gymnasia, reading and lecture rooms, gardens, theatres, and the like—being, as a whole, the most gigantic places of recreation ever built or known in any age or in any country.

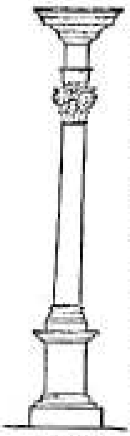

Fig. 13.

SAXON-NORMAN STYLE.

There are very few specimens of the Saxon style now in existence. It is distinguished by rounded arches over doors and windows, or in the entablature of turrets and walls. Sometimes the arch was composed of semicircles of different widths, swelling from a small to a larger compass, and thus affording a convenient entrance to porches in churches. An example is presented in fig. 14.

Fig. 14.

This style commenced at the establishment of Christianity among the Saxons in the sixth century, and takes its name from its having prevailed during the reigns of the Saxon and Norman kings in England. It continued to be used in England till about the year 1135, in the reign of King Stephen.

All ancient structures having semicircular arches belong to what is called the Anglo-Gothic or Norman-Gothic—a style the leading features of which are massive pillars supporting these half-circle arches, and arched doors and windows. The best specimens of this style are impressive, in spite of its inherent clumsiness; as in the Temple Church, London, and the chapel of the Tower of London. The peculiarities of the style may be met with in many of the English cathedrals—as, for instance, in those of Norwich, Canterbury, Gloucester, Worcester, &c.; and exemplifications of its external characteristics may also be seen in some of those edifices, and in the White Tower, Tower of London.

GOTHIC OR POINTED STYLE.

The term Gothic is a modern error, which, being now impossible to correct, is suffered to remain as the generally distinguishing appellation of the kind of architecture possessing pointed arches. This style, according to some, originated in Germany about the middle of the thirteenth century; according to others, it was introduced by the Crusaders from the East, where it is said to have been known long before that period. Be this as it may, for three centuries after its introduction it was zealously pursued as the leading fashion for ecclesiastical structures all over Europe. Executed by a class of skilled artisans, who wandered from country to country,* the finest specimens of the pointed style are the cathedrals of Strasburg, Cologne, and Antwerp, and the splendid abbeys of Melrose and Westminster (fig. 15).

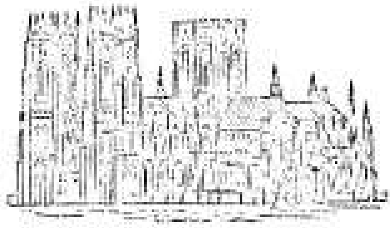

Fig. 15.

In this fanciful and picturesque style of architecture, the slender columns, always united in groups, rise to a lofty height, resembling the giants of the grove, in whose dark shade the ancient Teuton used to build his altar. 'No attentive observer,' says Bishop Warburton, 'ever viewed a regular avenue of well-grown trees intermixing their branches overhead, but it presently put him in mind of the long vista through the Gothic cathedral—or ever entered one of the larger or more elegant edifices of the kind, but it presented to his imagination an avenue of trees; and *this alone is what can truly be called the Gothic style of building.* Under this idea of so extraordinary a species of architecture, all the irregular transgressions against the art, all the monstrous offences against nature, disappear; everything has its reason; everything is in order; and a harmonious whole arises from the studious application of the means and proportions to the end. Nor could the arches be otherwise than pointed, when the workmen were to imitate the curve which branches of two opposite trees make by their insertion with one another; nor could the columns be otherwise than split into distinct shafts, when they were to represent the stems of clumps of trees growing together. On the same principles they formed the spreading ramifications of the stonework of the windows, and the stained glass in the interstices—the one to represent the branches, the other the leaves of an opening grove; and both concurred to preserve that gloomy light which inspires religious reverence and dread.' Some are even of opinion that the stained glass windows and oriels were constructed on purpose to imitate the harmonious and chastened gleams of sunshine passing through the branches and openings of the richly-variegated foliage. The decoration of the ancient Christian churches is therefore by no means an accidental ornament. They speak a figurative religious language; and at the tabernacle or ciborium, over the altar, where the pyx is kept, the whole temple is presented in miniature to the view of the beholder. In these edifices, every one must admire the accurate proportions, the bold yet regular construction, the unwearied industry, the grandeur of the bold masses on the exterior, and the severe dignity in the interior.

In England, the transition from the Saxon to the

* We here allude to the order or craft of Free-masons, the origin of whose associations may be dated from the ninth or tenth century, and who attained their greatest numerical strength and importance at the introduction of the Gothic or pointed style of architecture. Afterwards the order became a speculative society, unconnected with the practice of architecture, and finally has sunk before the spread of universal intelligence, and a common philanthropy which recognises all men as brothers.

pointed style of arch is observed on various old buildings. The accidental intersection of rounded Saxon arches with each other produces sharp points at the intersections, and this is believed by some to have been the origin of the pointed forms. The crossings of the boughs of trees in an avenue also afford a familiar illustration of the same fact. In the Temple Church the two arches may be found united, and other specimens may be seen in the church of St Cross near Winchester; and Fountains Abbey, Rivaulx Abbey, and Roche Abbey, in Yorkshire.

When the circular arch totally disappeared in 1220, the early English style commenced. The windows of this style were at first very narrow in comparison with their height; they were called lancet-shaped, and were considered very elegant: two or three were frequently seen together, connected by dripstones. In a short time, however, the windows became wider, and divisions and ornaments were introduced. Sometimes the same window was divided into several lights, and frequently finished at the top by a light in the form of a lozenge, circle, trefoil, or other ornament. A specimen of this kind may be seen in the beautiful church of St Saviour's, Southwark, which has lately been thrown open to view by the improvements connected with the erection of the New London Bridge; and another, and a very beautiful

Fig. 16.

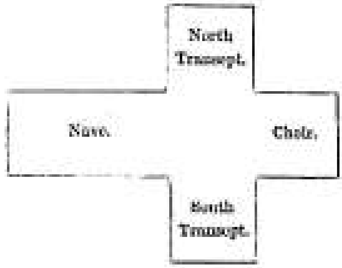
example, in the 'Lady Chapel,' near London Bridge, on the Surrey side of the Thames. A specimen of the pointed or Gothic doorway is offered in fig. 16.

About the year 1300, the architecture became more ornamental, and from this circumstance received the name of the decorated English style, which is considered the most beautiful for ecclesiastical buildings. The windows of this style are very easily distinguished: they are large and wide, and are divided into several lights by mullions, which are upright or perpendicular narrow columns, branching out at the top into tracery of various forms, such as trefoils, circles, and other figures. York Cathedral affords a fine specimen of this sort of architecture, and there is a beautiful window of the same style in the south transept of Chichester Cathedral. The west front of that of Exeter is another specimen, and the doorway of Lincoln Cathedral is in the same style.

The transition from the decorated to the florid or perpendicular style was very gradual. Ornament after ornament was added, till simplicity disappeared beneath the extravagant additions; and about the year 1380, the architecture became so overloaded and profuse, that it obtained the title of florid, which by some persons is called the perpendicular, because the lines of division run in upright or perpendicular lines from top to bottom, which is not the case in any other style. King's College Chapel, Cambridge, begun in the reign of Henry VI., though not finished till some time after; Gloucester Cathedral; Henry VII.'s Chapel at Westminster; St George's Chapel at Windsor; Wrexham Church, Denbighshire; and the chapel on the bridge at Wakefield, Yorkshire—are all of this character. Many small country churches are built in this style; and their size not admitting of much ornament, they are distinguished from structures of a later date by mouldings running round their arches, and generally by a square head over the obtuse-pointed arch of the door. A peculiar ornament of this style is a flower of four leaves, called, from the family reigning at that period, the Tudor flower.

Definitions of Parts.

Gothic architecture being for the most part displayed in ecclesiastical edifices, it may be of service to explain the usual plan and construction of these buildings. A church or cathedral is commonly built in the form of a cross, having a tower, lantern, or spire, erected over the place of intersection. The part of the cross situated towards the west is called the *nave*. The opposite or eastern part is called the *choir*, and within this is the *chancel*. The transverse portion, forming the arms of the cross, is called the *transept*, one limb being called the northern, and the other the southern transept:—



Generally, the nave is larger than the choir. If the nave, choir, and transepts be all of the same dimensions, the form is that of a Greek cross. When the nave is longer than the other parts, forming a cross of an ordinary shape, the edifice is said to be in the form of a Latin cross. The different open parts usually receive the name of *aisles* or *aisles*, from a word signifying a wing: the nave or largest open space is called the main aisle. Originally, the floors of all such edifices were unencumbered with fixed pews or seats, and as the floors were usually of mosaic or tesselated pavement (see No. 21, p. 327), the effect was exceedingly imposing.

The roofing of Gothic churches is of stone, in the form of *groins*, in which the arches are poised with intersecting points, and the whole skilfully adjusted so as to bear on the side rows of pillars (fig. 17). Any high building erected above the roof is called a *steeple*; if square topped, it is a *tower*; if long and acute, a *spire*; and if short and light, a *lantern*. Towers of great height in proportion to their diameter are called *turrets*.

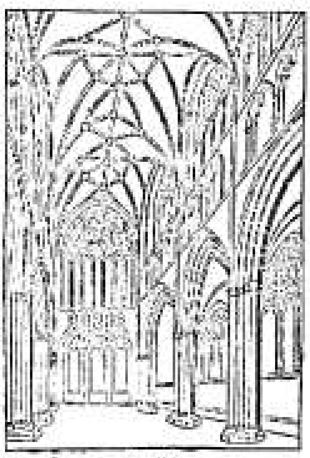


Fig. 17.

The walls of Gothic churches, on which the outer strain of the roof arches ultimately rests, require to be of great strength; and the imparting this necessary degree of resistance without clumsiness is the glory of this style of architecture. The plan adopted is to erect exterior *buttresses* (fig. 18). These rise by gradations from a broad basis to narrow-pointed *pinnacles*, and placed opposite the points of pressure, secure, without the slightest appearance of clumsiness, the general stability of the building. Slanting braces, which spring from the buttresses to the upper part of the roof, are called *flying* buttresses; such, however, are not always required in those modern edifices in which the roof is of wood and lead.

Fig. 18.

The summit or upper edge of a wall, if straight, is called a *parapet*; if indented, a *battlement*. Gothic windows were commonly crowned with an acute arch; they were long and narrow, or if wide, were divided into perpendicular lights by *mullions*. The lateral spaces on the upper and outer side of the arch are called *spandrils*; and the ornaments in the top, collectively taken, are the *tracery*. An *oriel*, or *bay window*, is a window which projects from the general surface of the wall; a *wheel*, or *rose window*, is large and circular; a *corbel* is a bracket or short projection from a wall, serving to sustain a statue, or the springing of an arch; the Gothic term *gable* indicates the erect end of a roof, and answers to the Grecian pediment, but is generally more acute.

The polished tastes of the architects employed in constructing Gothic edifices, led to numerous devices in the form of the pillars. Sometimes the column was single, round, and massive; at other times it was composed of seemingly a cluster of smaller pillars, and this had always the lightest effect; but occasionally the column was given the appearance of several shafts twisted, or of a single shaft with a festoon of flowers twined spirally around it. In the chapel at Roslin there are some highly ornamented pillars of this kind.

The Gothic style of building is more imposing, and more difficult to execute than the Grecian. This is because the weight of its vaults and roofs is upheld at a great height by supporters acting at single points, and apparently but barely sufficient to effect their object. Great mechanical skill is necessary in balancing and sustaining the pressures; and architects at the present day, hampered by principles of economy, find it difficult to accomplish what was achieved by the builders of the middle ages.

ITALIAN STYLE.

After the dismemberment of the Roman Empire, the arts degenerated so far that a custom became prevalent of erecting new buildings with the fragments of old ones, which were dilapidated and torn down for the purpose. This gave rise to an irregular style of building, which continued to be imitated, especially in Italy, during the dark ages. It consisted of Grecian and Roman details, combined under new forms, and piled up into structures wholly unlike the antique originals. Hence the names Græco-Gothic and Romanesque architecture have been given to it.

After this came the *Italian style*, which was professedly a revival of the classic styles of Greece and Rome, but adapted to new manners and wants—a kind of transition from ancient to modern times. Its great master was Andrea Palladio, a Venetian (born 1518—died 1580). This highly accomplished man expelled much of the Græco-Gothic taste, and established in the sixteenth century what may be called a new era in architecture. The majestic simplicity of the ancient orders was always present to the mind of Palladio, and he has left behind him many beautiful buildings which attest the purity of his taste. The writer in the Encyclopædia Britannica, already referred to, alludes to some peculiarities of the Italian style:—'Prostyles being almost unknown in Italian architecture, antæ are not often required. Pilasters, however, are very common—so common, indeed, that they may be called pro-columns, as they are often used as an apology for applying an entablature. They are described as differing from columns in their plan only, the latter being round, and the former square; for they are composed with bases and capitals; they are made to support entablatures according to the order to which they belong, and are fluted and diminished with or without entasis, just as columns of the same style would be. When they are fluted, the flutes are limited to seven in number on the face, which, it is said, makes them nearly correspond with the flutes of columns; and their projection must be one-eighth of their diameter or width when the returns are not fluted; but if they are, a fillet must come against the wall. Pedestals are not considered by the Italo-Vitruvian school as belonging to the orders, but they may be employed with them all, and have bases and surbases or cornices to correspond with the order with which they may be associated. Following Vitruvius, the Italian school makes the central intercolumniation of a portico wider than any of the others. Arched openings, in arcades or otherwise, are generally about twice their width in height; if, however, they are arranged with a columnar ordinance, having columns against the piers, they are made to partake of the order to which the columns belong, being lower in proportion to their width with the Tuscan than with the Doric, and so on; and the piers are allowed to vary in the same manner, from two-fifths to one-half of the opening. With columnar arrangements, moulded imposts and archivolts are used; the former being made rather more than a semi-diameter of the engaged columns in height, and the latter exactly that proportion (fig. 19).

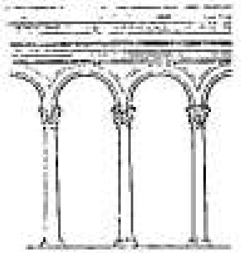

Fig. 19.

Variously moulded keystones are also used, projecting so that they give an appearance of support to the superimposed entablature. Smaller columns with their entablature are sometimes made to do the duty of imposts, and sometimes single columns are similarly applied; at others, columns in couples are allowed to stand for piers to carry arches. In plain arcades, the masonry is generally rusticated, without any other projection than a plain blocking course for an impost, and a blocking course or cornice crowning the ordinance. Niches and other recesses are at times introduced in the plain piers, which are in that case considerably wider than usual, or in the spandrels over wide piers. Very considerable variety is allowed in these combinations, which will be best understood by reference to the examples. Doors and windows, whether arched or square, follow nearly the same proportions, being made in rustic storeys generally rather less than twice their width in height, and in others either exactly of that proportion, or an eighth or a tenth more. If they have columned or pilastered frontispieces, these are sometimes pedimented; and, except in rustic storeys, whether with or without columns, a plain or moulded lining, called an architrave, is applied to the head and sides of a door or window. This architrave is made from one-sixth to one-eighth the width of the opening it bounds, and it rests on a blocking course or other sill, as the case may be.

The rule for the form, composition, and application of pediments in Italian architecture, if it may be gathered from the practice of the school, appears to be to set good taste at defiance in them all. We find pediments of every shape composed of cornices, busts, scrolls, festoons, and what not, and applied in every situation, and even one with another, to the number of three or four, and each of these of different form and various composition. The proportion laid down for the height of a pediment is from one-fourth to one-fifth the length of its base, or the cornice on which it is to rest. Balustrades are used in various situations, but their most common application is in attics, or as parapets, on the summits of buildings, before windows, in otherwise close continued stereobates, to flank flights of steps, to front terraces, or flank bridges. Their shapes and proportions are even more diversified than their application; that of most frequent use is shaped like an Italian Doric column, compressed to a dwarfish stature, and consequently swollen in the shaft to an inordinate bulk in the lower part, and having its capital, to the hypotrachelium, reversed to form a base to receive its grotesque form. The base and coping cornice of a balustrade are those of an ordinary attic, or of a pedestal whose dado may be pierced into balusters. The general external proportions of an edifice, when they are not determined by single columnar ordinances, appear to be unsettled.

There is considerable variety and beauty in the foliate and other enrichments of an architectural character in many structures in Italy, but very little ornament enters into the columnar composition of Italian architecture. Friezes, instead of being sculptured, are swollen; the shafts of columns are very seldom fluted, and their capitals are generally poor in the extreme; mouldings are indeed sometimes carved, but not often; rustic masonry, ill-formed festoons, and gouty balustrades, for the most part supply the place of chaste and classic ornaments.

SARACENIC, MOORISH, AND BYZANTINE STYLES.

The Arabs, or Saracens, as they are more usually called, and the Moors, introduced into Spain certain forms of architecture which differed considerably from the Grecian in appearance, though founded on its remains in Asia and Africa. The chief peculiarity of this architecture was the form of the arch: the Saracens are understood to have made it of greater depth than width, thus constituting more than half a circle, and therefore unphilosophical and comparatively insecure (fig. 20); while the Moorish style was principally distinguished by arches in the form of a horse-shoe, or a crescent. The Saracens and Moors, however, were so much one people that the works of each are not easily pointed out in the present day; both styles were highly ornamented with flowery tracery, called *arabesque*, and the pillars supporting the arches were generally slender and elegant. The crescent-like or bulging dome of the Oriental mosque was likewise introduced by the Moorish architects into Europe. It is common, for example, in the church spires of the Netherlands, having been brought thither by the Spaniards when in possession of the country.

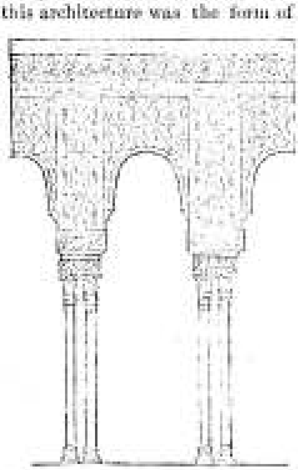

Fig. 20.

We associate with these styles another, which arose at Constantinople, called the Byzantine, likewise formed on the remains of Grecian art, and partaking of a slightly Eastern character. It became known in western Europe along with the Lombard, another degenerate Grecian style, about the ninth and tenth centuries. The two united received the name of the Lombard-Byzantine, and were employed upon the cathedrals of Worms and Mayence, and several other ecclesiastical structures in Germany. This style is distinguished by small arches resting on connecting central pillars, like the Saracenic, and sometimes there are rows of such arches one above another. Either pure or mixed, the Byzantine style remained in vogue till it was superseded by the Gothic, about the middle of the thirteenth century (p. 450).

CHINESE STYLE.

Of the date and origin of Chinese architecture we know nothing, except that it is evidently founded on the type of the Oriental tent—the primitive habitation of their Tartar ancestors of nomadic origin. So close, indeed, is the resemblance to the tent, that, from the accounts of travellers, a Chinese city looks like a large permanent encampment. Chinese roofs are concave on the upper side, as if made of canvas instead of wood. A Chinese portico is not unlike the awnings spread over shop windows in summer time. The verandah, sometimes copied in dwelling-houses, is a structure of this sort. The Chinese towers and pagodas have concave roofs, like awnings, projecting over their several storeys. A representation of this barbaric style of erection is given in fig. 21. Such structures are built with wood or brick; stone is seldom employed. Composed chiefly of timber, the houses of the Chinese are light and gay in appearance—the roofs, porticos, and verandas being generally variegated with different colours and varnishes. 'The law,' says Mr Cleghorn, 'has from time immemorial laid down strict regulations, rigidly enforced, for the plans, dimensions, and materials of the houses of all ranks and casts—from the palaces of the emperor and the princes of the first, second, and third degree, to the habitations of the nobles of the imperial family, the grades of the empire, the citizens, and all classes.' Hence the extraordinary uniformity remarked by all travellers.

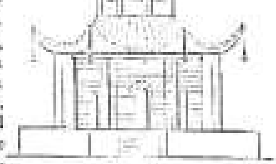

Fig. 21.

Without the gates of several cities in China lofty towers or pagodas are erected, which, according to Davis, are of a religious nature, and, like the steeples of churches, were at first attached to temples. The most remarkable of these—and which may be taken as an illustration of the whole—is that of Nankin, called the Porcelain Tower (fig. 22), from the roofs of its different storeys or stages being covered with porcelain tiles beautifully painted. It is of an octangular figure, contains nine storeys, and is about 200 feet high, raised on a very solid basis of brickwork. The wall at the bottom is at least 12 feet thick; and the building gradually tapers to the top, which forms a sort of spire. It is surrounded by a balustrade of rough marble, and has an ascent of twelve steps to the first floor, from whence one may ascend to the

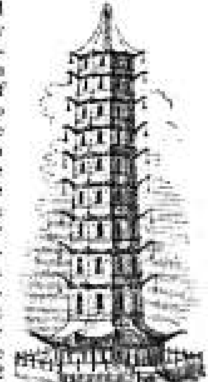

Fig. 22.

ninth storey by very narrow and incommodious stairs. Between every storey there is a kind of pent-house on the outside of the tower, from the eaves of which are suspended little brass bells, diminishing in size as they approach the top, and set in motion by the wind. Each storey is formed of strong beams of timber well boarded; the ceilings of the rooms are adorned with paintings; and the light is admitted through lattices of wire. There are likewise niches in the walls filled with idols; and the variety of ornaments that embellish the whole render it one of the most unique, as it is undoubtedly one of the most beautiful structures in China.

TUDOR—ELIZABETHAN—MODERN GOTHIC.

Throughout England may be seen many aged castles, some still in a state of good preservation, but the greater number in ruins, and occupying, with their picturesque remains, the summit of a rising ground or rocky precipice. These castles are of a style which prevailed during the feudal ages in Europe, and was brought to this country by the Normans, who erected them as fastnesses into which they might retire and oppress the country at pleasure. The same kind of buildings are also frequent in Scotland, where the barons ruled with the same feudal power as in the southern parts of the island.

The feudal castles in England, like those on the Rhine, consisted for the most part of a single strong tower or keep, the walls of which were from six to ten feet thick, and the windows only holes of one or two feet square, placed at irregular intervals. The several floors were built on arches, and the roof was flat or battlemented, with notches in the parapet, from which the inhabitants or retainers of the chieftain might defend themselves with instruments of war. The accommodations for living were generally mean, and what would now be called uncomfortable. Around, or in front of the main tower, there was usually a courtyard, protected by a high wall, and the arched entrance was carefully secured by a falling gate or portcullis. Outside, there was in many cases a regular wet ditch or fosse. Castles of greater magnitude consisted of two or more towers and inner buildings, including a chapel and offices for domestics, and horses and other animals. Some of them were on a great scale, and possessed considerable grandeur of design.

As society advanced, and civil tranquillity was established, these military strengths gradually assumed a character of greater elegance, and less the appearance of defence. The wet ditch disappeared, and was superseded by a lawn or shrubbery. Instead of the drawbridge and portcullis, there was a regular approach and gate of ordinary construction. The windows became larger, and were fitted with glass frames, and stone was abandoned for the greater comfort of wooden floors. Instead also of a bare region around, in which no foe might lurk, gardens were established, and a long avenue of trees led to the front of the modernised mansion. In some instances, the pepper-box turrets at the upper corners of the buildings remained. Of the class of structures that sprung up in this period of transition, which we may refer in England to the fifteenth and sixteenth, and in Scotland to the seventeenth centuries, there are several highly interesting remains. These edifices of the nobility and gentry were no longer called castles: they took the name of *halls*; and such had attained so great a pitch of magnificence in the reigns of Henry VIII. and Elizabeth, as to have subsequently given a name to a new style—namely, the *Elizabethan*. Latterly, and with no very distinct reference to any particular period, this remarkable fashion of building has been pretty generally called the *old English* style of architecture. One of the best existing specimens of this species of architecture is Haddon Hall in Derbyshire, the property of the Duke of Rutland.

A writer in the Quarterly Review, speaking of this species of architecture, takes occasion to notice that 'in a few of the houses built during the reign of Henry VIII., we may observe some slight traces of the Italian architecture, which in the next reign was more liberally introduced, and mixed up with the original Tudor, or early English, into an irregular, certainly, but in most instances an exceedingly rich and effective composition.' This was traceable to the influence of the Italian architects in England, whose 'fame was a subject of deep interest in this country, where the rage for building was no less strong and general than in Italy. In the brilliant reign of Elizabeth, the English nobles and princely proprietors vied more than ever with each other in the magnificence of their mansions. It might have been supposed that the noble Tudor houses, with their panelled walls, buttresses, and battlements, traceried windows, sculptured dripstones, florid pinnacles, and embossed chimney-shafts, were sufficiently rich and gorgeous to satisfy the prevailing taste for splendour; but in their anxiety to strike and surprise the admiration of their countrymen, many deserted the native styles, and sought for designs, and even artists, from abroad. Italian architecture became by degrees the mode; and even where the indigenous style was adhered to in the general design, many of the enrichments and ornamental features were borrowed from the Italian. First of all, the porch or gateway, as the most conspicuous points on which to exhibit these exotic novelties, were decorated on each side of the entrance, and perhaps a second or third storey above, with pilasters belonging to the different Greek orders; the doorway itself exchanged the low-pointed or Tudor for the circular arch; the deep, elegant, and sweeping Gothic mouldings for the Vitruvian architecture, cut across by the awkward projecting imposts. Next was introduced the cupola, whose invention in Italy had made so much noise, that it appears our country squires were anxious to have miniature specimens of it at home. It was applied as a covering to the high turrets, round, square, or polygonal, which flanked the entrance or terminated the angles of the building, and surmounted with gilded vanes, certainly produced a rich and imposing effect. Then followed the removal of the panelled battlements, and the substitution of a parapet, carved into fantastic notches or scrolls, or perforated with oval openings, and ornamented with obelisks, balls, busts, statues, and other singular decorations. These ran up the gables, which were often twisted into strange shapes, and sometimes wholly replaced by the level balustrade; and thus the most characteristic features of the old style—its numerous steep gables and spiry pinnacles—were succeeded by the uniform horizontal straight lines of the new. At length the whole building was surrounded by columns or pilasters, rising tier above tier, to the exhaustion sometimes of the five orders; open arcades took the place of the entrance porch; and nothing remained of the Tudor style but the mullioned window, which, however, was of itself sufficient to give a peculiarly picturesque and old-fashioned aspect to the whole building.'

'It has always appeared to us,' continues our authority, 'that this architecture of the Elizabethan age constitutes a style of its own—a compound of two extremely different modes, the Italian and the Tudor Gothic. It is evident that the Italian design was always greatly altered to suit the climate and the taste of England. Indeed, were we not afraid that the comparison might be considered profane, we should say there is something in the rich irregularity of the Elizabethan architecture, its imposing dignity, gorgeous magnificence, and quaint and occasionally fantastic decoration, reminding us of the glorious visions that flitted across the imagination of Shakspeare, the immortal bard of the same age. He, like the architects of his day, borrowed largely from the foreigner, but made his importations appear exclusively his own. The architectural garden, which always accompanied this style of mansion, is not the least pleasing part of it. We delight in its wide and level terraces, decorated with rich stone balustrades, and these again with vases and statues, and connected by broad flights of stone steps—its clipped evergreen hedges—its embowered alleys—its formal yet intricate parterres, full of curious knots of flowers—its lively and musical fountains—its steep slopes of velvet turf—its trim bowling-green—and the labyrinth and wildness which form its appropriate termination, and connect it with the ruder scenery without. This kind of ornamental garden came from Italy, with the change we have been discussing in domestic architecture.

The quadrangular embattled mansion of the last Henries affords scope for the display of much grandeur and magnificence, and adapts itself more conveniently to the plan of a modern house. The carved oriel, and deep many-lighted bay window, often projecting in a multitude of capricious angles and curves, besides the regular octagon, the panelled angled turrets, with richly-embossed finials, and the wreathed chimney-shafts, are characteristic beauties of this class of building. The gabled manor-house, together with these ornamental features, admits at the same time of a much greater irregularity of form and outline, so as to accommodate itself to every variety of disposition, and to buildings of every size, from the baronial residence to the parsonage and grange. All the forms which particularly mark the Elizabethan style, may be wrought in the cheapest materials with comparatively little labour; and a small portion of ornamental work, tastefully disposed, is capable of producing very considerable effect. Lastly, the Elizabethan house is distinguished by the number and size of its rectangular and many-mullioned windows, which gave a peculiar lightness and elegance to its several parts. The roof-line may be either horizontal or broken with gables, turrets, and cupolas. In either case it is enriched with perforated parapets, balustrades, or other architectural devices, while similar embellishments ornament the entrance, and the terraces which connect the building with the garden.'

Fortunately, this light and elegant style of domestic architecture is gradually superseding the bald Græco-Italian style of the eighteenth century. A better taste is evidently extending itself, particularly as regards the erection of villas, cottages, hunting-seats, gate-lodges, and other rural residences. To these the old English style is peculiarly well adapted. The leading feature of this style applied to cottages is the dispensing with unbroken lines. The house is composed of different parts, projecting at right angles from each other, with also a projecting porch, and the outshot octagonal windows commanding views in three different directions. It also sometimes exhibits an open rustic arcade along a portion of the front or back, which will be found useful and agreeable both in sultry and cold broken weather. It is not uncommon for a

Fig. 23.

cottage of this kind to have on the ground-floor two parlours, communicating by folding-doors, 14 feet by 12 each, and 10 feet in height; a kitchen and scullery, with a porch 7 feet by 5 feet 6 inches, opening to a staircase 17 feet 6 inches by 8 feet, with three rooms above. The gables are enriched with pendants and ornamental dressings to the doorways and windows, and handsome octagonal chimney-stacks. We offer a representation of a cottage in this elegant style in fig. 23.

In erecting ornamental cottages of this kind, there ought to be a lightness in the pointing of the upper projecting windows, with a sharp angularity in the roof; and the chimney-stacks ought to stand well out, in order to create effect in different points of view. When the little gardens adjacent are well trimmed and blooming, and the woodbine and ivy trained round the porch or mullioned window, the prospect exhibited is such as it would be impossible to surpass in rural elegance. We have not here room to enlarge on this interesting topic, and must conclude by recommending that, in applying cottage architecture to a residence, much care ought to be taken to preserve the simplicity of the component parts, or the idea of the cottage will be lost in the magnitude of the dwelling. Loudon's Encyclopædia of Cottage and Villa Architecture should certainly be consulted by gentlemen and others in the country, before fixing on the style or mode of construction of their residences—that is to say, when skilful architects are not employed.

Improvement is also shown in the style of church-building, particularly in the northern part of the United Kingdom, where there was most room for it. Since the Reformation, churches have been built in Scotland with very little regard to elegance; and in the last century particularly, there flourished a style, the products of which are scarcely to be distinguished from barns and granaries. Within the last twenty years, very few ecclesiastical structures have been erected without an effort being made to unite some degree of taste with a regard for conveniency. A modest Gothic style has become very prevalent, which, though not always free of faults, is a surprising advance upon the homely edifices of the last century.

Fig. 24.

In fig. 24, a representation is given of one of these improved ecclesiastical structures, suitable for a rural scene, or any other situation in which economy of means requires to be consulted. In general, these handsome Gothic churches are calculated to accommodate from a thousand to twelve or fourteen hundred sitters, are neatly fitted up with pews and galleries, and cost from three to four thousand pounds.

MODERN BRITISH ARCHITECTURE.

During the sixteenth century, as has been mentioned, an extraordinary effort was made in Italy to restore the purity of Grecian architecture; and in this attempt Palladio was followed by the not less eminent Michael Angelo Buonarotti, who, at an advanced age, in 1546, undertook the continuation of the building of St Peter's at Rome, a work on which the greatest splendours of the Italian style are lavished. Into England, this revived taste for the Grecian was introduced at the beginning of the seventeenth century by Inigo Jones, to whose contemptuous observations on the German or pointed style the term *Gothic* has been traced; and after his decease, the Grecian, or more properly the Italianised Grecian, was perpetuated on a scale still more extensive by Sir Christopher Wren. The edifices erected by this great master are characterised by the finest taste, and his spires in particular are models of elegance. The greatest work of Wren was St Paul's cathedral in London, in which the Italian is seen in all its glory.

The eighteenth century was an era of decline in architectural taste. Every other style merged in that of a spiritless and often mean Græco-Italian, out of which the architects of the nineteenth century have apparently had a difficulty to emerge. Latterly, there has been a revival in England of a purer kind of Grecian, and also, as we have already said, of old English, and the Gothic or pointed style, and in most instances with good effect. It is only to be lamented that, by the manner in which state patronage is distributed in this branch of the fine arts, some of the largest and most expensive structures—Buckingham Palace and the National Gallery, for example—have been erected on the poorest conceptions of the Grecian style, and with a general effect far from pleasing. In Paris there now exist some modern structures after correct Grecian models, which cannot be too highly praised; we would, in particular, instance the building called the Madeleine, the Bourse, and the interior of the church of St Genevieve, which are exceedingly worthy of being visited by young and aspiring architects from Britain.

Houses and Streets.

Till about the year 1820, the street architecture of Britain was on a poor scale; the houses ranging evenly with each other, being plain stone or brick edifices, of generally three storeys in height, overtopped by a slanting and tasteless roof of slate or tile; in London and some other places, the ugly tile roof was hid by a portion of the front wall carried upwards as a parapet. At the above period, a new era may be said to have begun in town architecture, whereby the houses were built more in a bold continental style, in which the Græco-Italian was aimed at with more or less success; and latterly, this improved taste has altogether superseded the barren architecture prevalent during the reign of George III. According to this revived taste, the houses are now constructed of polished sandstone, or covered with a plaster to resemble that material; the doors and windows are enlarged and ornamented,

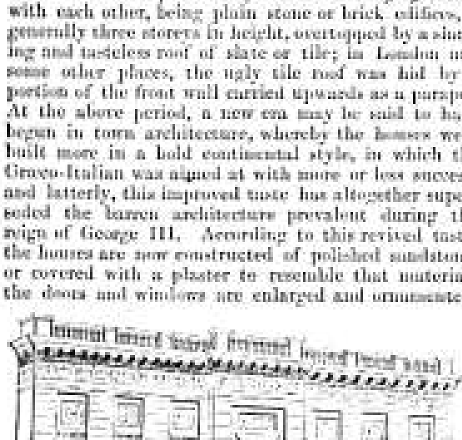

Fig. 25.

the floors more spacious and lofty, and the roof is invariably secluded from the eye by a balustrade or elevated coping. Some of the edifices erected at the west end of London, to accommodate clubs of gentlemen, are reckoned among the finest examples of the revived Italian style, and worthy of the best days of Palladio. The preceding cut (fig. 25), represents the front of the Oxford and Cambridge University Club-House, in Pall Mall, erected from a design of Mr Sydney Smirke and his brother Sir Robert, and which is distinguished for the richness of its cornice and entablature, as well as its generally imposing effect.

The various changes effected in recent times in general street architecture, are not more remarkable than those on the construction of shop-fronts, some of which now vie with the greatest efforts of the old Italian masters. A century ago, shop-fronts were little else than open booths, with an overhanging canopy. They afterwards were closed, and, as is well known, attempts were finally made to Grecianise them with pillars and pediments. The increasing rivalry and taste of shopkeepers, however, did not stop here; and in the present day, very extraordinary efforts are making to place shop-fronts among the works of classic architecture. The design, generally, is to supersede plain Grecian or Roman models by highly ornamental designs after the Italian style. The most favourable specimen we can present of this elaborate and splendid style of

Fig. 26.

shop-frontage is that observable at the corner of the Quadrant, Regent Street, London (fig. 26). As an architectural composition, it possesses considerable merit, presenting, with the lightness of the plate-glass windows, the appearance of sufficient solidity and strength, and not looking as if likely to be crushed by the upper part of the edifice.

Notwithstanding this appearance of revival, there is too much ground for the complaint that the majority of our architects and builders are merely parcel-Greek. 'Their attention,' says the author of Ancient and Modern Art, 'seems exclusively directed to the orders themselves and their details, as if in that consisted the secret and excellence of Grecian architecture. The Doric is their favourite order. *Every* master-mason, every plasterer, every carpenter who knows how to work a Grecian Doric column and entablature, piques himself on his knowledge of Grecian architecture, and looks with ineffable contempt on the Roman and Italian styles, and the ignorance of his predecessors. Every dwelling-house and shop-front must have its tiny, fluted, baseless, Pæstum Doric columns. Every public building, be it a church or meeting-house, a palace or hospital, a college or club-house, a theatre or jail, has its Grecian, Doric, or Ionic portico. Whatever may be the style or character of the building, it becomes henceforth a genuine Grecian structure.' To this may be added the authority of the Quarterly Review:—'That the porticos themselves are admired, we need no other evidence than the universal fashion, we had almost called it *mania*, for their application. In our suburban streets we have salmon and mackerel lying in stately funeral under Doric pillars, and tripe surmounted with metopes, triglyphs, and guttæ, of the most classic proportions. In some of our fashionable club-houses, after every accommodation has been provided for the members, a portico is superadded, apparently commensurate, not so much with the building itself, as with the unexpended residue of the subscription, and adorned, like the family picture of Dr Primrose, with as many columns as the artist could afford for the money: while undecorated windows are left, like Tilburina's maid, in primitive simplicity, a portico, the indispensable necessary of architectural life, is patched on to any visible wall of our pseudo-palaces.'

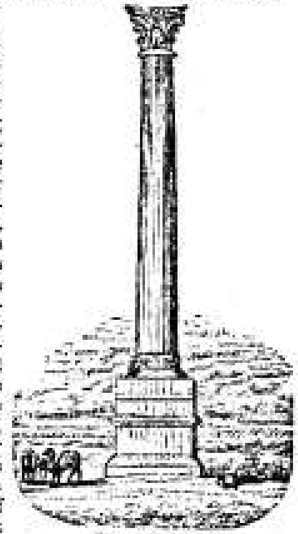
A pediment or portico, unless the termination of a real roof, and an integral part of the building, is a meaningless ornament, and is no indication whatever of the Grecian style; and in like manner, if the columns do not support the roof, they are nothing more than the ornaments into which they were degraded by Roman taste. But in point of fact, the term Grecian among us merely means *something not Gothic*. 'It would be of essential advantage to the progress and purity of the art, and be the means of preventing much error and misconception, were the three styles carefully distinguished from each other both in theory and practice. Our common street elevations, shop-fronts, and dwelling-houses, mimic, in mock majesty and tawdry plaster enrichment, the style and decoration of palaces; while our public buildings are meagre without simplicity, ornate without magnificence, and costly without grandeur or durability. In the metropolis, stone is rarely used for private houses, and not always for public buildings. Everything is sacrificed for present effect—for the caprice, novelty, and excitement of the moment. We are perfectly contented with that tawdry glitter and brilliancy, that vicious and overcharged ornament, which strikes the vulgar and ignorant. We have no classical taste, no extended views, no perseverance, no ambition to hand down lasting and national monuments to future ages.'

But the invention of window-glass in the sixth century rendered a purely Greek building practically obsolete. The few windows of the ancients were placed high in the walls, and many chambers were lighted exclusively by torches. In some temples the colonnade supporting the roof was open. Windows are now a grand feature in the building, for cupola light is not always attainable or always desirable; and windows, therefore, instead of being merely 'poked out,' should exhibit some distinctive characteristic of the order. The glass windows are not incongruous in themselves, being a modification of absolute necessity in the present age; but unluckily they are mere holes in the wall, with no more reference to the Doric than to the Gothic style of architecture. But this is a solitary grievance. The prevailing fault is the abuse of the classical forms as mere nicknacks, while the prevailing folly is the Grecian name we give to the anomalous result.

The Gothic, in like manner, becomes in our hands merely ridiculous. Baby-house towers and turrets—battlements where no battle can be waged—mock machicolations—niches in the walls for dolls instead of statues—what can be in more pitiful taste! 'The Gothic,' says Mr Macculloch, 'is not fit for dwelling-houses. Its dwelling-houses were its abbeys and castles, and were on a large scale. When we attempt to reduce them to a small scale, they become mean. The turrets of the castle, which were meant to contain men, will scarcely hold a cat; the towers will hardly admit of staircases, much less of chambers; the battlements are like the ornaments of an escutcheon; and instead of the machicolations, we have a paltry pretence.'

MONUMENTAL COLUMNS.

The erection of triumphal or monumental columns was a favourite idea of the Romans. Augustus erected a column of white marble near the Temple of Saturn, in the Forum at Rome, as a centre whence the account of the miles began in the calculation of distances from the city. This celebrated column, which is still in existence, is, however, not of great altitude. Among the principal triumphal columns of antiquity now remaining, is what is called the column of Pompey, constructed of red granite, and situated on a rock, about a mile without the walls of Alexandria in Egypt. The total height of this column is variously mentioned as being 92 feet and 114 feet. The spectator can never be tired with admiring the beauty of its Corinthian capital, the length of the shaft, or the extraordinary simplicity of the pedestal. To whom this famous pillar was erected is not now known with any degree of certainty. Notwithstanding its common appellation, it is agreed that it could not have been raised to the memory of Pompey, as neither Strabo nor Diodorus Siculus has spoken of it. Abulfeda, in his history of the country, calls it the Pillar of Severus; but an inscription on the west side, now nearly effaced, seems to prove that it was erected in honour of the Emperor Diocletian by the then prefect of Egypt.



Pompey's Pillar.

The Trajan Column, which falls next to be mentioned, is one of the most celebrated monuments of antiquity. Its height, including the pedestal and statue, is 132 feet. This monumental column was erected in the centre of the Forum Trajani, and dedicated to the Emperor Trajan for his decisive victory over the Dacians, as is testified by the inscription on the pedestal. It is of the Doric order, and its shaft is constructed of thirty-four pieces of Greek marble, joined with cramps of bronze, and so curiously cemented as to appear but one entire stone. Within, there is a spiral staircase leading to the summit, to which the light is admitted by a number of loop-holes; and the outside is adorned with bas-reliefs, representing the principal actions of the emperor. It is now inappropriately surmounted by a statue of St Peter, instead of the golden urn in which the ashes of Trajan were deposited. For elegance of proportion, beauty of style, and for simplicity and dexterity of sculpture, it is the finest in the world. The figures on the pedestal are masterpieces of Roman art. There are other columnar erections in Rome; one of which is the column of the Emperor Phocas, near the Temple of Concord; it is of Greek marble, fluted, and of the Corinthian order, 4 feet diameter, and 54 feet high, including the pedestal.

Trajan's Pillar.

The column which ornaments the British metropolis, better known as the Monument, was designed by Sir Christopher Wren, and erected by order of parliament, in memory of the burning of the city of London, anno 1666, in the very place where the fire began. This pillar was begun in 1671, and finished in 1677. It is of the Doric order, fluted, 202 feet high from the ground, and 15 feet in diameter, of solid Portland stone, with a staircase in the middle, of black marble, containing 345 steps. The lowest part of the pedestal is 28 feet square, and its altitude 40 feet; the front being enriched with curious bas-reliefs. It has a balcony within thirty-two feet of the top, on which is placed a blazing urn of gilt brass.

The column in Phœnix Park, Dublin, differs from any other work of this description. It was erected in 1745. It stands in the centre of an area where four great avenues meet, and from which there are entrances to the vice-regal lodge, and that of the chief secretary. The trees which shade the avenues form vistas, through which the perspective view of the column forms a picturesque object. The pillar is formed of Portland stone, and is of the Corinthian order, fluted, and highly ornamented. The base and pedestal are 5 feet in height, the shaft and capital 20 feet, and the phœnix which surmounts the column 5 feet, so that the whole presents an object 30 feet high.

The Napoleon Column has justly been considered as the greatest ornament of the French capital. It stands in the Place Vendôme, and was erected to commemorate the successful result of Bonaparte's arms in the German campaign of 1805. Its total elevation is 135 feet, and the diameter of its shaft is 12 feet. It is in imitation of the Pillar of Trajan, and is built of stone, covered with bas-reliefs (representing the various victories of the French army), composed of 1200 pieces of cannon taken from the Russian and Austrian armies. The bronze employed in this monument was about 360,000 lbs. weight. The column is of the Doric order. The bas-reliefs of the pedestal represent the uniforms and weapons of the conquered legions. Above the pedestal are festoons of oak, supported at the four angles by eagles, in bronze, each weighing 500 lbs. The bas-reliefs of the shaft pursue a spiral direction from the base to the capital, and display in chronological order the principal actions of the campaign, from the departure of the troops from Boulogne to the battle of Austerlitz. The figures are three feet high; their number is said to be 2000; and the length of the spiral band 840 feet. Above the capital is a gallery, which is approached by a winding staircase within, of 176 steps. The capital of the column is surmounted by an acroterium, upon which stands the statue of Napoleon, measuring 11 feet in height, and weighing 5012 lbs. The total expense of this sumptuous monument was 1,500,000 livres.

There are also several smaller columns, but of beautiful proportions, in various parts of England, in imitation of the above, but mostly of the Grecian or pure Doric order—as the Anglesea Column, erected in commemoration of the battle of Waterloo, and the noble earl of that name, in the island of Anglesea; the column at Shrewsbury, erected in commemoration of the same event, and of another noble general, Lord Hill; the Nelson Columns at Yarmouth and in Dublin; the Wellington Column at Trim, in the county of Meath, Ireland; the monument commemorative of Lord Melville at Edinburgh; and a similar one at St James's Park of the Duke of York, &c. A very common error is committed in the erection of monumental columns, by loading their summit with a clumsy mass of masonry, on which the statue is placed, and technically called an *acroterium*. The Melville monument at Edinburgh presents a notable instance of this kind of defect. If there must be an acroterium, it cannot be too modest in its proportions, or too little seen by the spectator.

BRIDGES.

The art of bridge-building is traced to the Romans, to whom must be ascribed the honour, if not of the discovery, at least of having first put in practice the principle of the arch. In the brightest days of the Grecians, when their fine style of architecture was complete, when their porticos were crowded with paintings and their streets with statues, the people of Athens waded or ferried over the Cephisus for want of a bridge. We cannot, therefore, imagine a people otherwise so ingenious, to have been sufficiently, if at all, acquainted with the value of the arch. After the construction of the Roman sewers, the aqueducts, and the cupola over the Pantheon of M. Agrippa, a bridge over the Tiber was of easy execution; and the invention of the architecture of stone bridges, as practised in its best and most effectual manner, must be conceded to this great and indefatigable people. The most celebrated bridges of ancient Rome were not distinguished by the extraordinary size of their arches nor the peculiar lightness of their piers, but, like the rest of the magnificent works of this city, as far as construction is concerned, they are worthy of study from their excellence and durability. The span or chord of their arches seldom exceeded 70 or 80 feet, and the versed sine or height was nearly half of the chord, so that they were mostly semicircular, or constituted a segment nearly of that form. Martellinis speaks of one near Narni, built by Augustus, consisting of four arches, whose spans were respectively 75, 114, 135, and 142 feet, and whose height was 102 feet. The latter appears to be the most magnificent bridge the Romans constructed in Italy, though in the provinces there were several of much more extensive dimensions. Thus that of Merida, upon the Guadiana, in Spain, consists of sixty-five arches, its total length being about 1300 paces; and that of Alcantara, upon the Tagus, of six arches, its length being 670 Spanish feet, and its height from the bottom of the river to the roadway not less than 205 feet.

After the revival of the arts in Europe, though power and wealth were directed chiefly to the erection of religious edifices, yet we are not without examples of such utilitarian structures as bridges, and these often of very superb dimensions. Thus the bridge of Avignon, on the Rhone, built between 1176 and 1188, consisted of eighteen arches; that of Lyons, of twenty; and that of St Esprit, of twenty-six. Perronet mentions an arch at Verona of 160 feet span, and another at Ville-Brioude, on the Allier, of not less than 183½ feet. Venice, from her peculiar situation, early boasted of more bridges than any other city—these at one time numbering between three and four hundred. The finest is the Rialto, a single arch of 98½ feet span, and only 23 feet of a rise. It was designed by Michael Angelo, and erected between 1588 and 1591. Within the last two centuries, several superb bridges have been erected in France, among which we may mention the following:—The Pont Royal, which was thrown across the Seine at Paris in 1685, consists of five arches, the central one of which has a span of 82¼ feet. The bridge at Blois has eleven arches, the central one being about 92 feet in span, with a breadth over the parapets of 53¾ feet. The new bridge upon the Loire at Orleans, erected in place of an old structure of nineteen arches, was completed in 1760, and consists of nine elegant arches, the largest of which has a span of 98½ feet. The bridge of Nantes, on the Seine, which was completed in 1756, consists of three arches, the middle one having a span of 120 feet; and that of Neuilly, consisting of five arches, each having a span of 128 feet, with a rise of 32 feet.

In England, the art of bridge-building seems to have taken its rise about the middle of the ninth century; but the structures of that early period are not to be compared with those of the same era on the continent. The most ancient bridge in England is the Gothic triangular bridge at Croyland, in Lincolnshire, said to have been built in 860. The ascent is so steep, that none but foot passengers can go over it—a common peculiarity of old bridges. The earliest of any importance, however, were London Bridge, finished in 1209; that of Newcastle-on-Tyne, built in 1281; and that of Rochester, much about the same time. The former originally consisted of nineteen arches; but in 1758 the middle pier was removed, and the two adjacent arches converted into one of 72 feet span. Since then, a number of bridges have been built across the Thames—all of which may be justly regarded with interest, seeing that an artificial foundation has to be prepared for the piers, and this in a river where the tide rises twice every day from thirteen to eighteen feet. That of Westminster, begun in 1738, and opened to the public in 1750, is universally allowed to be one of the finest in the world. It consists of thirteen large arches and two small ones, making a total length of 1223 feet, with a breadth of 44 feet. The arches are semicircular in form, and spring from about two feet above low-water mark; the centre one is 76 feet in span, and the rest decrease on each side equally by 4 feet. That of Blackfriars, begun in 1760, and completed in 1770, is another imposing structure, consisting of nine elliptical arches, the middle one of which has a span of not less than 100 feet, with a breadth of 43½. The arches are low in proportion to their span; but as the bridge is built to accommodate the navigation of the river, the upper surface of the whole forms a portion of a very large circle, and appears a gentle swelling ground under foot all the way. Waterloo Bridge, begun in 1811, and completed in 1817, is another of those costly erections which modern enterprise has thrown across the Thames. It consists of nine arches, all of one span and height, so as to form a level roadway; and this road is continued on either side the river, and supported on a number of brick arches. The length of the stonework or bridge is 1242 feet, the brickwork of forty arches on the Surrey side is 1250 feet, and of that on the Strand side 400 feet. Each stone arch has a span of 120 feet, and the height of the road above the river is 50 feet. The New London Bridge, begun in 1825, and opened in 1831, is the last of the stone structures over the Thames which we shall notice. It consists of five arches—the centre one having a span of 152 feet, the two on each side a span of 140 feet, and the abutment arches a span of 130 feet. The rise of the middle arch is 32 feet, that of the abutment arch falls to 25 feet. The extreme length of the structure is 950, and its breadth 55 feet. With the exception of the packings, it is constructed of granite of the finest description and workmanship; and including the approaches, is said to have cost about £2,000,000 sterling.

But it is not in the neighbourhood of the metropolis alone that we find structures of this class evincing both boldness and ingenuity of design. The Severn, the Ouse, the Tees, the Tyne, and other English rivers, are spanned by stone arches, some of which are of surprising dimensions. The centre arch of the bridge in Blenheim Park is 101½ feet span; a single arch across the Tees at Winstone is 109 feet; and one across the Taaf, in Wales, is not less than 140 feet. The architect of this bridge was a poor uneducated man; and the persevering courage with which he pursued his object till the completion of the edifice is worthy of record. His first attempts failed, in consequence of the enormous pressure of the haunches or sides of the bridge, which forced up the keystone; and to obviate this, he pierced the stonework with cylindrical apertures, which remedied the defect. All these, however, are inferior to some which recent railway requirements have called into existence. Thus Victoria Bridge, over the Wear, at a place called Penchar, and on the line of the Durham Junction Railway, consists of four main arches, and of six smaller ones to support the roadway. Of the main arches, that beneath which the river flows is 160 feet span; the north arch 144 feet; and each of the end ones 100 feet. The total height of the structure, from the foundation to the top of the parapet, is 156 feet; the clear width of roadway 21 feet; and the length 820 feet.

Scotland can also boast of some very handsome bridges; chiefly, however, of modern erection. The Tay at Perth, for example, is crossed by one of nine arches, the largest of which has a span of 77 feet; the Tweed, at Coldstream, by one of five arches; the North Esk, near Montrose, by one of seven; the Tweed, at Kelso, by one of five arches, each with a span of 73 feet; the Spey, near Gordon Castle, by one of four arches, the largest having a span of 95 feet; and the Tay, at Dunkeld, by one of seven arches, the largest having a span of 90 feet—which is perhaps the finest structure of the kind in Scotland. Of Scottish bridges having a large span and height, we may mention that over the Dee Burn, near Aberdeen, whose span is 130 feet; that over the Dee, near Kirkcudbright, having a span of 118 feet; the North Bridge of Edinburgh, consisting of three large and two small arches—the large ones having each a span of 72 feet, and a height of 65; the Pease Bridge, thrown across a deep dingle on the Edinburgh and Berwick road, consists of four arches, each 55 feet span, and 124 feet in height; and the Dean Bridge, near Edinburgh, the main body of which is composed of four arches, each 90 feet span, and from the river to the level of the roadway 106 feet high.

Iron Bridges.

Within the last half century, iron has been frequently substituted for stone in the construction of large arches; so that, instead of a solid vault of masonry, we have now a light but substantial framework of metal. The first iron bridge of any importance constructed in Britain was one near Coalbrookdale, on the Severn—the invention of Mr Obiah Darby. It was completed in 1779, and consists of a single arch 101½ feet span, with a rise of 45. In 1796, another was erected at Buildwas, near Coalbrookdale, under the direction of Mr Telford, the span of which is 130 feet, and its rise only 17. In the same year, Mr Burdon completed the celebrated iron arch across the Wear at Sunderland, the span of which is 240 feet, and its elevation above low-water fully 105 feet. This elevation consists of 75 feet of stone pier, and 30 of a rise in the arch—thus allowing large vessels to pass under without striking their masts! In 1803, an elegant iron bridge, somewhat resembling that of Sunderland, was erected at Staines, having a span of 180 feet, and a rise of only 16½. Since then, a number of others have been constructed, of 80, 90, and 100 feet span, some rising so little in their curve as 5 feet. But all these works have been far exceeded in extent and importance by those built over the Thames. Vauxhall Bridge, which was completed in 1816, consists of nine arches of cast-iron, each having a span of 78 feet, and 11 and 12 feet rise; and that of Southwark of three arches, each 240 feet span, and only 24 feet rise! In most of these structures the iron arch rests on stone piers and abutments; but in some the piers are also of iron, thus giving to the whole a lightness and elegance which it is impossible to equal in stone erections.

Suspension-bridges are such as are hung on chains, these chains being supported on piers or pillars, and stretched across the chasm or water-course over which it is designed to form a passage. From the chains a platform for the roadway is suspended, by means of a series of equidistant vertical rods. In Peru, China, and other remote regions, bridges on this principle, though of an extremely rude and perishable construction, and forming a most unstable and oscillating path, seem to have existed anterior to anything which is at present known of the history of those countries; but the introduction of suspension-bridges into civilised states, at least on a large scale, and of a substantial fabric, is of very recent date. By far the most stupendous in Britain, and indeed in the world, at the date of its erection (1826), is that constructed by Mr Telford across the Menai Strait, to connect the island of Anglesea with the mainland of Wales. The span of the suspended or central arch, between the highest points of the chains on the top of the piers, and 153 feet above high water, is 560 feet. Seven stone arches, of 52½ feet span, make up the rest of the bridge; four of those being next the island, and three on the Welsh coast. The chains, of which there are sixteen, reach over the whole structure, and, besides, descend 60 feet in sloping pits or shafts, to where they are secured by means of cast-iron frames ingrafted in the rocks; the entire length of each chain being 1714 feet, or almost the third of a mile. The two suspension piers of the great arch rise 52 feet above the roadway, and are surmounted by cast-iron blocks and saddles, movable upon friction rollers, for the purpose of allowing the chains which pass over them to move freely when expanding or contracting under change of temperature. The suspension platform, elevated 100 feet above high water, is occupied by two carriage-roads, each 12 feet wide, with a footpath of 4 feet between them. These pass through arches in the suspension piers; and each is separated, and strongly railed in, by lattice iron-work, both for protection and for stiffening the roadway, to prevent vibration. Each of the chains is fivefold, and of such complexity in design, that any part of the chain may with safety be removed at any time for repair, or be replaced by a new one.

The Menai Bridge, however—we quote the *Encyclopedia Britannica*—has been greatly surpassed, both in length and in height, by a far lighter and much less expensive one, though of great strength, which has since been constructed by M. Chaley of Lyons, over the Saane at Friburg, in Switzerland. This was completed in 1834. The span is 870 feet, and the roadway is elevated 167 feet above the river. The lightness of this bridge is in a great measure owing to its neither being suspended by chains nor solid iron rods, but by four cables of iron wire, each containing about 1200 wires, the united strength of which could support three times the weight of two rows of loaded wagons extending over its whole length. The wires are simply laid together, and bound in a cylindrical form by means of annealed wire wound round them at distances of two or three feet; and the whole is painted white, both for preservation, and that the least tendency to rust might be detected at once. But iron, even in its most approved form of wire cable, has been surpassed by the employment of steel; for we learn from the 'Register of Arts,' that in 1832 a bridge of this material was erected over the Danube, near Vienna. The span of this structure is 234 feet, with a rise of only 15. A saving of one-half in the total weight is calculated to have been effected by the use of steel instead of iron; and the strength is also said to be much greater.

PRACTICE OF ARCHITECTURE.

Architecture is practically conducted by two distinct classes of men—*architects*, whose profession consists in planning designs of buildings according to the wish of an employer; and *builders*, who, assisted by operative masons and other artisans, work out the plans in all their various parts. Some architects derive celebrity for designs for churches and public edifices, others for domestic structures, and a third class, who are sometimes styled *civil engineers*, are eminent for their plans of piers, quays, bridges, docks, aqueducts, and other great public works.

In representing proposed edifices by drawings, architects make use of the plan, elevation, section, and perspective. The *plan* is a map or design, of a horizontal surface, showing the ground-work, with the relative position of walls, columns, doors, and other details. The *elevation* is a drawing of the front, without any perspective effect. The *section* shows the interior of the building, as if the outer wall were removed. The *perspective* shows the building as it appears to the eye at a little distance, and is generally executed so as to give the effect of a picture. Along with the different designs, *specifications* of the work to be executed are put into the hands of the builder; these specifications are minute definitions of what must be done in the departments of the stone-mason, bricklayer, joiner, slater, plumber, glazier, and plasterer, as well as of the nature of the materials to be employed. [For an account of stones, bricks, tiles, mortars, cements, and other materials employed in building, roofing, and paving, the reader is referred to the sheets devoted to MINERALS and FICTILE MANUFACTURES.]

The rules of building require, that in a whole fabric judiciously and elegantly erected, there should be solidity, convenience, and beauty, along with simplicity and harmony of design. The structure, whatever it is, must be in character, or look like that for which it is intended. If a church, it should have the appearance of a church; if a house, a house; and if a castle, a castle. Some tastes would construct a cottage in the shape of a Norman fortress, with battlements and loop-holes; but all such oddities are essentially vulgar. It is an important principle in architecture to preserve character, and to make a building expressive yet simple in its outlines, and all of a piece. If there is ornament, it must be duly distributed, not overloaded at one part, and meagre at another. The design, to be striking, must also be of a height and breadth sufficient to fill the eye of the spectator. To aid in this desirable object, the buildings should be well placed, and, if possible, at the summit of slightly rising grounds, where they will stand clear of ungraceful objects. Unfortunately, this principle has not always guided our architects. Magnificent temples which crowned the summits of rising grounds in Greece, we find imitated in hollows; and the eye of the spectator, instead of taking in a bold and lofty outline of pillars relieved against the clear blue sky, is offended by looking down upon clusters of chimney pots. Thus innumerable public buildings in England and Scotland, possessing, intrinsically, good architecture, are greatly spoiled by the want of taste in those who have placed them in unseemly awkward situations.

It appears to us, likewise, that far too little attention is paid by architects to the nature of our climate. We cannot recall to remembrance one public edifice in the Grecian style in this country which does not exhibit a dingy damp look. At every projecting point, and particularly over the pediments, pillars, and flat cornices of doorways, there is generally an ugly spot covered with moisture, and exhibiting the early rudiments of vegetation on the walls. All this offends the eye of the spectator, and excites universal notice, except among those who can see nothing but beauty in Grecian architecture, however clumsy it may be, and however much out of place. Architects likewise require to guard against introducing forms which will revive recollections of unpleasing or mean objects. Fine buildings have been rendered ridiculous by inattention to this point. One structure is defaced by a dome the exact model of an inverted punch-bowl; the pinnacles of another resemble the upturned legs of a footstool; the front of a third is like a grenadier's cap; and the corners of a fourth are defaced by turrets the shape of pepper-castors.

Another point requires consideration. In cases where ornament is not introduced on a large scale, masses of wall will be greatly improved by being thrown into different projections; and this leads us to notice that the effect of interiors, when ornamented with pillars, is vastly enhanced by causing some to project and others to recede, thus gratifying the eye with what is seen, and raising hopes of beauties in those parts which are partially hid from observation. This breaking into seen and unseen parts is well exemplified in the church of St Genevieve at Paris.

Certain practical matters equally require attention in the erection of buildings. The foundation must be laid on a solid basis of rock, clay, or concrete; and if the situation be soft, or of doubtful stability, the ground should be fixed by piles of timber driven to a considerable depth. It is likewise a point of first importance to have the stool or lower part of the house free of damp; and this is only attainable by excavating the loose earth, by digging drains, and paving the surface with a material impervious to moisture. In general, in the construction of cottages and villas, far too little attention is paid to this particular.

In designing windows, the approved rule is to make each twice its width in height; those in the upper floor storey are generally made nearly square, but it is preferable to make them a third higher than broad. The stairs should be of easy access; the rise of each step to be 6 or 7 inches, and the breadth at least 10 inches,

HEATING—LIGHTING—VENTILATION.

Upon judicious means of heating, lighting, and ventilating apartments, manufactories, and several classes of public buildings, very important consequences depend, including not only the ordinary comfort, but the health of human beings. We propose here to treat the three subjects—confining our attention chiefly to plans involving scientific principles, as well as ingenious mechanical contrivance.

HEATING.

It is scarcely necessary to remark, that the mode of heating apartments most prevalent in Britain is by a fire of coal placed in a grate, having a chimney above, through which the vaporised products of the fuel are carried off. Of one class of results from this mode there can be no doubt. The fire glowing in its appropriate receptacle, has an air of cheerfulness and comfort which strikes every beholder, causing the domestic group to cluster around it with that feeling of satisfaction which makes an Englishman regard his fireside as amongst the most precious things connected with his existence. But while the common open fire is almost an object of worship amongst us, on account of its pleasant look and power of concentrating the whole family in one social circle, it is not unattended with certain drawbacks, difficulties, and disadvantages; nor can it be applied well in any place save an ordinary apartment. The greatest drawback is the uneconomical use which it makes of fuel. About one-half of the heat produced by a common fire ascends with the smoke; the smoke itself being an unconsumed part of the fuel. Finally, about a fourth of the heat which is radiated into the apartment is, in ordinary circumstances, carried into the chimney between the fire and the mantel-piece, and thus lost. It is calculated by Dr Arnott, that only about one-eighth part of the heat-producing power of the fuel used in common fires is realised, all the rest being dissipated into the surrounding atmosphere. Count Rumford gave even a more unfavourable calculation, making the dissipated or lost part to be no less than fourteen-fifteenths. He probably over-estimated the loss considerably; but that a very large portion of the efficacy of fuel is forfeited in the use of common chimneys, is just as certain as it is that an open fire is an object which every eye delights to rest upon. It is also unquestionable that often a common fire is found to give a partial kind of warmth, heating the side of our persons next to it, but leaving the rest cold; that it produces draughts into our rooms which are anything but safe or agreeable; that frequently one active fire deranges the action of the chimneys of other fires, and fills the house with smoke; that smoke and dust are annoyances more or less inseparable from it in all its shapes; and that it is by no means a mode of heating free from danger to both property and persons. These are disadvantages of which every one is aware; and although they are not sufficient to extinguish the pleasure which we take in our 'sea-coal fires,' they may certainly be allowed to furnish reason for inquiring if, by any modification of present plans, fuel could be applied more economically, and at the same time agreeably. There is also, we must recollect, the necessity for modes of heating applicable to public buildings, where the common fire is of little service.

Warming by Highly-Heated Surfaces.

One of the first attempts to arrive at a mode of warming more economical than the common fire, and applicable to large buildings, suggested the raising of plates of iron to a high temperature, and causing air to pass over them on its way to supply the rooms or halls where it was required. In some part of the building a furnace was employed to heat the plates, which were of cast-iron, and the air, after passing over them, was sent forward through a tunnel, and ushered into the hall or other space required to be heated, either through a grated aperture in the floor, or by pipes distributed round the walls or galleries. This mode was introduced into many churches in the early part of the present century, and it was fully tried in the London Custom-house. In the latter building there are several large rooms, in which a great number of clerks and other officers are assembled for business. Into one, called the 'Examiners' Room,' the air rushed at a temperature of 170°, to be reduced to a more moderate heat by its mixing with the air already in the apartment. In another, called the 'Long Room,' the air entered at a temperature varying from 90° to 170°, being liable to be reduced by a regulated admission of cold air into the apartment from without. It is not easy to excuse the ignorance which dictated this mode of heating. When air passes over plates raised to a red heat, as these were, it is desiccated, or deprived of its natural humidity; animal and other matters floating in it are decomposed; it is charged with noxious fumes from the iron; and lastly, by the drying or desiccation, it is thrown into a state highly electric. The condition of the air is then nearly the same with that which African travellers recognise with terror under the name of the simoom. The consequence in the Custom-house was, a general falling off in the health of the officers, which became at length so alarming, that this mode of warming the apartments had to be given up.

The mode of warming by highly-heated surfaces is now generally condemned, on account of its deleterious effects on the air; but it is still in practice to some extent, and we have therefore thought ourselves called upon to introduce a brief description of it, in order to have an opportunity of explaining its unsuitableness, and warning against its use. It may be safely set down as a first principle in the science of heating, that no mode which materially alters the ordinary character of the air can be compatible with health. Common stoves are liable to this objection in greater or less degree, and are therefore rarely used, excepting in lobbies and similar apartments.

Warming by Moderately-Heated Surfaces.

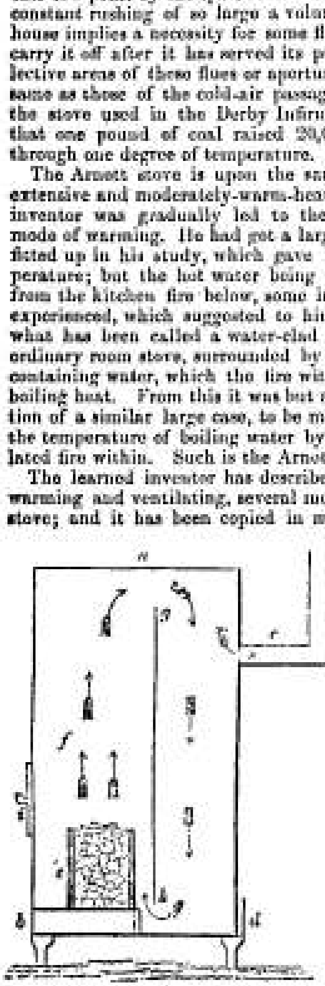
The objections to the above mode of heating would obviously be in a great measure overcome, if, instead of a small surface highly heated, a large one moderately heated were used. This may be done in various ways, as—1. By a furnace operating upon the heat-giving surface, as in a stove; 2. By steam in tubes; or 3. By hot water also in tubes:—

Stoves.—The first attempt of which we are aware to give warmth by hot air from large moderately-heated surfaces, was made by Mr William Strutt, of Derby, in 1792. The cotton-mill of the copartnery to which he belonged was in that year fitted up with a stove constructed upon this principle; and the same plan, after being tried in his own house and those of his friends, was introduced, with all the improvements of which it was deemed capable, into the Derby Infirmary in 1807. It has since been adopted, with some slight modifications, in various public and private buildings.

Briefly, and dismissing unimportant details, the Strutt stove consists of a *cockle*, or plate-iron box, of about two feet in height by one in breadth of sides, inverted with the open mouth downwards over a small close furnace, which heats it to about 260°. Another somewhat larger box surmounts this, leaving the space of an inch or so between. This outer box is perforated with numerous holes, into which short open tubes are fitted, projecting outwards. This apparatus being constructed in a small close room, a channel or culvert of considerable width is made to communicate between that room and the open air on the outside of the house. On the fire being kindled in the furnace, the cockle is heated to the desired height, and no more—a control being exercised over the fire by a valve for communicating air to the furnace. The air immediately without the cockle is warmed, and by virtue of its increased temperature, begins to ascend. To replace it, fresh air is drawn in through the culvert, and through the numerous tubular apertures of the outer case, and made to rush against the heated vessel within. This air is accordingly heated too, and pursues the same line of ascent. Thus there is a constant flow of moderately-heated air upwards. This may either be allowed to pass into an open hall, staircase, or any other single space which it is desired to warm, or it may be carried along in flues, and distributed into different rooms. It will be observed that the instrument or medium for warmth in this case is a stream of heated air: the temperature desired for it is about 64°, and it is kept at this low point by the spaciousness of the culvert. The constant rushing of so large a volume of air into the house implies a necessity for some flues or apertures to carry it off after it has served its purposes. The collective areas of these flues or apertures ought to be the same as those of the cold-air passages or culverts. In the stove used in the Derby Infirmary, it was found that one pound of coal raised 20,000 pounds of air through one degree of temperature.

The Arnott stove is upon the same principle of an extensive and moderately-warm-heating surface. The inventor was gradually led to the adoption of this mode of warming. He had got a large box of hot water fitted up in his study, which gave the requisite temperature; but the hot water being supplied by a pipe from the kitchen fire below, some inconveniences were experienced, which suggested to him the fitting up of what has been called a water-clad stove—namely, an ordinary room stove, surrounded by a close outer case containing water, which the fire within maintained at boiling heat. From this it was but a step to the adoption of a similar large case, to be maintained at about the temperature of boiling water by a small and regulated fire within. Such is the Arnott stove.

The learned inventor has described, in his essay on warming and ventilating, several modifications of this stove; and it has been copied in many various ways, generally with little regard to the original principle. We shall select for description one simple form, which seems to have been the first exemplified by Dr Arnott, and in which the fundamental principle seems to be as well brought out as in any other. This stove consists of a sheet-iron box (*a b d*), which may be of any dimensions, in proportion to the size of the room to be heated. It is divided by the partition *g h* into two chambers of unequal dimensions, which communicate freely at the top and bottom. A fire-box (*e*), composed of iron lined with fire-brick, rests at the bottom of the larger chamber. Access is obtained to it, for the purpose of supplying fuel, by the door *i*, which must fit closely. The refuse of the fire falls into an ash-pit, the door of which is at *b*. Here also is a valve for the supply of air to the fire-box. The fumes and heat of the fire pass in the direction indicated by the arrows, giving warmth to the outer case. The smoke finally passes off by the flue *c*, into an adjoining chimney. The aim of the inventor was to heat an extensive surface to about 200° Fahrenheit, so as to diffuse a moderate warmth into a room. He attains the power of keeping the heat at this height by the valve for admitting air. When this is opened widely, a large stream of air enters, and combustion becomes active. When, on the contrary, the aperture is reduced, a comparatively small stream is admitted, and combustion languishes. The temperature of the outer case is raised or depressed accordingly. By the revolution of the heat and smoke round the division of the chambers, their power of giving forth warmth is expended as far as possible on the plates of the outer case, so as to be serviceable for the end in view; and it might be possible to exhaust the whole for that end by lengthening the flue, or causing a greater extent of it to pass through the air of the room before entering the chimney. This apparatus certainly makes the most economical use of fuel of any species of contrivance for producing artificial heat yet known. Six pounds of Welsh coal or coke, of the value of one penny, will, it is said, supply an ordinary one for a whole day.



The Arnott stove is capable of something nearly approaching to self-regulation. When it was invented, about 1824, there was in existence a well-known means of adjusting the temperature of bakers' ovens by a self-acting thermometer. Though an old expedient, some person had recently secured a patent upon it, and Dr Arnott was therefore unable to take advantage of it for his stove. There are, however, many modes of producing the same curious mechanical results, and a few of these he specifies. That which he has employed in the stoves made under his own care, consists of a glass tube inserted horizontally into the upper part of the heated chamber of his stove, with a downward bend on the outside. Mercury is put into the bend of this tube, leaving the part which is within the stove empty of all but common air. This air of course expands in proportion to the heat of the stove, and in doing so, presses upon the mercury in that part of the outer bend next to it. The mercury in the other part of the bent tube accordingly rises. A float on its surface is thus raised. Connected with the float is a wire, which acts upon a valve at the door of the fire-box, causing it to open and shut according as the float falls or rises. By such simple means, the least increase of heat within immediately and unavoidably brings about a diminution of the supply of air to the fire, which therefore instantly begins to burn less intensely. So also any decrease of heat instantly produces a larger supply of air, by which the fire is, as it were, *poked*, and begins to burn more brightly. The cooling from a fresh supply of coke must of course cause that increased supply of oxygen which is necessary to make the new materials glow; and the new and great heat thus brought about must immediately check itself by the closing of the valve. It is also obvious that, when the materials are nearly burnt down, and the supply of air thus increased, the only consequence is, that the air rushes in as long as there is anything to burn, and no longer.

The express advantages of the thermometer stove are enumerated by the inventor under the following heads, which we shall abridge:—1. Economy of fuel. While in the case of a common open fire, seven-eighths of the heat goes up the chimney, nearly the whole heat is secured by the stove. A gentleman known to us saw Dr Arnott put a few leaves of a pamphlet into his fire-box, the ignition of which immediately heated the whole stove, and diffused an agreeable warmth throughout the room. An ordinary room can be kept warm by the stove for twenty-four hours, at the expense of one penny in coke or anthracite. 2. The temperature diffused by the stove is uniform throughout the room. 3. The stove is always alight, to the saving of much of that inconvenience and loss of time occasioned by the going out and kindling of ordinary fires. 4. No smoke, of the character of the smoke of a common fire, arises from the stove, but only a slight stream of volatile gases. 5. No dust is diffused throughout the room. 6. The dangers to which children, old people, and others, are exposed from a common fire, are obviated. 7. The danger to property is as little as the danger to persons. 8. The stove is obedient to command, and could be managed by a child. 9. It can be established at little expense. 10. It saves all expense for attendance. 11. It is easily moved. 12. It may be fashioned into any graceful or convenient form, so as to ornament a room. The inventor mentions that it may be in the form of a statue. 13. A drawer inserted into the heated chamber of the stove would serve for cooking meat, and a pot for boiling might be placed upon the fire-box; it is therefore, as the inventor remarks, peculiarly the *poor man's* stove. 14. No sweeping-boys or the like are required.

Under a sense of professional honour, Dr Arnott did not take out a patent for his stove. Regarding it as an invention for the improvement of health, he presented it to the world, as he had previously done his hydrostatic bed. It was therefore made by many furnishing ironmongers in the metropolis and elsewhere, some of whom took out patents for what they considered as improvements upon it. Though the intention of the inventor was good, his liberality has had a bad result. The principle, simple as it appears, was not well understood. The stoves made by all, except a very few ironmongers, were constructed erroneously, the prevalent fault being a diminution of the heating surface in proportion to the strength of the furnace. It is a curious fact in science, well worthy of being noticed, that twelve patents were taken out in one year for modifications of this stove, *all of which Dr Arnott considered to be upon false principles.* The consequence has been that many Arnott stoves, which had been introduced into houses with a good hope of their acting beneficially, have been given up on account of the inconvenience felt from the species of heat which they generated. It is also, however, to be observed that the stove, made even upon the most approved principles, would require certain adjuncts and conditions in order to operate healthfully and agreeably.

All metal surfaces, however well the principle of a large superficies moderately warmed may be observed, raise the temperature by two means—namely, by radiation and by conduction. Radiated heat, which is that given by a common fire, is perfectly safe; but the heat produced by the air coming in contact with a warmed surface is more or less deteriorated. The air, which forms the instrument or medium for heating the rest, has been altered in its character, particularly in being desiccated, or deprived of its humidity. It is necessary to counteract this result by an artificial infusion of humidity into the atmosphere. This may be done in various ways. The most common plan is to place a large open dish of water upon the stove; but in this case the evaporation does not proceed rapidly enough. It is better to keep a large wet cloth hanging near the stove. Perhaps the best possible arrangement is that consisting in a trough of water, with a roller moving in it, and a similar roller, forming a windlass, about two feet above. Between the windlass and the roller an endless piece of towelling revolves. The bottom of the piece of towelling passing of course through the water, it is only necessary to turn the windlass a few times in order to make the whole wet; and this process may be repeated as often as necessary. The vapour constantly arising from the cloth will, if sufficient in quantity, make good the want of humidity in the stove-heated air. Such an arrangement is necessary, not only in connection with the Arnott stove, but with Mr Strutt's contrivances, and with all the modes of heating by warmed metal surfaces. We shall consider some further arrangements which such modes of heating render necessary, under the head VENTILATION.

Sylvester's stove or grate, said to be coming into pretty extensive use, is a recent invention, the object of which is to moderate as much as possible the loss of heat which the open hearth involves, and yet to retain all the advantages of the open fire. It is thus briefly described by the editors of 'Knapp's Technology:'—'The fuel is placed upon a grate, the bars of which are even with the floor of the room, and air is supplied to the ash-pit below by a series of passages which pass under a hearth composed of separate bars of iron, arranged in a radiating or otherwise ornamental manner in front of the grate. The radiant and conducted heat from the fire is thus made to warm the hearth and the air passing below it, which is consequently warmed before reaching the fuel, and in an economical point of view this is of course advantageous. The warm hearth and the low position of the fire are also means of disseminating the heat much more effectually than is done by the ordinary arrangement of the fireplace. The sides and top of these stoves are constructed of double casings of iron, and in the sides a series of vertical plates, parallel with the front facing, are included in the interior, which collect, by conduction, a great portion of the heat generated from the fire—the mass of metal of which these are composed being so proportioned to the fuel consumed, that the whole can never rise above the temperature of 212° Fahrenheit under any circumstances. The sides and top of the stove are thus converted into a hot chamber, offering an extensive surface of heated metal; at the bottom, by an opening in the ornamental part, the air is allowed to enter, and rises as it becomes warmed, traversing in its ascent the different compartments formed by the hot parallel plates, and is allowed to escape at the top by some similar opening into the room. A current of air is thus constantly traversing the hollow sides and top of the stove, collecting the heat communicated to the metallic mass, and disseminating it through the room.' If allowed to enter the room by the top aperture, the air requires to be artificially moistened, as in the case of the other stoves above-mentioned. The Sylvester stove can either be placed in an ordinary chimney recess, or be made to stand ornamentally forward into the room. The feeding draught may be either taken directly from the apartment, or brought by flues from the outside of the building.

Hot Water and Steam Tubes.—In the hot-water and steam apparatus, the immediate agent for heating is the same as in the Strutt and Arnott stoves—namely, an extensive metallic surface moderately heated. But the heating is in these cases effected by hot water and by steam respectively, and the arrangement and character of the warm surfaces are different.

The idea of warming rooms by pipes filled with hot water occurred to the Marquis de Chabannes, who first exemplified it in his own house in England. The plan has latterly been patented, and extensively acted upon by the ingenious copartnery of Perkins and Heath, London. It proceeds upon a simple law of heat, that particles of any fluid warmed above the temperature of those surrounding them ascend. Thus in a kettle of water upon a fire, the particles at the bottom are heated first, and immediately ascend to the surface, their place being instantly taken by cool particles from above, which again in like manner ascend as soon as heated; so that there is a constant flow of cool particles downward and warmed particles upward, until the whole are heated. The hot-water heating apparatus consists of a stout metal pipe, pervading the house in all the parts which are desired to be heated, having a valve at the top, and a coil at the bottom exposed to a furnace. This tube being filled with water from the top (*b*), and the fire being kindled in the furnace, warm particles begin to ascend, and are quickly felt at the very highest part of the pipe. The water heats gradually from the top downward, until the whole is warm. The pipe then gives off heat to the surrounding atmosphere. Such is the principle. The arrangement of the pipe may be various: the plan generally followed is to place a considerable coil of it within a pedestal or bunker, with open trelliswork in front, in a convenient part of the room. It may also be made to wind round the room, behind the skirting-board, which, being perforated with holes, will allow of the entrance of the warmed air. The amount of pipe allowed to a room ought of course to bear a proportion to the size of the room, and other circumstances affecting its temperature. The pipes are generally round, and from three to four inches in diameter; but flattish pipes have sometimes been used. In the earlier stages of the history of the apparatus, a boiler was employed at the bottom for the heating of the water; but this was soon found to be attended with great danger, in consequence of the tendency of water in a tube to burst any vessel of capacity into which it may descend. The substitution of a coil of pipe was an improvement suggested by Mr A. M. Perkins. At the top of the apparatus, the pipe expands into what is called the expansion tube (a), which is left empty, to save the risk of bursting by the expansion of the water. Fifteen per cent. of space is found by experience to be an ample allowance for the expansibility of the water. A compendious and readily-understood specimen of the apparatus, calculated for a house of three storeys, is presented in the accompanying engraving. It is important to observe that the pipe, while operating, is closed in every part, the air having been previously pumped out of it. The heat usually maintained is 180°; but it can be increased to 400°, where such is necessary, as it is, for example, in certain drying-houses.

The hot-water apparatus has been fitted up by Messrs Perkins and Heath in various public buildings, warehouses, and gentlemen's houses; and, while sufficiently effective for the desired end, it has been proved to be attended with as few drawbacks as any regulated mode of heating whatever. But there is a great obstacle to its general adoption in its expensiveness. If this difficulty were not insuperable, the plan, from the natural principles on which it is founded, could be applied very easily to several buildings at once, or even to a considerable part of a town—if not, indeed, to an entire city. From some central establishment, on a low level, where the heat was applied, there might proceed pipes to the various houses, in the same manner as the pipes from a gaswork. There would of course be a waste of heat in all those parts of the pipe which passed through streets, and between one house and another; but this might be amply compensated by other economical features in the arrangement. [For a minute account of the hot-water plan, the reader is referred to Richardson's 'Treatise on the Warming and Ventilation of Buildings.']

There is a variation of the hot-water apparatus, in which it is made to take much of the form of Mr Strutt's plan, a large coil of pipe in one hot-air chamber being the means of supplying warmed air to be distributed over the building. The plan, in its ordinary form, has been likewise applied to vineries, conservatories, and forcing-houses, to which it must be considered as undeniably appropriate, if there be no objection on the score of expense.

Heating by steam-pipes is the only mode which remains to be considered. It was suggested nearly a century ago in the 'Philosophical Transactions,' but was not for many years after reduced to practice. At length it began to be introduced into factories, where a great facility existed for its operation in the boilers connected with the steam-engines. As respects its power of heating, and effect upon the surrounding air, it is identical with the plan last described, excepting that the surface of the pipes in this case can never be at a higher temperature than 212°. The size of the pipes and other arrangements are considerably different. The following is an account of the apparatus fitted up on this plan in the printing-office from which the present work is issued:—An iron tube, on which there is a stopcock, carries the steam from the boiler to a connected series of long tin pipes within the building. The diameter of these tin pipes is about ten inches, and they hang from the ceiling by means of small chains a few inches in length, so as to be quite clear of every article of furniture, and every head passing beneath. There is only one pipe going along each of the two lower storeys in this manner; and from each a small waste pipe goes outside, to let off the waste steam and condensed water. The pipes are varnished black, to cause the heat to radiate freely from them. The whole apparatus is exceedingly simple, and is managed with perfect ease. The smallest turn of the stopcock permits the steam to rush through, and to fill the pipes, when an immediate radiation of heat commences. So effectual is the process, that if the steam be admitted only twice a day, for an hour at a time, the premises are kept in a state of the most agreeable warmth for the whole of the day.

There can be no proper comparison betwixt this plan of heating and that of common fireplaces. Coal fires cannot warm the air in large workshops; they only heat the air in their own immediate neighbourhood; hence the workmen are often obliged to draw near the grate to warm themselves. According to the plan we have adopted, every part of the house is equally heated, and the whole of the workmen are as comfortable during the hardest frosts as if they were working in a pleasant summer day. In consequence of this abundant warmth, all the fires have been withdrawn. It is difficult for us to say what is the probable expense of supplying the heat, seeing that we happen to draw our steam from a boiler which is always in operation for other purposes. We believe, however, that the expense of keeping up a necessary supply of steam for such an apparatus must be very small, perhaps not more than that for a single coal fire. Our apparatus cost about £60, a sum which was saved in the course of a few winters. A similar plan of steam-heating by means of cast-iron pipes is pursued in many places, but we approve most of tubes of sheet tin soldered together. Tin is light and cheap, and allows the heat at once to operate, and, in case of explosion from improper management, would rupture or give way without causing any mischief; whereas iron is heavy and dear, takes long to heat, and in bursting would perhaps cause some injury. Excellent, however, as is the process which we have mentioned, we do not believe that it is calculated for private dwelling-houses. In the first place, few domestic servants can be trusted with the management of any apparatus of this description, and this forms an almost insurmountable obstacle to the general introduction of the process; secondly, the pipes are clumsy, and therefore unsuitable for passing through elegant apartments; and thirdly, there is at times a noise of the rushing of the steam in the pipes, which would be insufferable in a private residence.

'To determine,' says Dr Arnott, 'the extent of surface of steam-pipe or vessel necessary to warm particular apartments, it is to be considered that the loss of heat from them occurs in three ways—*1st*, rapidly through the thin glass of the windows; *2dly*, more slowly through the thick substance of the walls, floor, and ceiling; and *3dly*, in combination with the air, which escapes at the joinings of the windows and doors, or at other openings purposely made for ventilation. Different writers and manufacturers have made very different estimates of the quantities of heat lost in these various ways, and as yet no exposition of the matters has been made with the accuracy which the subject deserves; but an intermediate estimate, as applied to common cases, may be shortly stated thus—that in a winter day, with the external temperature at 10° below freezing, to maintain, in an ordinary apartment, the agreeable and healthful temperature of 60°, there must be of surface of steam-pipe, or other steam-vessel, heated to 200° (which is the average surface temperature of vessels filled with steam of 212°), about 1 foot square for every 6 feet of single glass window, of usual thickness; as much for every 120 feet of wall, roof, and ceiling, of ordinary material and thickness; and as much for every 6 cubic feet of hot air escaping per minute as ventilation, and replaced by cold air. A window with the usual accuracy of fitting is held to allow about 8 feet of air to pass by it in a minute, and there should be for ventilation at least 3 feet of air a minute for each person in the room. According to this view, the quantity of steam-pipe or vessel needed, under the temperatures supposed, for a room 16 feet square by 12 feet high, with 2 windows, each 7 feet by 3, and with ventilation by them, or otherwise, at the rate of 16 cubic feet per minute, would be—

For 42 square feet of glass (requiring 1 foot for 6), .	
— 1230 feet of wall, floor, and ceiling (requiring 1 foot for 120), ...	10¼
— 16 feet per minute, ventilation (requiring 1 foot for 6), ...	2⅔
Total of heating surface required, . .	20

which is, 20 feet of pipe 4 inches in diameter, or any other vessel having the same extent of surface—as a box 2 feet high, with square top and bottom of about 18 inches. It may be noticed that nearly the same quantity of heated surface would suffice for a larger room, provided the quantity of window glass and of the ventilation were not greater; for the extent of wall, owing to its slow conducting quality, produces comparatively little effect.'

LIGHTING.

The possibility of producing artificial illumination depends upon the well-known fact, that the action of high degrees of heat upon bodies which are not volatile is always attended with the *evolution of light*. There is, however, another important circumstance besides temperature to be attended to—namely, the density of the luminous body; for though hydrogen, for example, burns with intense heat, its pale-blue flame is wholly unsuitable for the purposes of illumination. There must, therefore, be present not only *burning* matter to produce heat, but *incandescent* (solid) matter, which, in consequence of the heat, shall evolve light. Carbon and hydrogen (carburetted hydrogens) become illuminators on this principle when they undergo simultaneous combustion; and the flame of an oxyhydrogen blowpipe, one of the palest but hottest of flames, produces the most intense light when directed against a solid indestructible substance like limestone. The natural and artificial products fitted for illumination are extremely numerous, and are derivable alike from the mineral, vegetable, and animal kingdoms. Economically, however, only a few are employed—these being the animal and vegetable oils, tallow, wax, resin, and coal. To their application in the form of candles, lamps, fires, and the like, we do not mean to advert, but shall restrict our remarks to their condition as gases in the ingenious process of

Gas Illumination.

The existence of an inflammable air, as a natural production, has been known from a period of great antiquity. It was observed to issue spontaneously from fissures in the earth; and we are told that it has been employed in such situations, as a source of light and heat, both in ancient and modern times. This natural gas is also found in abundance in some coal mines, where, being liable to mix largely with the air when ventilation is defective, it constitutes the 'fire-damp' so destructive to the miner. From an old wrought-out seam at Wallsend colliery, 'a discharge of this gas takes place, through a four-inch metallic pipe, of two cubic feet per second. The pipe is carried up as high as the head-gear above the shaft; and from its orifice issues, with a roaring sound, the stream of gas, which, having been ignited, forms a flag of flame seven or eight feet in length, conspicuous by day, and at night illuminating the entire neighbourhood.'

The artificial production of an inflammable air from coal is first mentioned in a letter by Mr Clayton, rector of Crofton, at Wakefield, in Yorkshire. In this letter, addressed to the Royal Society, May 12, 1688, he states that he distilled coal in a close vessel, and obtained abundance of gas, which he collected in bladders, and afterwards burnt for the amusement of his friends. Other experimenters, among whom Bishop Watson is conspicuous, followed Mr Clayton; and the properties of coal-gas, and the method of preparing it, thus became well known to chemists about the beginning of last century.

It was only, however, esteemed as a philosophical curiosity until the year 1792, when it attracted the attention of Mr Murdoch, an engineer, then residing at Redruth, in Cornwall. In that year he commenced a series of experiments on the gases obtained by the action of heat upon coal, wood, peat, and other inflammable substances, and actually prepared coal-gas on a scale sufficiently large to light up his own house and office. Five years after, while living at Cumnock, in Ayrshire, he again erected a coal-gas apparatus. In 1798, he was engaged to put up his apparatus at the manufactory of Messrs Bolton and Watt, Soho, near Birmingham, where he continued to experiment, with occasional interruptions, until the year 1802. It does not appear, however, that much attention was excited by these first efforts at gas-lighting, except among a very few scientific individuals, until the general illumination at the peace of Amiens afforded an opportunity for a more public display. On this occasion the front of the manufactory was brilliantly lighted up by the new method, and it at once attracted the wonder and admiration of every one who saw it. 'All Birmingham poured forth to view the spectacle; and strangers carried to every part of the country an account of what they had seen. It was spread about everywhere by the newspapers; easy modes of making gas were described; and coal was distilled in tobacco-pipes at the fireside all over the kingdom.'

By the exertions of a Mr Winsor, a company was formed in 1804 for supplying London with gas; but it struggled for many years with the difficulties at once of inexperience and public prejudice, and was a source of loss to many individuals. At length most of these difficulties were overcome, and gas-lighting began to spread over the kingdom. Its progress in dwelling-houses has been retarded by several considerations, most of which are now in a great measure overcome. It was injurious to delicate furniture, and to many of the wares exposed in shops; it often caused headaches when used in close apartments; and above all, it was dirty, and had a most disagreeable smell.

Science, however, has not been deaf to these complaints urged against the obnoxious qualities of her gift; by means of the joint labours of the chemist and practical engineer, all reasonable grounds of objection have been long ago removed; and the art is now so perfected in our best gasworks, that it is doubted whether much remains to be discovered either for simplifying the process or improving the quality of the product. It is true that unburnt gas has still a disagreeable smell, but this, instead of being an evil, is in reality a most valuable property; it thus gives warning of its own escape, at once directing the attention of the consumer to his stopcocks or fittings, without some imperfection of which the smell of gas cannot be perceived.

The success which has attended gas-lighting wherever it has been introduced, has now effected its adoption in almost every town and village of any importance in Great Britain. The continental nations are slowly following our example—employing coal, oil, and other sources of gas, according to circumstances. In America, it is used extensively in the large towns; and it has even reached the remote colony of New South Wales, the town of Sydney being now lighted in this manner. The employment of gas at a distance from towns is limited by the expense of the apparatus compared with the quantity of light required; but where the annual expenditure for light is not less than £40, it is probable that gas might be made with advantage.

The employment of gas made by the decomposition of oil was at one time common in Britain. It had two great advantages over coal-gas—namely, a greater brilliancy of light, and a much simpler mode of preparation. These qualities, however, have not enabled it to compete with the superior economy of its rival; and the several oil-gas establishments which were erected at different places are now converted into coal-gas manufactories, or entirely abandoned. Though refuse oily matters are still common as a source of gas on the continent, and though these, as well as resins, turf, wood, and the like, might be advantageously employed where good bituminous coal is scarce, we shall not advert to their treatment, but confine our notice to the manufacture of coal-gas, as commonly practised in Britain.

Nature and Properties of Coal-Gas.

In their physical properties gases are similar to common air, which is itself included among them. Like it, they are elastic, for the most part invisible, and possessed of little weight when compared with liquids and solids. They are either simple—by which is meant that they consist of only one ingredient—or compound. We find among them some that are capable of burning when supplied with common air; others that do not burn, but, like common air, assist the combustion of inflammable substances; while a third class have neither of these properties.

The gas prepared from coal is neither a simple nor a single gas; it is a very variable mixture, chiefly composed of two inflammable gases, commonly known by the terms olefiant gas and light carburetted hydrogen. Both these gases are compounded of hydrogen and charcoal in definite proportions. The first—namely, olefiant gas—is composed of 2 atoms of hydrogen with 2 atoms of charcoal; or by weight, 2 hydrogen to 12 charcoal. Its specific gravity—that is, its relative weight when compared with common air—is ·9722, common air being considered as unity, or 1·000. The weight of 100 cubic inches is 29·652 grains. When passed through red-hot tubes, it is easily decomposed, depositing charcoal, and evolving light carburetted hydrogen, and hydrogen. When pure, it has no taste, and scarcely any smell; it burns with a dense white light, combining with three times its bulk of oxygen; or by weight, 14 olefiant gas with 48 oxygen.

The second—namely, light carburetted hydrogen—is composed of 2 atoms of hydrogen, combined with 1 atom of charcoal; or by weight, 2 hydrogen to 6 charcoal. Its specific gravity is ·5555; the weight of 100 cubic inches is 16·944. It does not part with its carbon when passed through red-hot tubes unless the heat is very intense. It is this gas which is met with in coal-mines. According to the experiments of Sir Humphry Davy, it forms explosive mixtures with air when the latter is mixed with it in any proportion between 5 and 14 times its bulk; it burns with a yellowish flame, combining with twice its bulk of oxygen; or by weight, 8 light carburetted hydrogen to 32 oxygen. (See CHEMISTRY, p. 297.)

Other gases enter into the composition of coal-gas, though in smaller proportions; thus hydrogen, carbonic oxide, and nitrogen, are uniformly present; and it is inferred from the result of experiments by Dr Faraday on oil-gas, that coal-gas also contains certain other compounds of hydrogen and charcoal in a state of vapour. To these last, in which the proportion of charcoal is very high, both the smell and a considerable increase in the luminous property are attributed.

An analysis of 100 measures of coal-gas, of specific gravity ·650, by Dr Henry, is as follows:—

Olefiant gas,	10
Carburetted hydrogen,	82·2
Carbonic oxide,	3·2
Nitrogen,	1·3

Mr Clegg has given an analysis of 100 parts of gas, specific gravity ·471, as follows:—

Olefiant gas,	8
Carburetted hydrogen,	72
Carbonic oxide and hydrogen,	13
Carbonic acid,	4
Sulphuretted hydrogen,	3

The relative proportions of the different ingredients in coal-gas are ever varying, being dependent upon the quality of the coal from which it is made, and to a considerable extent upon the methods employed in its preparation; and, as may be supposed, it must vary also in its specific gravity and luminous quality. When it is made in the best manner from good coal, the specific gravity is sometimes as high as ·675, or even ·700; in other circumstances, it is as low as ·400, or even lower. The former specific gravity indicates with tolerable certainty a large proportion of olefiant gas; the latter a superabundance of light carburetted hydrogen and hydrogen. And as the amount of light evolved by combustion depends greatly upon the quantity of olefiant gas, which has a high specific gravity, the specific gravity of any specimen of coal-gas may be taken as a pretty correct indication of its actual illuminating value—the heaviest gas giving the greatest amount of light, and *vice versâ*.

It is a curious fact, that the dilution of the heavier gases by hydrogen does not only deteriorate their quality by the actual amount of dilution—as in the familiar example of spirits and water—but to a much greater extent. This fact, important to the makers of gas, has been experimentally proved by the author of the article *Gas-Light*, in the Encyclopædia Britannica. In this article it is thus stated:—'In the first experiment, we took a portion of coal-gas, of the specific gravity ·67, which we found consumed at the rate of 4400 cubic inches per hour, and yielded the light of 11 candles, being 400 cubic inches per hour for the light of one candle. This gas being diluted with a fourth part of its bulk of pure hydrogen, acquired the specific gravity ·55, and wasted away at the rate of 6545 cubic inches per hour, yielding the light of 10 candles. As a fifth part of the compound gas was hydrogen, the remaining four-fifths, amounting to 5236 cubic inches, was the quantity of the coal-gas, which, in its diluted state, gave the light of 10 candles for an hour; so that 524 cubic inches of the original coal-gas were requisite to give the light of one candle for the same time. But in its unmixed state, 400 cubic inches were sufficient to give the light of one candle for an hour, and consequently the deterioration caused by the dilution was in the ratio of 524 to 400, or of 100 to 76, being 24 per cent.'

A similar or even greater proportionate deterioration is caused by the carbonic oxide and nitrogen commonly present in coal-gas. Their amount, however, is small when compared with the hydrogen occasionally found, and is much less under the control of the gas-maker. Two other gases—namely, carbonic acid and sulphuretted hydrogen—are sometimes mixed with coal-gas; but they are to be regarded as impurities which ought to be separated by the manufacturer, and not as constituents of the gas. They may be detected by the following processes:—1. Shake a portion of the gas, with limewater, in a phial. If carbonic acid be present, the water will become turbid by the formation of carbonate of lime. 2. Write on, or wet a slip of paper with a solution of sugar of lead; and while still wet, expose to a stream of the suspected gas. If sulphuretted hydrogen be present, even to the amount of one part in twenty thousand, it will be at once detected by the browning or blackening of the solution of lead.

Manufacture of Gas.

The best coal for gas-making is that which is called *cannel*, or parrot. It is characterised by its great hardness and close texture; its colour is dark-brown, approaching to black; it does not soil the fingers when handled; and it has a splintery conchoidal fracture, the broken surface exhibiting a peculiar velvety lustre.

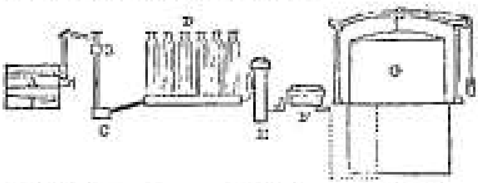
The best parrot we have seen is procured from the Fife and Mid-Lothian coal-fields, having a specific gravity of from 1·2 to 1·5.—The produce of gas from this coal, on the large scale, is usually about 1000 cubic feet from 200 lbs., and its specific gravity is sometimes as high as ·700. We have seen a small balloon filled with 800 cubic feet of this gas, which would not ascend, to the great disappointment of the experimenter, who had found no difficulty on former occasions with an inferior quality of gas.

The analysis of Newcastle coal, according to Dr Thomson, is as follows:—

Carbon,	75·28
Hydrogen,	4·18
Nitrogen,	15·96
Oxygen,	4·58

to which may be usually added sulphur and earthy matters.

When the coal is exposed to a high temperature, these ingredients are separated from each other, and enter into a new series of combinations, giving rise not only to coal-gas, but at the same time to a variety of other products—namely, water, tar, naphtha, carbonate and sulphate of ammonia, carbonic acid, and sulphuretted hydrogen. These substances are separated from the gas in the apparatus which we have attempted to exhibit by the following woodcut:—



Where dimensions are stated, they are taken from a small gaswork belonging to a town of 5000 inhabitants. A represents the retort, of which several are commonly in use at once. It is a cylindrical, elliptical, or D shaped vessel of clay or cast-iron, about 8 feet in length, and 20 inches internal diameter. It is built horizontally into a furnace, either singly or otherwise, in such a way that the fire can act completely around it, so as to keep it at a full red heat. Iron retorts have, until of late, been almost exclusively used, but they are inferior in almost every respect to the clay retort which has been lately introduced. For instance, the latter is only one-third of the cost of iron, and we state with confidence that it is more durable, that it can be heated with less fuel, that it is easier kept at a uniform heat, and that it consequently produces a larger quantity of gas. It is now the practice at some works to use a combination of clay and iron retorts—the former being so disposed as to receive the highest temperature.

The retort, whether of clay or iron, has two openings, both external to the building; one of them is the end of the cylinder, which is furnished with a closely-fitting lid of iron; the other is an aperture in its upper surface for the exit-pipe, which passes from the retort to B, a vertical section of the hydraulic main—this is a round or square vessel of iron, about 10 inches by 14 in size. It passes above and in front of the whole line of retorts; it is half filled with liquid, into which the exit-pipe dips; it serves to collect the gas and other matters from any number of retorts, and to cut off its escape by any retort which may be open. It is connected by means of a wide pipe with C, the tar-cistern, in which the tar and everything deposited from the gas by cooling is collected. From the tar vessel a tube rises in a sloping direction to D, the condenser—a series of tubes through which the gas is made to pass, that it may be thoroughly cooled. To the condenser there is sometimes attached E, an upright cylindrical vessel filled with brushwood, through which the gas passes before it is sent to F, the chemical purifier. There are usually several vessels of this kind, and of various forms; they contain quicklime, either dry or mixed with water to the consistence of cream. From the purifier, a tube passes to the bottom of the tank in which G, the gasometer, is suspended. This is a large vessel of sheet-iron for holding the gas, generally of a cylindrical form, and single; but sometimes, for the economising of space, made of several cylinders, which fit one into the other, and rise as they are charged with the gas, in telescope fashion; hence known as 'telescope gasometers.'

The retort being heated to a red heat, the charge of coal, about 200 lbs. or upwards, is quickly shovelled in, and immediately gives off dense smoke and flames. The mouth of the retort is now closed by its lid, which extinguishes the flame by shutting off the air, and leaves no outlet for the dense vapours arising from the coal, except by the exit-pipe; they rush through this tube, and are heard bubbling up into the hydraulic main until the charge is exhausted.

It is of importance in this part of the process to attend to the temperature of the retort; for if it is too hot, some of the heavy gas will be decomposed, depositing part of its carbon, and forming light carburetted hydrogen; if, on the contrary, it is not of a certain temperature, there will be formed a large proportion of tar, and the gas will be light and of bad quality. It is also essential to draw the charge before it is quite exhausted, as the last portions of gas consist chiefly of hydrogen and carbonic oxide, both of which, as already stated, have a most injurious effect upon the quality of the whole product.

The time required for a charge of cannel coal is from three to four hours. As soon as one is withdrawn in the form of coke, a second is thrown in, the process being thus continued uninterruptedly night and day. It is of considerable importance that the coals be thoroughly dried, and in pieces about the size of the hand; by these means much waste of fuel is avoided, and the process greatly accelerated.

The dense vapours which pass from the retort into the hydraulic main consist of coal-gas mixed with tar, water, naphtha, salts of ammonia, carbonic acid, sulphuretted hydrogen, &c. Being subjected to a process of cooling in all parts of the apparatus as far as the brushwood box, the impurities are condensed, with the exception of the carbonic acid and sulphuretted hydrogen; and from the sloping or descending direction of the apparatus to the tar-cistern, they collect in it, and are pumped off as occasion requires. A considerable quantity of carbonate and sulphate of ammonia is also deposited in the tubes of the condenser in a crystalline form, and requires to be cleared out periodically. This is easily accomplished by passing a current of steam down each pair of tubes, by which these salts are at once dissolved. The gaseous matter still retains particles of tar mechanically mixed with it, from which it is freed by being forced through the brushwood vessel. It is now made to enter the chemical purifiers, where it is either washed by agitation with a mixture of quicklime and water, or is passed through a succession of trays covered with thin layers of this substance in a slightly-moistened state. In this process the lime combines with the sulphuretted hydrogen and carbonic acid, forming hydrosulphuret and carbonate of lime, which, being both solid, are retained, and the gas, now purified, is at once passed into the gasometer, where it is stored for nightly consumption.

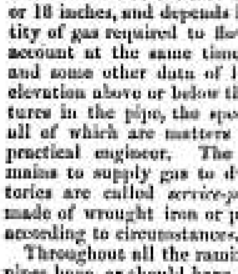
Various improvements are every year being effected in the manufacture of gas—these modifications having reference chiefly to the retorts, the purifying apparatus, and the separation of the impurities, so as to render them available in some of the useful arts. Thus clay and iron retorts of various shapes are now used; ammonia is separated by using alum, green vitriol, or dilute sulphuric acid; gasometers are also variously constructed; the tar is economically employed as fuel or in the preparation of naphtha; and this naphtha is used either as a solvent, as an independent source of light, or in the impregnation of coal-gas, whereby its illuminating power is vastly increased. (See p. 458.)

Distribution of Gas.

The distribution of the gas from the gasometer to its places of consumption is effected in cast-iron pipes called *mains*. They are cast in pieces of from 4 feet 6 inches to 9 feet in length, according to their diameter, and are jointed together to any required length. The diameter of the mains varies from 1½ inches to 16 or 18 inches, and depends in every case upon the quantity of gas required to flow through them, taking into account at the same time the distance it has to flow, and some other data of less importance—such as the elevation above or below the horizontal line, the curvatures in the pipe, the specific gravity of the gas, &c. all of which are matters of exact calculation to the practical engineer. The pipes branching from the mains to supply gas to dwelling houses or manufactories are called *service-pipes*. They are commonly made of wrought iron or pewter, and vary in diameter according to circumstances.

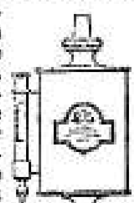
Throughout all the ramifications of the fittings, the pipes have, or should have, an inclination to the main, and the main itself should incline towards the gas-work. The necessity for this arrangement arises from the presence of watery vapour in small quantity in the gas; being condensed into water in the pipes, it naturally collects in the lowest part, and at last interrupts the continuous flow of gas, so as to cause a flickering of the flame in the burners. Where the proper inclination of the pipes cannot be attained, this is obviated by placing a stopcock and pipe at the part where liquid is apt to collect, so that it can be let off from time to time as it accumulates.

The quantity of gas charged for by gas companies was at one time regulated by the number and kind of burners employed, and the time they were allowed to burn; but this was everywhere found to be a most uncertain and unsatisfactory method of guessing the consumption by any individual. It is now obviated by the use of a very simple and ingenious instrument invented by Mr Clegg, and subsequently improved by Mr Crosby; it is called the *gas-meter*, and consists of a hollow case of iron, containing an inner cylinder or drum, so constructed, that the gas passing through it, by the pressure it receives at the gas-work, causes it to revolve on an axis; each revolution allows a known quantity of gas to pass through the water, with which the outer vessel is partially filled, to the exit-pipe, and as the revolutions are registered by wheel-work and an index, the quantity of gas consumed is indicated with considerable accuracy. It is usually examined quarterly by a person employed by the gas company, who charges the consumer according to the quantity indicated. Various improvements have recently been effected in the common meter, chiefly with a view to prevent fraudulent consumers from tampering with the apparatus, in order to make the gas pass without marking register.



The rate at which gas escapes from an open burner is determined, and to a certain extent regulated, by the pressure applied to it at the gas-work. This is increased or diminished by the application of weights to the counterpoise of the gasometer, and is measured by the elevation of a column of water in a bent glass tube. The usual pressure is about one inch of water above the atmospheric pressure. By the experiments of Messrs J. Milne and Son, Edinburgh, it appears that every addition of one-eighth of an inch to the pressure causes an extra expenditure equal to about fourteen per cent., and variations to a much greater amount than this are not unfrequent. It is of usual occurrence, for instance, in the vicinity of large manufactories, when their lights are extinguished; and though attention is usually paid to this at the gas-work, it is impossible so accurately to regulate the pressure according to the quantity of gas required by any particular main, as to obviate all loss or inconvenience from this cause.

An increase of expenditure is also experienced in the lights that remain burning. When other lights in the same premises have been put out, the gas that supplied these burners increases the pressure in the pipes, and is diffused over the other lights in the premises; and if not checked, there will be comparatively little reduction in the expenditure, although one-fifth of the lights are extinguished. To obviate these inconveniences, instruments called *governors* or *regulators* have been constructed; some operating as permanent escapes, and others opening and contracting by means of springs and levers acted upon by the current of gas. The following woodcut represents a regulator invented by Messrs J. Milne and Son, which has been found to answer well in the premises where this sheet is printed. It can be readily placed upon any service-pipe, and being adjusted to the pressure required, it gives a regular flame and expenditure of gas, notwithstanding any variation of pressure in the main.



It is a very general complaint in cotton-mills, that the light in the under floor is deficient, while at the upper floors there is a greater supply of gas than is necessary. This inconvenience arises from the upper floors being subject to less atmospheric pressure than the under one, every additional rise of ten feet making a difference on the pressure of about $\frac{1}{10}$th of an inch. Suppose a mill of six floors is supplied from the gas mains at a pressure of $\frac{6}{10}$ths, and that the difference of altitude between the highest and lowest lights is equal to fifty feet, the gas in the highest or sixth floor will issue from the burners at a pressure of $\frac{11}{10}$ths, the fifth floor at $\frac{10}{10}$ths, the fourth at $\frac{9}{10}$ths, and so on. To gain full advantage in this case from the regulator, one should be placed in each floor; and in this manner a regulator placed in the top or sixth floor, and adjusted to $\frac{6}{10}$ths of an inch pressure, will send the surplus pressure of $\frac{5}{10}$ths to the floor below; another regulator placed in the fifth floor, also set to $\frac{6}{10}$ths, will send the surplus pressure of $\frac{4}{10}$ths down to the fourth floor; a regulator on the fourth floor will send the surplus $\frac{3}{10}$ths to the third floor; and the regulator in it will send its surplus $\frac{2}{10}$ths to the second floor. Between that floor and the ground, the fall being ten feet, the remaining surplus of $\frac{1}{10}$th is lost; and thus a uniform pressure of $\frac{6}{10}$ths will be established over the whole building; and to prevent any inequality from outward pressure, a regulator ought to be placed in the ground-floor also.'

Burning of Gas.

When coal-gas is burning, it combines with the oxygen of from 10 to 12 times its bulk of common air, or even more, the quantity varying according to the quality of the gas. By this combination, which in fact constitutes combustion, watery vapour and carbonic acid are formed—the former being composed of all the hydrogen of the gas, with 8 times its weight of oxygen, the latter consisting of all the charcoal, united with oxygen, in the proportion of 6 to 16 by weight. These products, which are similar to those from a candle or lamp, mingle with the air of the apartment, and are removed with it in the course of ordinary ventilation. In some circumstances, the watery vapour is condensed on the windows; and in street-lamps it may be seen, when the weather is cold, bedewing the inside of the globes, and even collecting in considerable quantity at the bottom. The carbonic acid is not removed in the same manner by condensation, and it may accumulate to a hurtful extent; this can only happen, however, where ventilation is peculiarly defective, and the remedy is sufficiently apparent. When the carbon is not all consumed, it flies off in smoke—an occurrence which should be guarded against, not only on account of its offensive qualities, but also from the great loss of light in proportion to the gas expended, which it invariably indicates.

The emission of light, though usually an effect of combustion, is yet a different phenomenon. Many substances, as already stated, are incapable of burning, and yet emit the most brilliant light when they are intensely heated. Gases possess this quality in a very feeble degree. Air, indeed, may be so hot that a solid body becomes luminous in it, while it gives off no light of itself. The temperature at which solids begin to emit light is about 800° of Fahrenheit; they are then incandescent, or red hot; and if the temperature be increased, they become more and more luminous, until, at 4000° or 5000°, they are so brilliant, that the eye cannot look on them without pain.

The lime-ball-light is an example of this fact; it gives an intense light without being itself burnt. Pure hydrogen burns with a pale bluish flame; and coal-gas, when made to burn without depositing its charcoal, by reducing the flame to a speck, or by previously mixing it with common air, gives also a feeble blue light. The light from coal-gas, then, actually comes not from the gas itself as gas, but from the particles of charcoal which are separated from their gaseous combination by the incipient combustion: they exist as solid charcoal in the flame, and being heated by it to intensity, they are highly incandescent.

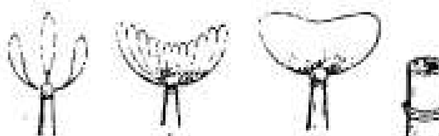
The presence of charcoal in a free state can be detected in a gas or candle flame by the very simple experiment of introducing the edge of a white plate into it; at the lowest part of the flame, where it is still blue, the plate is not affected—the charcoal is not yet deposited; the same happens at the top of the flame, the charcoal being now burnt; but in the middle, at that part whence the light is seen to be chiefly emitted, the plate is instantly coated with pure carbon.

It will now be understood that the manner in which gas is burnt may actually have an effect upon the amount of light derivable from a given quantity, the condition for obtaining the largest amount being, that the charcoal deposited in the flame shall be heated to the greatest possible intensity. This condition is very differently attained by the different burners in common use. It is found by experiment, that when an argand burner is constructed with holes of a proper size, and of a proper distance from each other, with an internal tube so proportioned as to admit the exact quantity of air necessary for the perfect consumption of the gas, it gives more light than can be obtained from the same quantity of gas by any other method of burning.

In the argand, the flame is steadied and the current of air increased by the use of a glass chimney, which sensibly diminishes the size of the flame, at the same time increasing its brilliancy. It has been proposed to improve this burner by heating the air with which it is supplied by means of a double chimney, the outer glass being so constructed that the air must descend between it and the inner glass before it arrives at the burner; and it has been stated that a saving of gas to the extent of 20 per cent. may be effected in this manner. This assertion has, however, been contradicted by other experimenters; and certainly the plan has not been adopted into common use.

The proper size of the holes for an argand burner, and the length of flame which gives the greatest proportion of light, have been experimentally determined by various individuals. Drs Christison and Turner state, that the diameter which appeared to answer best for coal-gas of the specific gravity ·6, when the holes are ten in a circle of three-tenths of an inch radius, was a thirty-second of an inch; the distance between the holes should be about one-seventh of an inch. A series of experiments, by the same individuals, on the relative amount of light from flames of different lengths in an argand burner, show that the light is increased about six times for the same expenditure by raising the flame from half an inch to three or four inches; but beyond this height the gain was comparatively little in the burners experimented on.

Other burners in common use are known by the names—single jet, cockspur, union-jet or fan, fish-tail, and bat-wing. In the single jet, the gas issues from a single aperture; in the cockspur (*a*), from three apertures, as shown in the figure; in the union-jet (*b*), from a series of small holes, so that all the jets may unite laterally; in the bat-wing (*c*), from a slit instead of a



a *b* *c* *d*

series of holes; in the fish-tail, by making two jets cross each other, and yet issue from the same hole; and in the argand (*d*), from a circle of small holes, the centre of which is an open space for the admission of air. The relative quantity of light which they yield from the combustion of similar quantities of gas is thus given by Dr Fyfe; namely, single jet, 100; fish-tail, 140; bat-wing, 160; argand, 180.

These burners are commonly used in street-lamps, and they are convenient in some circumstances; for instance, in small apartments where less light is required than is given by an argand burning at its full height—namely, three or four inches; and it should be distinctly known, that the greatest amount of light is only obtained from any given quantity of gas by burning it in this manner.

The single jet burners, with an aperture from a twenty-eighth to a thirty-sixth of an inch, give most light in proportion to the gas burnt when the flame is five inches in height. In the experiments of Drs Christison and Turner, they found that in the case of coal-gas of specific gravity ·602, while the lights emitted from a two-inch and five-inch flame were as 556 to 1978, the corresponding expenditures were to each other as 605 to 1437. Hence the ratio of the lights in reference to the expenditure was as 100 to 150.

If the flame smokes in an argand, it is evident that some adjustment is necessary, and the gas should either be lowered or the chimney contracted, until it gives a clear cylindrical flame of three or four inches in height. In the fish-tail burner, if the flame flares, or makes a noise in burning, the gas should also be lowered; but to diminish either much below these points, does not effect a saving of gas in proportion to the diminution of light. Hence the important conclusion, that it is more economical when the light is too strong to procure a smaller kind of burner, or where several lights are used, to put out some of them altogether, than to lower the flame in the whole.

Various calculations of the relative expense of gas-light, compared with other lights, have been made. Thus when tallow candles are 9d. per lb., wax candles three times the price of tallow, train oil 2s. per gallon, and coal-gas 9s. per 1000 cubic feet, it is computed that the relative expense will be as under—namely,

Wax,	100	Oil,	5
Tallow,	25	Coal-gas,	3

In a recent paper by Dr Fyfe, the relative expense is computed as follows:—Gas giving 12 per cent. condensation with chlorine—that is, containing 12 per cent. olefiant gas, at 8s. 6d. per 1000 cubic feet—being 1, the expense of wax-light of equal quantity will be about 14; sperm-oil, 8; tallow candles, 7½; rectified whale-oil, 5; common train-oil, in an improved description of burner, 2.

Many individuals, who complain that the adoption of gas-light has proved no saving to them, will be surprised at the above statements. They will find, however, on examination, that they now light up their houses far more brilliantly than they were accustomed to do when candles or oil-lamps were in use, and that their equal expenditure is thus accounted for.

In addition to its greater economy, gas-light may also be pronounced safer than any other ordinary light. It produces no sparks, it cannot be carelessly placed in contact with bed-curtains or substances easily ignited, and it requires scarcely any attention. It may be turned down in an instant to the most minute speck of flame, ready to be restored, when necessary, by the simple turning of the stopcock; and even when it escapes by the carelessness of an attendant, or a defect in the fittings, it at once indicates the accident to the whole household by the disagreeable smell which it occasions. From the large quantity which must be mixed with air before it becomes explosive, it is scarcely possible that this accident could occur in any ordinary apartment, even if the gas were allowed to escape on purpose. And as its smell so well indicates its presence in cellars, or other confined situations, where it may have escaped in quantity from the accidental breaking or leakage of a pipe, it is only by the grossest carelessness or ignorance that a light will be approached to it before it has been allowed to escape by the free admission of air. There is no such thing as the bursting of a pipe or the blowing up of a gasometer. A gas pipe may be broken, as any other pipe, by accident; and if a leaky gasometer is covered over by a building, an explosion may then take place; but these are accidents which can very rarely occur, and they do not concern in any way the ordinary consumer of gas.

Bude Light.—We have now to notice a comparatively recent method of using coal-gas, invented by Mr Goldsworthy Gurney, and called the 'Bude Light,' from the name of his residence in Cornwall, where it first became known to him. In 1823, Mr Gurney published a work on the elements of chemical science, in which he described the powerful light produced from lime by the action of the mixed gases. This light, about seven years afterwards, was employed by Lieutenant Drummond on the Trigonometrical Survey of Ireland, in consequence of which it took the name of the 'Drummond Light.' A committee of the House of Commons on lighthouses, in 1834, recommended the lime-light to be experimented on, with a view to remove the practical difficulties connected with the subject, and adapting it for lighthouse illumination. In consequence of Mr Gurney having first announced the discovery of the light, he was recommended by the committee to the Trinity House to carry out the experiment. In the course of his engagement in this office, he discovered the present light, which he considered better for lighthouse purposes, and, as already mentioned, called the Bude Light. This light is produced by introducing oxygen gas in the interior of the flame of a lamp. An ordinary flame is hollow, the exterior part being only ignited by the atmosphere; the interior part is unburnt, containing the vapour of oil and carburetted hydrogen; and the burning of this unused interior vapour, as quickly as it is distilled, by the admission of oxygen, forms the principle of the Bude Light. As soon as a small tube, conveying a stream of oxygen, is introduced into the heart of the flame, the light is immediately increased in its intensity. Since this valuable discovery was made, Mr Gurney has effected various alterations and improvements on the light. Formerly he used oil, but now he employs common street gas. This gas, however, is made to pass through a box containing naphtha, which naphthalises it, and renders it equal to the best oil, without the trouble of wicks. The London street gas, it is necessary to explain, is of bad quality, and is improved by the vapour of naphtha. The Edinburgh gas being much superior to it, would not require any such assistance. The apparatus for supplying the oxygen to the light, as used in the House of Commons, is placed in a vault beneath. It consists of two iron retorts built over a furnace, and in these is put a certain quantity of oxide of manganese, from which oxygen is evolved, and led away in pipes to a gasometer; from the gasometer small pipes proceed to the burners in the House, each conducting a stream of oxygen into the heart of the flame. The light so produced is most intense in brilliancy, but is softened by the intervention of ground glass, and illuminates with a powerful effect the whole interior of the apartment. A more perfect substitute, in every respect, for daylight, could not be found. The flame being supplied freely with oxygen, a comparatively small quantity of atmospheric air is abstracted or consumed, and all offensive heated air from the combustion is carried off by a small tube. Before the introduction of this beautiful light, the House of Commons was illuminated with 240 wax candles, dispersed about in different parts—a method of lighting which Sir David Brewster has described 'as most absurd, and such as no person at all acquainted with the physiological action of light on the retina, and the principles of its distribution, could have adopted.' Dr Ure, on being examined by the committee of members respecting the power of the Bude Light, previous to the substitution of gas for oil, observed—'I made experiments upon it very carefully in my own house last night, and compared its relative illuminative powers with argand lamps and candles with great pains, both by the method of shadows, and also by Mr Wheatstone's photometer. Mr Gurney's larger Bude lamp, furnished with a wick of five-eighths of an inch, but emitting a white flame of only three-eighths in diameter, was found to afford thirty times more light than a wax candle, and nearly three times more light than the standard flame of the mechanical lamp, which was equal to from ten to eleven candles. Secondly, Mr Gurney's smaller Bude burner, with a flame one-quarter of an inch, was found by the same methods to afford a light eighteen to twenty times greater than a wax candle.'

The adoption of the Bude Light in the House of Commons, as now improved and simplified by the substitution of gas for oil, has completely set at rest all theoretic speculations on the subject. The light is not only by far the most brilliant, without distress to the eye, but is cheaper by two-thirds than the old wax-candle plan of illumination. We believe the expense of using the Bude Light, in which naphtha is required, is about twelve times greater than that of common London gas, sizes of flame being equal; but that as the Bude flame gave twelve times more light, the expense was in reality the same, without the inconvenience of many burners, and a great consumption of air. The property of giving little heat, in comparison to what is produced by common gas, is in itself of great importance. Another useful property is, that the light may be varied in tone, from the most perfect white, down to the red ray, by increasing or diminishing the quantity of oxygen.

Inconveniences from Artificial Light.

We have now briefly to notice certain inconveniences occasionally attending the employment of gas, as well as every other kind of artificial light in common use. There are, in the first place, headache, giddiness, and other unpleasant symptoms, which are sometimes complained of in small or ill-ventilated apartments where gas is burned. These may be justly attributed to the heat and carbonic acid produced during the combustion of the gas, although they also depend to some extent upon similar changes effected on the air of the room by respiration, and would occur even to a greater degree were common oil or candles employed, so as to give an equal amount of light. The remedy for these evils is simply *ventilation*. The other inconvenience is of a more insidious nature, and may be ultimately attended with serious consequences; we allude to the injurious effect of artificial light upon the organ of vision.

It is well known that the eyes become fatigued and painful, and are actually weakened for a time, by exposure to any object strongly illuminated. This may be proved by reading even for a few minutes with one eye tied up, and then comparing the power of vision of this eye with the other. It is also remarkable that, although illumination by artificial means be much less brilliant than daylight, its weakening effect upon the eye is perceived in a greater degree. For example, let the same experiment be repeated by candle or gaslight. The exposed eye will be found now to be more weak than in the former case. The sensibility of its nervous structure in these circumstances is actually impaired for a time, and requires a short period of rest to restore its power. If the eyes be habitually exposed to this stimulus for long periods without rest, as is often the case with literary men and others, who work to late hours with artificial light, there is no doubt that a permanent weakness of the eyesight may be occasioned, which may even terminate in the destruction of the sensibility of the eye—a disease known by the term *amaurosis*, or nervous blindness.

The first intimations of these injurious effects are usually a sensation of heat and soreness of the eyelids, and pain of the eyeball, particularly at night, when artificial light is used; in some cases there is an unusual degree of irritability of the eyes, followed by flashes of light when they are touched, or specks floating before them, and ultimately dimness of vision, so that a stronger and stronger light is required. These symptoms may arise from other causes; but it is certain that they are often produced or augmented by the injudicious use of strong artificial light, when minute objects are contemplated. Happily, they may be obviated to a great degree without difficulty. To effect this, the eyes should in the first place be protected from the direct rays of the light itself, not only by raising it above the object out of the line of the eye, but also by the use of a shade placed upon it, so as to prevent its rays from falling upon the face; a minute object is now seen more distinctly than before, even with a less amount of illumination.

There is another method which may be adopted, and it has the advantage of being equally simple, though more philosophical. It is derived from the examination of the nature of light, and of the difference between daylight and that which is obtained from combustion. Sir Isaac Newton made the discovery, that light was not simple, but a compound of seven different coloured rays, such as are seen in the rainbow. More recent discoveries have reduced the number of simple rays to three—red, yellow, and blue—which exist in daylight in the following proportions; namely, red 5, yellow 3, blue 8. In artificial light the proportions are different, yellow and red preponderating to a great degree. Experiment proves that each of these rays can act separately upon the eye. For example, if the red ray only be admitted into it, as by looking at the sun through red glass, the nervous structure of the eye is for a time weakened to the stimulus of red; and when the uncovered eye is now turned to a white object, the other rays only are seen—namely, the yellow and blue, giving it a greenish tinge. If again the sun be looked at through a green glass, a white object seen immediately after will appear to be red, the eye being insensible to the complementary colours, yellow and blue. For a similar reason, when the eye, passing suddenly from daylight, views objects by means of a candle or gas flame, they appear of a yellowish hue; and, on the contrary, passing from artificial light into day, the whole prospect has a blue or purplish aspect.

It is also proved by experiment that the red and yellow rays have a more weakening effect upon the eye than blue; hence, to a certain extent, the more injurious effect of artificial light, which, as already stated, contains these rays in excess. This fact at once suggests a method of obviating the bad effects of gas or candle light, which is either to make it pass through a blue glass shade, so as to obstruct a portion of the red and yellow rays, or to reflect down blue rays by placing a blue reflector above the light; in this manner the quality of artificial light is made more nearly to approach to that of the sun, and objects are seen by it of a purer white, and agreeably cool and refreshing to the eye.

VENTILATION.

In a subsequent article on the Preservation of Health, the necessity of a constant supply of fresh air for that object will be so fully explained, that on this occasion little more than an allusion to the subject is required. Each human being consumes the oxygen of the sixth of a cubic foot per minute, replacing it from his lungs by carbonic acid gas, a substance which cannot be inhaled again without injury. Hence the necessity for a constant change of the atmospheric contents of any room in which human beings are placed—and the same law holds with regard to all the warm-blooded animals. In an ordinary apartment heated by a common open fire, there is an imperfect kind of ventilation always going on by means of the fire, which draws in through the door, windows, and other apertures, fresh air to supply that consumed by itself, or which the chimney-draught otherwise carries off. This is imperfect, in as far as the draught may only clear a certain space near the bottom of the room between the door or windows and the fireplace, and because it may over-rarefy the air of the room in instances where the apertures are usually well closed up; also, in as far as it only operates when there is a fire, and therefore not in the summer time. It therefore becomes desirable that a regulated mode of ventilation, calculated to be thoroughly and at all times effectual, should be applied to ordinary apartments. It is not less necessary that churches, court-rooms, theatres, and all large halls in which great numbers of persons assemble, should be subjected to a mode of ventilation regular, certain, and complete. Nor is it unworthy of notice that a regular means of ventilation is also required in stables, cow-houses, and other places where valuable animals are kept.

Ventilation by Apertures in Ceilings and Flues in Walls.

The simplest and perhaps the earliest expedient for ventilation was one formerly much employed in churches and other places of assembly. It consisted merely in a round hole of considerable size opened in the ceiling, and communicating with the outer air by a tube or trunk, having a cap over the top to keep out rain. The expired air of the assemblage, by virtue of its greater rarity, of course ascends to the ceiling, and tends to find its way out by this aperture; but it does not pass forth either rapidly or with certainty, and the plan is therefore to be considered as defective.

The plan adopted for carrying off used air in the Derby Infirmary, and other buildings warmed by Mr Strutt's plan, appears strikingly inferior in efficiency to the expedients for heating. The whole arrangement consisted in a flue from each room, terminating in the space under the roof, through which was a passage to the outer air, protected by a turn-cap. There cannot be, we apprehend, any certainty that such flues will act for the removal of used air.

Sir John Robison exemplified Mr Strutt's plans in his house in Randolph Crescent, Edinburgh, with an ingenious improvement upon the ventilation flues. Having small fires in each room—for the purpose, mainly, of drawing the warmed air from its reservoir, the well of the staircase, into each apartment—he passed the ventilation flues close beside the ordinary smoke chimneys. The consequence was, that the heat of the smoke chimney was imparted to the ventilation flue, an upward current established, and ventilation proceeded with certainty. This is a mode of ventilation which may be advantageously adopted in new houses, but could not easily be applied to those already built. In the instance above, the air of each apartment reached the ventilation flue through a slit masked by the stucco-work upon the ceiling.

In many cases it may be found expedient to adopt a simple mode of ventilation which was suggested by Dr Arnott, and applied in Buckingham Palace. An aperture of from four to six inches is cut in the wall over the chimney, as near to the ceiling of the apartment as may be convenient. Into this is fitted a short metal tube, having a valve suspended at the extremity next to the apartment, and capable of opening inward to the chimney, but not in the other direction, by which means a return of smoke is prevented. This simple apparatus may be painted, or otherwise made ornamental. It operates by virtue of the draught in the chimney. Whenever that is active from the presence of a fire, the valve is seen to open inwards, and a stream of air from the top of the apartment passes through into the chimney, and is carried off. The operation is precisely equivalent to the stream of air always passing into a chimney between the fire and the mantelpiece, but has the great superiority of draining off the most impure air in the room.

The Ventilating Fan and Pump.

This is a piece of mechanism which has for many years been used in factories, to which it is particularly applicable, from the readiness with which a mechanic power to keep it in motion can be obtained from the steam-engine. It is placed at the top of a flue, into which branches from all parts of the establishment proceed. Consisting simply of what its name imports, it only requires to be set in motion in order to draw off the air from every apartment communicating with it. Dr Ure calculates that a steam-engine of one-horse power will drive a fan which has equal effect with a draught produced by fuel equal to twenty-horse power; in other terms, the economy of ventilation is to that by chimney-draught as 38 to 1. Of its efficacy there seems no room for doubt; but as yet there has been scarcely any attempt to show how it can be conveniently applied elsewhere than in factories. Dr Arnott has shown pretty clearly that it has heretofore been used in a very uneconomical way, in consequence of ignorance. A far greater power has been in most cases applied than was strictly necessary, its constructors not being aware that air, like other fluids, cannot be forced more quickly through one part of a passage than it enters by another, without a super-expenditure of force. Under judicious arrangements, Dr Arnott thinks that fans which have required steam-engines to drive them, might be made to operate by a weight no greater than that required for a large clock. He seems, however, to prefer to the fan a valved piston moving like a pump in a square or round trunk. 'Such a pump,' says he, 'answers not only for extracting foul air, but also for forcing in pure air where wanted. It may,' he adds, 'be fixed in position, or may be a movable piece of furniture; to be used, for instance, to draw out air from the top of a window opened on a ball night, or from an opening in the wall, concealed from view by a picture frame. By such a pump, air of perfect purity, and in any quantity, may easily be sent from any neighbouring situation, as from the top of a tower, to supply a dwelling placed where unwholesome exhalations might enter by the doors and windows.'

Fire-draught.

One of the most certain and effectual of all means of ventilation is that by fire-draught. It proceeds upon the simple principle, that combustion demands a constant supply of air; a fire being placed in a certain convenient situation, and closed up from all supply of air excepting through flues communicating with the rooms to be ventilated, a flow of air out of those rooms is necessarily established, and this will proceed as long as the fire is kept burning. The plan has been exemplified with success in mines, where a fire being lighted at the bottom of a shaft, air is drawn off in all directions around and sent up the shaft; to replace which, fresh air is constantly pouring down other shafts. There is one objection to fire-draught ventilation—that in most circumstances it requires both attention and considerable expense; but this might perhaps be overcome by a little ingenuity. There can at least be no doubt that, where established, it most completely answers the end in view, while it is equally true that in some situations there are means of arranging it in such a way as to require neither attention nor expense.

The plan has been exemplified of late years by Dr D. B. Reid, first in his class-rooms in Edinburgh, afterwards in the temporary House of Commons, and since then in various other structures, public and private. We shall endeavour to give an account of Dr Reid's arrangements, but deem it necessary first to advert to the plans of Mr Joseph Fleming of Glasgow. Mr Fleming originally contemplated ventilation in immediate connection with the objects of his profession (medicine), and in 1833 published a pamphlet on what he called a Disinfecting Apparatus, which he proposed to apply in hospitals and in beds for the sick generally. It consisted simply in tubes communicating between the top or back of the beds and a fire solely supported by air through those channels, so that any infectious virus arising from the patient was in every case carried off without coming in contact with those who stood near.

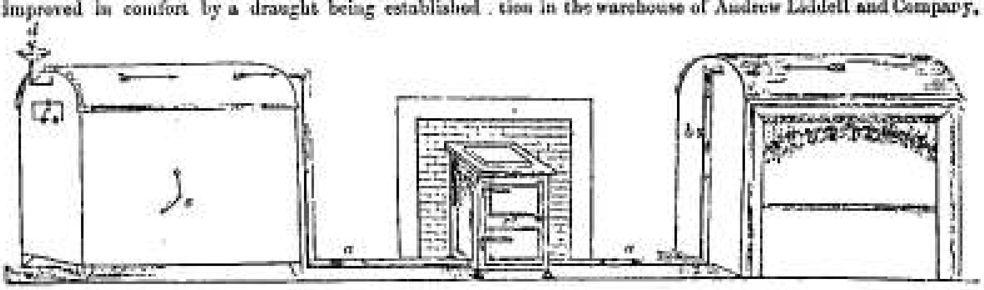
The plan was first tried in a large and densely-peopled house, which had long been remarkable as a focus of fever infection, in consequence of the wretchedness and filth of the inhabitants, and the narrow space allotted to them. This building, usually called, from its size and appearance, *the Barracks*, was connected with the factory of *Messrs* Houldsworth, in Anderston, a suburb of Glasgow. It was divided into a multitude of small apartments, each consisting of a single room and closet, and each devoted to the accommodation of a single family. The total amount of inhabitants is rarely under 500. We have inspected this building, and can testify that the habits of the occupants, with a few exceptions, are of that uncleanly and ill-ordered character which naturally results from a mode of life in which housewifely economy is not a part of female education. The huddling of so many human beings into such small space, joined to filth, poverty, and intemperate habits, rendered the building up to 1832 the permanent abode of pestilential disease. Five have been seen ill with fever in one room. In the two last months of 1831, the total cases of typhus were 57. It was then that Mr Fleming was allowed by the proprietor to apply his ventilating process. From an upper corner of each of the apartments he led a metal tube of about an inch and a half in diameter, which, passing into the adjacent gallery, there met and joined a general pipe, nine inches in diameter, suspended immediately under the ceiling. One of these general pipes passed along each gallery in the four storeys, and the whole joined in one vertical tube at the end of the house, communicating at the bottom with the base of an adjacent chimney-stalk serving the work. It follows that, when this flue is active—and practically it is so day and night—a draught is established upon the air contents of every room in the house. To regulate this draught according to necessity, a valve or damper is placed in the short horizontal channel of communication between the vertical tube and the basis of the flue. In ordinary circumstances, when the door of one of the rooms is shut, the rush of air into the aperture of the tube is sufficient to extinguish a candle held near. It becomes quite clear to any one inspecting the process, that while the chimney is active, and the aperture kept open, there must be a complete exchange of air in each room in no long space of time. It may be remarked, that no expedient has been adopted to obviate the chance of an over-rarefaction of the air contents of the rooms. The melancholy truth is, that the doors and windows are by no means deficient in the means of admitting a full supply of fresh air. At the same time, it is to be observed that few of the tenants complain of cold as a result of the ventilation.

Since 1832, when this apparatus was fitted up, Glasgow has suffered more from fever than any other city in the empire in proportion. During the five years ending with 1839, there were 55,949 cases. It may well be presumed from the ordinary conditions of the Anderston house, and its previous history, that it should have had its full proportion of fever cases during that period, which would have been about 112 (taking the population of the city at 240,000). But so far from this being the case, there were only four instances of fever in the house from the beginning of 1832 till December 1840, laying aside one year, during which it was not under Mr Fleming's charge, when there were a few more. Early in 1841, there were eight cases; but most of these, as of the previous cases, were ascertained to have been brought in from without. Since then, the house has remained free of fever. It is impossible to doubt that the change from extreme unhealthiness to the reverse is mainly owing to the ventilating apparatus—for no other condition has been changed. It is not unimportant to remark, that the expense of fitting up the apparatus in the Barracks was *under fifty pounds*.

Mr Fleming has since applied his ventilating apparatus in a steam vessel. There are no places adapted for the reception of human beings which require ventilation more than ships, for there the space allotted to each individual is necessarily smaller than anywhere else. The sleeping berths, in particular, would be much improved in comfort by a draught being established upon the close, stifling, and often positively fetid atmosphere which is generally experienced in them. Dr Reid, some years ago, showed how easily a ship might be ventilated in all its habitable parts; and in 1840-1, he was employed to exemplify his theory in the vessels destined for the Niger expedition. Since then, Mr Fleming has been called upon to adapt his ventilating plan to the Princess Royal steamer, a passage vessel between Glasgow and Liverpool. In this case he has led a small tube from the top of each bed into a general pipe passing along under the deck, the extremity of which enters the ash-pit of a common stove. There is thus a draught out of every berth in the ship; and the consequence is a degree of comfort for which every passenger feels thankful. It may be presumed that the ventilation of a ship or steamer would be made still more effectual if fresh air were supplied in some regular manner, instead of being merely drawn in by chinks in the cabin doors. It would be easy to have flues communicating directly between the outer air and a perforated board in front of each bed. It is also obvious that, in steamers, a valved passage into the funnel of the engine would answer the purposes of draught without the least danger.

In rooms where large numbers of workmen are assembled, a mode of ventilation is obviously of great importance. Not long since, conversing with a man who had once wrought as a journeyman tailor in London, we were informed by him that workmen of his order in that city are obliged to pursue their calling in warm close rooms, in consequence of it being thought by the masters that heat is necessary to the goods making a fair appearance in the eyes of customers. The consequence, said he, is, that working tailors generally break down at forty-five, and the latter part of their lives is often very miserable. Now, it may be true that a high temperature is necessary for the work; but a high temperature is not necessarily connected with defective ventilation. The rooms in which the tailors work might all be supplied with constant streams of fresh air, although Fahrenheit's thermometer should never stand in their apartments below 66°. A liberal-minded copartnery of clothiers in Glasgow, Messrs Lockhart, had their workroom fitted with a ventilating apparatus by Mr Fleming, the apertures in this case being distributed over the ceiling, while the means of draught was supplied by the furnace in which the irons were heated. The result in comfort was described as very great: we cannot doubt that in health also the best consequences followed.

The application of the plan to sources of morbid infection is equally simple. Mr Fleming has fitted up several specimens of ventilated beds for hospitals or private sick-rooms, and placed them for public inspection in the warehouse of Andrew Liddell and Company,



ironmongers, Glasgow. In addition to these, he has prepared a ventilating washing apparatus for the clothes of patients affected by infectious disease. The simplicity of the arrangement, united to its manifest efficiency, must be generally admired. In the accompanying wood-engraving, a stove is represented as placed in front of a common fireplace, having a bed for a patient on one side and a washing machine on the other. Air tubes (*a a*) branch off from the stove, and terminate, one in the semicircular roof of the bed, the other in the semicircular top of the washing apparatus. In the washing apparatus there is a plash-wheel, of which *c* is the handle, while *d* is a filler for the admission of air and water, and *e* a door.

Infected clothes being put in by the door *e*, a sufficient quantity of boiling water is poured into the washing box by the filler. The door being now kept shut, the plash-wheel is set in motion, and driven as long as may be thought necessary for disinfecting the clothes. During this process, the air to support combustion in the stove being supplied through the filler, passes on through the washing box, and carries with it to the fire, as soon as disengaged, all the infectious matter arising from the clothes. In place of boiling water, the clothes might be purified by steam or heated air, and the infectious virus would be carried off and destroyed in the same way. At the end of this disinfecting process, the clothes may be taken out and washed in the usual way, the foul water being previously run off through a tube placed in the bottom of the apparatus.

The infectious matter generated by a patient placed within the bed is in like manner carried off and destroyed in the fire. To insure its complete removal, the tube passing along the roof of the bed is perforated with a series of small holes. To regulate the ventilation, there is a stopcock at *b*, which the patient or his attendant may turn at pleasure. To prevent the escape of any infectious matter from the bed, the front only is left open. The opening may be increased or diminished at pleasure by the raising or depressing of the curtain at the top. It is clear that there must be a stream of pure air constantly passing into the bed, and that any one standing in front is as completely exempt from all noxious influences, as far as that patient is concerned, as if he were at many miles' distance.

A description of the arrangements made by Dr Reid in the House of Commons involves the principles of heating, or rather of temperature regulation, as much as those of ventilation. 'The air,' we quote the account given by Drs Reynolds and Richardson of this much-agitated affair, 'is supplied from Old Palace Yard to the basement of the building, passing first through a fibrous veil 42 feet long by 18 feet 6 inches deep, for the exclusion of visible soot, it arrives at the heating apparatus, consisting of large chambers intersected by steam pipes, and proceeds from thence to other chambers, where it can be mixed with cold air, and brought to any required temperature. The floor of the house is double, and the space below the floor can be connected by means of valves with the hot-air chamber. The floor is perforated by a great number of apertures, and these are covered with hair-cloth, so that the hot air in escaping from the floor into the body of the house is infinitely divided, and no perceptible current is experienced. Having performed its functions, the vitiated air ascends to the ceiling, which is also double and perforated, in the same manner as the floor, whence it is carried off by the draught created by a powerful fire under a chimney shaft erected in another part of the building.' [For further information on this subject, the reader is referred to Dr Reid's work entitled 'Illustrations of the Theory and Practice of Ventilation.'—Longmans, London, 1844.]

The plan adopted by Mr Barry for warming and ventilating the House of Peers, the royal antechamber, and the public lobby, differs from that just described both as respects the admission of the air and its removal. The floors of the rooms are impervious, and are heated in the first instance simply by the passage of hot air below them; the hot air then escapes by passages along the external sides of the rooms to the ceiling, which is divided into two compartments—the one for the admission of the warm air, entering at the sides from below the floor, and the other for the exit of the viciated air. The warm air, after passing below the floor to the roof, becomes somewhat cooled, so that its temperature on entering the ceiling is a few degrees lower than that actually present in the room; it consequently descends to the level at which it is at once heated again; and deteriorated by combustion, respiration, &c. rises through the centre of the room, passing through the ceiling to a foul-air chamber above, whence it is conducted to a chimney, and carried off by the peculiar motive power first applied by Mr Bell to the production of draught. This power consists of a jet of steam, which, when produced under a pressure of 32 lbs. to the square inch, is capable of setting 217 times its bulk of air in motion; 10,000 cubic feet of air are thus gradually diffused through the three apartments per minute, no draught of any kind is perceptible, and no inconvenience is experienced from dust or other solid particles being carried mechanically forward by the air, as is said to be the case when the air enters from below.

In other cases, as at the prison in Millbank, warm air is admitted at the ceiling, and carried off by the draught of a chimney in connection with the sides or lower part of the rooms. At the Reform Club House, and at the new Hospital for Consumptive Patients at Brompton, warm or cold air is forced forward, or pumped into channels, conveying it over the whole building by a steam-engine in the basement, and is allowed to find its own escape through chimneys and other apertures. Although it is not probable that precisely the same arrangement can be adopted for heating and ventilating all extensive buildings, differing in construction, and in the uses to which they are applied, yet it is to be hoped that the various experiments which are now being tried upon a large scale, may lead to a knowledge of the most effective and economical plan for gaining an object so conducive to health and comfort.

It is abundantly evident that the choice of a mode of ventilation, and also its minor arrangements, must often be determined by considerations of local convenience and of economy. A factory and a steam-vessel present an ever-active furnace or chimney, into which a flue for ventilation can be conducted. In these situations, accordingly, there may be ventilation absolutely without cost. In the same situations, the mechanic power for a fan or pump can be readily obtained; but in that case the power is both a matter of cost, and it requires attention to regulate it. Generally, therefore, though not perhaps in all instances, the plan by fire or chimney-draught will be preferable in such situations. Where there is an apparatus for warming as well as for ventilating, and where economy is an object, the draught might without much difficulty be effected by the fire which is used for the former purpose. It would only be necessary to conduct flues from the various rooms down to the ash-pit of the furnace. In this case, however, there would be a certain loss of control over both processes. In buildings already completed, there might be a tolerably efficient ventilation obtained by flues conducted into the kitchen chimney, which, being always active, would keep up a nearly unvarying draught. Dr Arnott has suggested that the fresh air in entering might be heated to nearly the desired temperature, especially in churches and other crowded places of assembly, if the flues for its admission were made to pass longitudinally through the centre of those by which the used air was passing out. Another and simple mode of draught has been practised in connection with the hot-water warming apparatus, consisting merely of a flue into which a small coil of the hot water-pipe is introduced. This small coil, situated in the flue, and near its bottom, acts precisely like the fire in the chimney for ventilating the Houses of Parliament.

For obvious reasons, the admission of warm air is generally at the bottoms of rooms, while the used air is drawn off by apertures in or near the ceiling. Mr Perkins, it appears, pursues exactly the reverse plan, conceiving that it 'introduces the warm temperature insensibly, and removes the impurities of the room more effectually.' Mr Alfred Ainger, an architect, also adopts this plan; he remarks that, 'with upward ventilation, a great part of the vitiated atmosphere [of crowded rooms] being specifically heavier than common air, is liable, by the slightest check or condensation, to be thrown down and mixed with the air which is already partly unfitted for the purposes of life. But let the current descend, we have a bright atmosphere, consisting of an immense reservoir of pure air, arriving immediately at the lungs, and which, as it becomes contaminated, is drawn downwards by a force with which most accidents will co-operate.'

In conclusion, we thoroughly concur in the opinion that 'the plans proposed and carried out in some of the large buildings of the metropolis, and in other places, are so various, and in many cases new, that they must all be considered in the light of experiments, the respective values of which can only be ascertained after a more lengthened trial has been vouchsafed them. The main object is, however, the same in all, and involves the supply of a certain portion of fresh air to a certain locality, either warm or cold, within a certain space of time; the amount of air constituting this supply varying of course with each individual case. Indeed it does not appear that philosophers are agreed as to the mean quantity of air required by a number of individuals during a given time, and until this point has been definitively settled, the calculations which must obviously be based upon it will necessarily differ, according to the standard assumed by each observer. There can be no doubt, however, that it is preferable in the meantime, until that question shall receive a definite answer, to supply an excess of fresh air rather than a deficiency, which has as yet been the prevalent error in practice.' It may also be safely added, that much unnecessary matter has been written, and much labour and money expended in vain on the subject of ventilation. Where heating and ventilating are combined, some skill and mechanical ingenuity may be requisite; but where fresh ventilation is alone desired, nothing appears to be more direct and simple, if we could only live less in dread of 'draughts' and 'currents.' We enjoy, and are better for, the breeze in the open air, and we shrink from, and suffer cold under, the slightest in-door current, because we immure ourselves in packing-boxes, which we call apartments, and smother ourselves amid carpets, curtains, and drapery. Nature has surrounded us with an atmosphere of life and health: we exclude it by our absurd conventionalities, and then struggle to regain it by tinkering and patchwork.

PREVENTION OF SMOKE.

The smoke arising from the furnaces employed at factories has, within the last thirty years, been felt as a great nuisance in most manufacturing towns, polluting, as it does, the pure air of heaven, and begriming every exposed object within the range of its influence. Those employing furnaces have also become generally aware that smoke is only a volatile form of fuel, and that if either less of it were generated, or if, when generated, it could be consumed, there would be a great saving in the expense of raising steam. These circumstances have led to various devices for the combustion and prevention of smoke, the chief of which it is our duty to describe in this place.

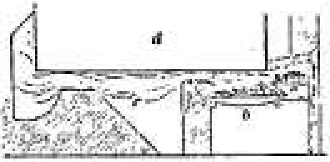
Ivison's plan consists in the projection of a stream of steam into the space between the fire and the boiler. It proceeds upon the supposition, that the steam so introduced being decomposed by the heat of the furnace, its oxygen unites with the carbon of the smoke, and causes the combustion of that material, while the hydrogen also burns through its own inflammable quality. The arrangement for the introduction of the steam is simple: a small iron pipe, proceeding from the top of the boiler, bends over and enters the furnace immediately above the door, the termination being fitted with a fan-shaped expansion, full of small holes, by which the steam is dispersed throughout the fiery space. By a stopcock on the pipe at the furnace door, the discharge can be regulated or altogether stopped. The due working of the apparatus depends on admitting into the furnace a certain quantity of hot air, and this is done through two pipes which, opening from the open air, pass into the furnace and out again, the inner terminations being inserted in the door. With regard to the prevention of smoke, Mr Ivison's plan seems to have established for itself a certain measure of success; but we understand that the hypothesis is extensively doubted, and that the plan is not likely to be universally adopted. It was tried on the furnace of the steam-boiler used in the office where this work is printed, and was found to be defeated, in consequence of the extremity of the steam-pipe being constantly liable to be destroyed by the fire. This difficulty may be obviated, and the whole benefit of the plan may, we believe, be secured, if the steam-pipe be introduced below the bars of the furnace.

Juckes's plan is designed for consuming smoke and economising fuel. The following description of it was given by himself at the meeting of the British Association at Manchester, June 1842. 'His grate-bars are endless chains passing over rollers, and moved forward about an inch per minute. The coals employed are common siftings or screenings, which are heaped on the bars outside the furnace door, which slides upwards. The door is left a little open, and by passing under it, the small coal is spread uniformly over the bars. The air is constantly supplied through the bars directly to the fuel while burning, and in this way perfect combustion is obtained. The bars, being slowly moved on, carry the ashes to the ash-pit, which lies at the back of the grate. Clinkers are prevented from incrusting the bars by their passing under a gauge, which effectually removes them; and the burning away of the bars is prevented by their constantly moving away from the hottest place. The bars or chains, with their rollers and driving-wheels, are fixed in a frame which can be completely drawn out from under the boiler, for the purpose of removing injured bars, or any other purpose. A boiler has been at work for two months at Mr Baird's saw-mill, Wapping, and given great satisfaction. No smoke is ever seen, and the consumption of coal is only 12 cwt. or thereby per day, whereas, with the old boiler, they had used a ton of coal, besides a ton of wood and sawdust.'

Smith's boiler was suggested by a consideration of the upper and under currents in the ocean and atmosphere often flowing in opposite directions. The inventor has tried to avail himself of this principle in his furnace, considering that, from the great rapidity with which the gases leave the fire, it is impossible to effect their perfect incorporation with atmospheric air and consequent combustion; and believing that, when these gases are allowed to pass off directly through the flues in nearly straight lines, the gases and air pass along in separate threads or films, sufficient time for their proper mixture not being given under the ordinary systems of combustion. Mr Smith, therefore, constructs a boiler and furnace in the following manner:—Beyond the bridge of the furnace he places a chamber within the boiler entirely surrounded by the water; this chamber only leaves room for a small water space along the sides and bottom of the boiler; it is arched elliptically, and of course, like all internal flues or fire-boxes, leaves sufficient space above for water and steam. The funnel or chimney is placed on the same side as the fire, and as low as possible. The hot gases and air rush over the bridge gradually, from the size of the chamber, losing their initial velocity. When they impinge against the opposite side of the chamber, the current is directed downwards; and the return current, with diminished velocity, flows back to the chimney under the stratum of gas and air issuing from the fire-bridge. In this way time is given for combustion, and the gases are inflamed or exploded before going up the chimney. From the chamber being quite within the boiler, nearly all the heat is made available. Mr Smith considers his plan particularly applicable to marine boilers and reverberatory furnaces. He lately had one established at Messrs Page and Grantham's, Liverpool, working an engine of ten-horse power, the pressure in the boiler being 50 lbs. This did as much work with 8 cwt. of coal as the best tube boiler which these gentlemen ever tried had performed with 12 cwt.

Waddington's patent is a contrivance for introducing coal in a gradual manner. Put in at the sides of the boiler, it is made to descend inclined planes to the bars, before reaching which it is coked by the fuel burning on the bars, and smoke is prevented. *Greenway's* plan is of considerable ingenuity, as well as simplicity. He employs in each case two boilers and two furnaces. The furnaces are supplied with dampers, so that their communication with their respective flues can be cut off, and a communication opened between the two fires by an intermediate flue. When fresh coals are put on one fire, the damper of that fire is shut, and the intermediate flue opened, so that the smoke is obliged to descend through the bars, and ascend through the burning fuel of the other fireplace. By alternating this as fresh coals are put on the fires, smoke is said to be prevented. Mr *Kurtz's* is by hollow bars admitting fresh and heated air to a hollow bridge. Mr *Samuel Hall's* is a plan of much the same nature, by air heated in a quantity of pipes in the flue between the boiler and the chimney, passing thence to perforations in or near the bridge. Mr *John Chanter's* is by an 'auxiliary boiler,' the bars under which are inclined, and have below an iron plate termed a 'deflector.' At the lower end of this furnace a common furnace is constructed, which receives the coke or charred coal in an incandescent state from the upper bars. Mr *E. Rodda's* is by a furnace divided into two parts, one for coking the coal, the other for receiving the coke—the gas from the coal passing through lateral openings into the second division, where they are to be destroyed by the bright fire. A stream of fresh air is admitted, joining the smoke in the passage, thus effecting its combustion.

Mr *Howard's* invention, which is simple and ingenious, and closely allied to that of Williams's, about to be described, will be most readily comprehended by referring to the accompanying diagram:—*d* is the boiler surrounded by common flues; *a* is a coking-plate; *b*, the body of the furnace, with the ash-pit beneath, which is closed against the admission of air; *e*, a fire-bridge, like that of a reverberatory furnace; and *c*, a space for the regulated admission of heated air. The coal is first coked on the coking-plate, and then pushed over on to the grate-bars, where there always exists a bright surface of burning coke. The gases generated in coking a fresh portion of coal pass over this heated surface before they come in contact with a fresh supply of warm air at *c*, and thus an almost perfect combustion of smoke is the result. The saving in fuel effected by this plan is said to vary from a fourth to a half of the whole. It is therefore deserving of attention; and where any prejudice exists against patent modes, the same results might be obtained by simply coking the fuel in the front part of the furnace, pushing it forward by degrees, and admitting a supply of air behind the fire-bridge.



It may also be remarked, that coal may be economised, and the escape of its fumes much diminished, without any peculiar contrivances, simply by careful and skilful feeding of the furnaces by the firemen. In Cornwall, where no contrivances exist, fuel is managed in such a way by the firemen that the consumption in general is only about 2½ lbs. per horse power per hour, and smoke is said to be 'never seen.' The coal is regularly weighed to the firemen, and the 'duty' of the engines is reported every week. This excites emulation among the men, and when a falling off in their attention takes place, it is instantly detected. The great object held in view is to keep thin bright fires, coking the coal in front.

Williams's plan is most in esteem at present, and seems likely to prove generally serviceable. The inventor aims not at burning the smoke, which he holds to be a chemical absurdity, but at preventing its formation. 'One of my objects,' he says in his treatise, 'is to show how the combustion of the volatile portions of coal may be effected as completely when issuing from the throat of a furnace as from the beak of a gas-burner.' To pursue the explanations afforded in the Polytechnic Journal:—'It is ascertained that 20 cwt. of bituminous coal affords about 10,000 cubic feet of coal-gas—some qualities more, some less; now, chemistry teaches that every measure of this gas requires for its perfect combustion ten measures of atmospheric air, thus making, from a ton of coal, a gaseous mixture of about 100,000 cubic feet. With more or with less air we still have imperfect combustion. This is the whole theory of the process; it is what every chemist has long known, and no obstacle is offered to its solution or comprehension. How can so large a body of air as ten cubic feet to every single cubic foot of gas by any possibility be admitted without cooling down the furnace? Opening the door would let in air enough, with the disadvantage of cooling the furnace and lowering the steam. The doctrine of the diffusion of gases, due to the elaborate and interesting experiments of Dr Dalton, comes to our aid. For perfect diffusion, we require time; the process of the furnace will not afford time. We must, then, resort to some mechanical arrangement to overcome this difficulty in the simplest possible manner. Now, we may have enough of air; but from having it applied in the wrong mode, as is done in opening the door, though we lose the smoke, we lose the steam also. In this case it is somewhat like the two conditions of gas burnt from a common pipe with and without an argand burner. Why does it in the one situation smoke and give little heat, while in the other it is smokeless and intensely hot, seeing it is surrounded in both instances with an abundant supply of air? Merely because the numerous minute jets of gas supplied by the argand burner afford that more perfect diffusion refused by the wide bore of a single orifice. So, in the furnace, if we can admit the ten measures of air in the same way by means of small jets, we do all we want by obtaining rapid diffusion, complete mixture, and therefore perfect combustion.'

In the 'Practical Mechanic and Engineer's Magazine' for 1841, there is a paper on Mr Williams's plan, illustrated by sections of the furnace and boiler. From this we learn that a long boiler is supposed, and that the grate is placed under one end, having its ash-pit below as usual. The fumes of the coal pass onward under the boiler, towards a chimney at the opposite extremity. Under the centre of the boiler, and quite separate from the ash-pit, there is a square chamber, having a flue by which air can be admitted from without. From the iron plate forming the roof of this chamber, three short vertical tubes, unclosed at the lower ends, project upwards into the space beneath the boiler along which the fumes pass. These tubes are perforated all round the sides and tops with holes of a quarter-inch, set one inch apart. The air, accordingly, passing first into the square chamber, then proceeds upwards, and rushes into the space above in the form of small jets. At every charge of fresh coal on the fire, the first product is, not smoke, but a very large body of crude impure coal-gas, the unconsumed portion of which, as it passes the bridge, meeting the air, mingles with it, and instantly inflames, being encompassed with a hot gaseous atmosphere. The effect then is, that each jet of air seems to be a common gas flame; and these vertical tubes have not inaptly been compared to trees of fire. To those who are not familiar with the fact of flame from a jet of air in gas, it may be interesting to quote the observations of Professor Brande on this subject:—'I fill a bladder with coal-gas,' says he, 'and attach to it a jet, by which I burn a flame of that gas in an atmosphere of, or a bell-glass filled with, oxygen; of course the gas burns brilliantly, and we call the gas the combustible, and the oxygen the supporter of combustion. If I now invert this common order of things, and fill the bladder with oxygen, and the bell-glass with coal-gas, I find that the jet of oxygen may be inflamed in the atmosphere of coal-gas, with exactly the same general phenomena as when the jet of coal-gas is inflamed in the atmosphere of oxygen.' The saving of fuel by these means is said to be about 25 per cent.

SUPPLY OF WATER—BATHS—SEWERS.

AMONG the complicated arrangements of civilised life, few are of higher importance than those which relate to the command of water. Whether for dietetic and domestic purposes, for the bath, or for carrying away the corrupting refuse of our towns and cities, a liberal supply of good and wholesome water is an indispensable requisite. Admitting the necessity, we intend in the following pages to give some account of the waterworks, baths, sewers, and other sanitary provisions adopted in reference to the supply and emission of this element, both in ancient and modern times—dwelling on what seems more especially applicable to the wants of our own populous localities.

SUPPLY OF WATER.

Water, as explained under CHEMISTRY, is a compound of hydrogen and oxygen, and is, when pure, and under the ordinary temperature of the atmosphere a transparent liquid, without taste, colour, or smell. In nature, however, it is never found in a state of absolute purity. In the ocean, it is salt and brackish, from the presence chiefly of chloride of sodium; in springs, it is either carbonated — that is, contains carbonic acid; sulphureous, from the presence of sulphuretted hydrogen; chalybeate, from the union of the sulphate or carbonate of iron; and so on, according to the nature of the mineral ingredients through which it percolates. When it contains a chemical compound of lime, it is said to be *hard*, and in this condition it decomposes the soap which is employed with it, and destroys its detergent properties. The impurity of water may thus arise either from chemical union or from mechanical mixture with other bodies. The latter can generally be removed by filtration; but when the union is chemical, distillation is necessary to produce a pure liquid. In this state of purity, water is seldom required in the arts, and apparently as seldom in the economy of nature. Under the ordinary pressure of the atmosphere it absorbs carbonic acid, and to the presence of this ingredient do our common spring and well waters owe their agreeable flavour. Distilled water is neither nourishing nor pleasant; both animal and vegetable life seem to thrive best when supplied with water holding in solution certain ingredients; and it is only where foreign ingredients are too largely present, or are of a deleterious nature, that the use of water containing them has to be avoided. 'It is probable,' says Dr Robertson in his Treatise on Diet and Regimen, 'that unless in the case of water being in a state of greater or less putridity, or of its containing a large amount of saline impregnation, or a perceptible impregnation of vegetable or animal matters, it has seldom much effect on the health of a population. When individual systems have once become habituated to its use, the instances are rare in which it proves to be of any importance whether the water reaches the surface by passing through sand, clay, limestone, or even shale; a small quantity of iron in water not appearing to have any bad effect on the health of those using it. In general, and more particularly in towns, the importance attaches rather to the quantity of water for domestic uses with which a district is supplied, than to the character of its mineral impregnation.' Admitting the force of these remarks, and asserting, moreover, that few of our populous towns can boast of anything like an adequate provision, we shall now briefly advert to the nature of the sources whence our ordinary supplies are derived.

Fresh or common water, as distinguished from that of the ocean, is obtained from rain, springs, rivers, lakes, or wells, and is characterised by peculiar properties, according as it is obtained from one or other of these sources. *Rain water*, if collected in mountain districts, far from human dwellings, is perhaps the purest of all; but if collected in the neighbourhood of towns, it is found to be largely impregnated with soot, and other extraneous substances; and the rapidity with which it putrefies, demonstrates the presence likewise of organic matter. Being soft, it is valued by the housewife for washing; but is unfit for internal or culinary purposes without undergoing rigid filtration. Unimpregnated with mineral substances, its action on lead is more rapid than that of other waters; and it should never therefore be kept in lead cisterns. All *spring water* is less or more impregnated with the substances through which it has percolated to the surface; but with the exception of those commonly termed 'saline' or 'mineral,' most springs yield water of sufficient purity for domestic purposes. Those issuing from the primitive and igneous rocks, or from extensive beds of sand and gravel, are generally the purest; those from the carboniferous and other secondary strata always hold in solution compounds of iron, lime, sulphur, salt, and magnesia. *River water*, which is a combination of rain and spring water, is often well fitted for human purposes. Its impurities are more of a mechanical than of a chemical kind, and may be removed by careful filtration. Much, however, depends upon the soil and district through which the river flows; meadows, morasses, and forests yielding organic matter, and factories and towns bequeathing heterogeneous impurities, not to be got rid of by any ordinary process. Water drawn from fresh *lakes* is less turbid than that from rivers; but is always (unless from deep mountain tarns) more largely impregnated with vegetable and animal matter. *Well or pump-water* is that obtained by boring or by sinking shafts into the rocky strata. It must of necessity, like spring water, partake more or less of the mineral ingredients through which it percolates; and not unfrequently is injured by the pumps, pipes, and other apparatus by which it is raised.

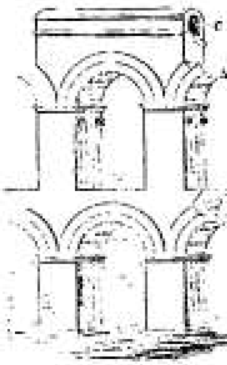
Such are the ordinary sources of fresh water. In rural or thinly-peopled districts little skill or mechanism is necessary to render them available. A trough for the spring, a hand-pump or chain and bucket for the well, or a simple dipping of the pitcher in the river, is all that is requisite. In towns and cities, where the supply must be great, and readily obtained, and where it must be brought from distant and unpolluted sources, aqueducts have to be built, pipes laid, pumping-engines erected, filtering apparatus constructed, and a system of distribution established, requiring all the skill and ingenuity of the machinist and engineer. To these means and appliances, as practically exhibited, we shall now direct attention.

Ancient Aqueducts.

The word *aqueduct* is derived from the Latin *aquæ ductus*, and signifies merely a conductor or conduit of water. In this sense all leaders or channels of water would be aqueducts; but the term is restricted to those artificial structures by which streams are conducted from their sources, by a uniform and continuous descent across valleys and through mountains, towards the city they are destined to supply. Passing over some imperfect traces of aqueducts in India, and advancing westwards, the first worthy of notice is that which Procopius records to have been built by Cosroes, king of the Persians, for the supply of Petra, in Mingrelia. This seems to have been a square conduit, covered by flags, and supported in part of its course upon three tiers of arches, each tier supporting a channel; so that no less than three streams were made available in Petra at different elevations. We have also accounts of aqueducts constructed under the reign of Solomon; and the remains of them still existing in Palestine, give evidence of an extensive acquaintance with the principles of hydraulics among the architects employed by the Hebrew rulers. The 'Pools of Solomon,' near Bethlehem, were evidently connected with a scheme for supplying Jerusalem with water. 'These large, strong, noble structures,' says Mr Stephens in his Incidents of Travel, 'in a land where every work has been hurried to destruction, remain now almost as perfect as when they were built. There are three of them about 480, 600, and 660 feet in length and 280 in breadth, and of different altitudes, the water from the first running into the second, and from the second into the third. The water from these reservoirs is still conveyed to Jerusalem (a distance of six miles) by a small aqueduct, a round earthen pipe about ten inches in diameter, which is sometimes above, and sometimes under the surface.' It was not, however, in the eastern hemisphere alone that the ancients excelled in the construction of aqueducts; we have evidence of the existence of kindred works in pre-Christian Central America. The ancient city of Mexico, which was built on several islands near the shore of the lake, was connected with the mainland by four great causeways or dikes, the remains of which still exist. One of these supported the wooden aqueduct of Chapoltepec, which was constructed by Montezuma, and destroyed by the Spaniards when they besieged the city.

It was among the Romans, however, that the construction of aqueducts was carried to the greatest magnificence and perfection. Masters of half the world, wealthy, and luxurious, it is not to be wondered at that they should have expended an enormous amount of labour in conducting streams into their cities; and less when it is considered that the capital of their empire was unfavourably situated by nature in regard to pure and wholesome water. The glory of a reign was in general perpetuated by the erection of a temple, palace, or other public building; what more fitting monument than an aqueduct—a species of structure susceptible of architectural display, as it was essential to the public welfare! It was to Appius Claudius, about 312 years before the Christian era, that the Romans were indebted for this scheme of improvement; but for several centuries after his time, additional works were constructed, as the necessities and luxuries of the city demanded. Among those who signalised themselves in this department of public utility were Curius Dentatus, Lucius Papirius, Quintus Marcus, Agrippa, Augustus, and Claudius; that erected by the latter being upwards of forty-two miles in length, and discharging about 97,000,000 of gallons in the twenty-four hours. In the remains of these aqueducts, some portions are elevated above the ground on solid stonework, or upon arches continued and raised one above another; while others are subterraneous, such as that seen at Vicovaro, beyond Tivoli, where a tunnel of about five feet deep and four broad pierces the rock for a distance of more than a mile. One of these aqueducts was formed of two channels, one above the other; they were, however, constructed at different periods, the most elevated being supplied by the waters of the Teverone (*Anio Novus*), and the lower one by the Claudian water. It is represented by Pliny as the most beautiful of all that had been built for the use of Rome. It was subsequently repaired and extended by several emperors, is now called *Aqua Felice* (after the conventual name, Brother Felix, of Sextus V.), and still administers to the supply of the modern city. The Aqua Marcia, Aqua Julia, and Aqua Tepula, entered Rome by one and the same aqueduct, divided into three ranges or storeys, each of which supported its own independent channel-way. This accounts for the extraordinary height of this structure, which far surpassed that of its compeers, which generally ranged from seventy to eighty feet, that being the height required to bring the plain which surrounded Rome to the average level of the city.

In general, the conduits or water-courses were built of stone, rough or hewn, occasionally of bricks, and in either case cemented by the finest tempered mortar. Some were of a square form, paved, and covered with flag-stone or tiles; others were arched over, as shown in the accompanying cut; and some were throughout of an elliptical form. This conduit, or stone pipe (*c*), if we may apply such a term, was conveyed through hills by tunnels, and across valleys upon single arcades, or even upon double and triple tiers of arches. In general, these arches supported only one water-course; but occasionally each tier had its own conduit, so that an aqueduct presented a double or triple form. The channels were constructed with an imperceptible descent, that the current might be accelerated by its own weight; and where following a direct line would have given too great an impetus to the flow, they were conducted over many miles of country by frequent and winding mazes. This device not only reduced the impetus of the current, and thereby preserved the interior of the channel from a rapid abrasion, but allowed the water to deposit its sediment, and to become softer and better fitted for domestic uses. For the latter purpose, tanks or cavities were formed in the channel in which the stream lodged, until it had precipitated its mud and feculence; and open ponds were constructed, in which it expanded, till purified and sweetened by atmospheric influence. There were also *spiramenta* at regular distances, by which a superfluous flow of water might be disembogued, and which also served for the discharge of the whole stream, in the event of the channel being stopped by accident or requiring repairs.



Parallel to the course of the conduit, in some of the more magnificent aqueducts, there were footpaths, forming at once a novel and cooling promenade. Having arrived at their destination, the waters were generally received in reservoirs, and conducted by leaden pipes, or by stone grooves, into private cisterns, or dispersed throughout the cities by means of public fountains, which were often adorned with all the magnificence and allegorical allusion of ancient architecture. These structures were invariably under the charge of a public functionary (see *Cloacæ*, p. 476); and it is from the treatise of Sextus Julius Frontinus, who was inspector of the aqueducts of Rome under the Emperor Nerva, that we derive most of our information respecting the water-works of the imperial city.

Without adverting more minutely to these structures, a general idea may be formed of their extent and importance, when it is stated that Rome was supplied with water from sources varying from thirty to sixty miles in distance, and that at one period of its history, not fewer than twenty aqueducts brought as many different streams across the wide plain or campagna in which the city stands. In the time of Frontinus (A.D. 100), the entire length of aqueducts exceeded 255 miles, the daily discharge of which was about 300,000,000 of gallons—a supply to which that of modern London is a mere insignificant dribblet.

The chief provincial cities of the Romans, as well as their own metropolis, were supplied with water by aqueducts; hence in Greece, Gaul, Spain, Italy, &c. portions of these extensive constructions remain to the present day. That of Nismes, built by Agrippa, son-in-law of Augustus, is perhaps the most ancient of their provincial aqueducts. It was about thirty miles in length, when entire, and traversed a very mountainous country, piercing through hills, and crossing valleys by means of arches upon arches. It was constructed of squared stones throughout, and was coated in the interior, which was 4 feet by 5½, with finely-prepared cement. The '*Pont du Gard*' is that part of the aqueduct of Nismes which crosses the deep valley in which flows the Gardon. It is composed of three ranges of arches, one above another. The first range under which the Gardon runs is formed by six arches, the second by eleven, and the third by thirty-five—all of which are semicircular, and form a total height of 160 feet above the water of the river. The entire length of the bridge is 300 yards. Passing the ancient aqueducts of Lyons, in which the inverted syphon, as well as the inclined channel-way, was used, and of Bourgas, near Constantinople, the only other provincial structure of the kind to which we shall allude is that of Metz, of which a number of the arcades still remain. 'These arcades,' says an ancient authority, 'crossed the Moselle, a river which is broad and vast at that place. The copious sources of Gorze furnished water for the representation of a sea-fight. This water was collected in a reservoir; from thence it was conducted by subterraneous canals formed of hewn stone, and so spacious, that a man could walk erect in them. It traversed the Moselle upon its superb and lofty arcades (3600 feet long, and 100 feet high), which may still be seen at the distance of two leagues from Metz; so nicely wrought and so finely cemented, that, except those parts in the middle which have been carried away by the ice, they have resisted, and will still resist, the severest shocks of the most violent seasons.

Modern Aqueducts.

Of the aqueducts erected within a comparatively modern period, we may mention the following:—The aqueduct of Spoleto, constructed in 741 by Theodoric, king of the Goths, to communicate with the town of Spoleto, situated on the summit of a mountain. It is one of the handsomest structures of the kind, and remains entire to the present day. In crossing the river *De La Morgia*, the channel-way is supported upon two tiers of Gothic arches, the lower containing ten grand arches, and the latter thirty. The length of this arcade is 800 feet, the breadth 44, and the height 420! The aqueduct of Caserta, built in 1753 by Charles III. of Naples, is also an expensive and gigantic structure, one of its arcades consisting of three tiers of arches, 1724 feet long, and 190 feet in height. In France, that which conducts the waters of St Clements and Du Boulidou to Montpelier is perhaps the most beautiful. It was built under the superintendence of M. Pitot, and required thirteen years for its completion. The principal arcade is 90 feet high, and consists of two tiers—the lowest containing 50, and the upper 210 arches. That of Arcueil deserves next to be noticed. It was originally built by the Emperor Julian, A.D. 360, to bring water to Paris, and supplied the palace and hot-baths, but was destroyed by the Normans. After it had been in disuse for 800 years, it was rebuilt in 1624; again repaired in 1777; and fresh sums have lately been devoted to the same purpose by the city of Paris. The arcade over the valley of Arcueil consists of 25 arches, is 72 feet high, and 1200 feet long.

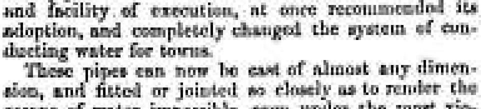
Of recent aqueducts, that of Lisbon and that of New York are the only two deserving notice. The former, completed in 1738, is about three leagues in length, and in some parts of its course has been excavated through hills; but near the city it is carried over a deep valley for a length of 2400 feet by several bold arches, the largest of which has a height of 250 feet, and a span of 115. The Croton Aqueduct, which conveys the waters of the Croton River for a distance of thirty-eight miles to the city of New York, is one of the most stupendous underakings of modern times. It was commenced in 1837, and finished in 1842, and is calculated to discharge upwards of sixty millions of gallons in twenty-four hours! Some idea of this magnificent supply may be formed from the fact, that the daily consumption of the principal London water companies (eight in number) amounts only to *twenty-one millions of gallons*. Of the architectural structure of the Croton Aqueduct, it would be impossible to convey any clear idea without the aid of sections and diagrams. A general sketch of the undertaking may, however, be presented:—The fountain reservoir covers about 400 acres, and is formed by a dam 38 feet in height, creating a source 166 feet higher than the city of New York. At this dam are sluices or gates for regulating the discharge of water, and of course under the superintendence of a competent manager. The interior of the aqueduct is throughout of an arched or elliptical form, founded upon hydraulic concrete, built of square stones, and finally lined with brick prepared for the purpose. In crossing flats slightly below the intended level, it is raised upon solid embankments; in crossing valleys or rivers, it is supported upon arches; and in passing through hills, these are tunnelled, to admit the mason-work of the aqueduct. Roads and other thoroughfares are of course left unobstructed by the erection of bridges, just as they are in our country when a railway is laid down. As the magnificence of aqueducts depends upon the height and number of arches requisite to carry them across valleys, it may give some idea of that under consideration, when it is stated that Harlem river is crossed by fifteen arches, seven of which are of 50 feet span, and eight of 80 feet, the greatest height being 150 feet from the foundation to the top of the mason-work. This, it is true, is the *chef-d'œuvre* of the aqueduct; but there are other bridges and embankments of no mean magnitude, the design and construction of which do credit to American engineering. No essential change occurs in the form of the channel-way from the fountain reservoir on the Croton to the receiving reservoir on the island of New York, a distance of thirty-eight miles, except in crossing Harlem river to reach the island, and in passing a deep valley on the island, where iron pipes are used instead of masonry, to provide for the pressure consequent upon a depression from the regular plane. Thus the course of this artificial stream may be said to combine two principles—that of the ancient aqueduct, and a descent and ascent as in ordinary pipes. (See p. 468.) Should it ever be resolved on to remove the tubes from these depressions, and to substitute arcades to maintain the regular inclination of the channel-way, a second tier of arches will be required in crossing the Harlem river, and a bridge of great elevation to span the ravine on the island.

Having by the means now described reached the receiving reservoir, at the rate of 1½ miles an hour, the surface-level of the water is still 119 feet above the level of mean tide. From this it is conducted (a distance of two miles) to the distributing reservoir, where the surface-height falls to 115 feet, this last being the height to which the water can be made available in the city. The receiving reservoir covers about thirty acres, and contains one month's supply; whilst the distributing, which is entirely built of stone, is 436 feet square, 45 feet deep, and contains 20,000,000 of gallons. This last reservoir may be considered the termination of the Croton Aqueduct, and is distant from the fountain reservoir 40¼ miles. The whole cost of the work, according to the published accounts, was about 9,000,000 dollars; and adding to this the cost of pipes, and arrangements for distributing the water in the city, it will make the total cost of supplying New York with water about 12,000,000 dollars.

Syphon-Pipes.

Till within the last century, the only mode of conducting supplies of water on a large scale was the covered channel or aqueduct; and where the ground presents a gradual and direct descent, no other mode can be more simple or satisfactory. But where hills have to be tunnelled, valleys crossed by tiers of arches, and rapid descents overcome by circuitous routes, the aqueduct becomes the most laborious and expensive of contrivances. The Romans and others must have felt the full force of this objection; but the condition of the arts and sciences among them left them no alternative. They must either have reared the magnificent, but toilsome and expensive aqueduct, or submitted to the privations which its absence implied. Not that they were ignorant of the hydrostatic principle of water always rising to its original level, no matter how tortuous or complicated the course by which it is led;* but that they were not in possession of any material sufficiently strong to resist the pressure of the contained fluid in its risings and fallings along the surface of the country. The syphon-pipes employed by them were of lead, a metal not well adapted to sustain a great degree of pressure, and objectionable besides on the score of communicating its deleterious properties to the water. There was therefore no alternative to the hydraulic engineer till the invention and improvement of cast-iron pipes, when that material, in point of cheapness and facility of execution, at once recommended its adoption, and completely changed the system of conducting water for towns.

These pipes can now be cast of almost any dimension, and fitted or jointed so closely as to render the escape of water impossible, even under the most violent pressure arising from the height of the fountain-head. All that is necessary is, to join the several lengths securely, and protect them from frost or from the heat of the atmosphere, by covering them with a few feet of soil. They are all but indestructible, and communicate no deleterious principle to the current of water. Thus, in the following diagram, if *a* represent a lake or reservoir situated in a mountainous district, and *b* a town separated by several miles of irregular country, then on a pipe (indicated by the dotted line) being laid from *a* to *b*, the water will issue with a force sufficient to raise it nearly to the height of the original reservoir—a certain amount of force being lost through friction and atmospheric pressure. Several of our large and many of our minor towns are now supplied by this mode; the whole system consisting of the feeding reservoir—which is generally situated in some hilly district—the line of pipes, with a few air-cocks for the escape of the accumulated air, branches or mains to lead the water into



the different districts of the town, and ultimately small service-pipes and cisterns for the houses of the consumers. We may take for illustration the Crawley line of pipes, from which the inhabitants of Edinburgh derive the greater portion of their supply. 'This spring,' we quote the Encyclopædia Britannica, 'issues from the side of a rising ground on the southern base of one of the Pentland Hills. It is scarcely seven miles distant from Edinburgh in a straight line, but eight and three-fourths in the line of the pipes, these having been carried round a considerable way to the eastward, to avoid the Pentland ridge, the eastern extremity of which lies in the direct line to the city. The spring is elevated 564 feet above the level of the sea, and 380 above the level of Princes Street. There is therefore ample height to carry it over the highest parts of the town. The original issue of the spring was greatly augmented by a drain, which was carried for about half a mile above the spring up the valley in which it is situated. The soil of this valley, consisting of an immense bed of gravel, in many parts forty feet deep, constitutes a vast natural filter, through which the water, descending from the high grounds on each side of the valley, percolates in a high degree of purity, and being all intercepted by the drain, is by it conducted, along with all the original discharge of the spring, into a reservoir or water-house, from which the pipes take their rise, and continue in one connected train all the way to the city.

In the first three miles they vary from 18 to 20 inches diameter, and descend 65 feet in a pretty regular series. In the remainder of the track they are 15 inches diameter, and descend 286 feet. The descent is not perfectly regular, being in some parts steeper than in others, according to the natural declivity of the country. In one or two instances also they undulate slightly. Near Burdiehouse, four miles from the city, they ascend a little; and after descending rapidly to Libberton Dams, they again ascend 20 or 30 feet to the high ground on the south side of the Meadows. There are, however, no sudden inequalities, all such having been carefully avoided by levelling; for which purpose considerable embankments and cuttings of the ground have been undertaken without scruple; and as the line approaches the city, it has been carried through a tunnel 2160 feet in length, under Heriot's Green, about 70 or 80 feet below the surface, and another under the Castle Hill, 740 feet through the solid rock, and 120 feet under the reservoir. From this main line of aqueduct a branch pipe leads off on the south side of the town to the reservoir at Heriot's Green, near Heriot's Hospital, which aids the former source in supplying fully the southern districts; a second leads off from the same place to the eastward, and affords an additional supply to the south side of the town, directly from the pipes; and a third leads off to the reservoir on the Castle Hill, and aids it in supplying the rest of the Old Town. The main body of the water, however, proceeds onwards to Princes Street, along Hanover Street, and across Queen Street; and from thence branch pipes are laid through all the other streets in the New Town, and from these again service pipes to each house or floor of a house.

Each pipe in this aqueduct is about nine feet in length, the metal being about half an inch thick. After being cast, their soundness was proved by a forcing-pump applied to each separately, and with a gauge-valve loaded with a weight equivalent to a pressure of 800 feet; and if under this they betrayed the smallest flaw, they were rejected. They are all joined together with what is termed spigot and faucet joint, the end of the one being let several inches into a swelled part or socket at the extremity of the other. This forms a much more perfect joint than by flanches and bolts, as it admits of a slight degree of expansion in the pipes without opening the joining. After being entered, a ring of hemp or rope-yarn is wrapped round the end of the pipe, and beat into the socket of the other, and then a mass of lead run in to fill up the opening, which the yarn prevents from running into the pipe: the lead being hard rammed, and stoved with a chisel, forms a joining completely water-tight. Air-cocks are placed at intervals all along the pipes to let off the accumulated air, which is done by the hand at regular intervals, perhaps every three or four days. The supply of water conveyed by this aqueduct amounts to 180 or 200 cubic feet per minute at an average.'—The simplicity and facility of this mode is so obvious, that it is sure to be adopted in every case where there is a sufficiency of fall between the fountainhead and the seat of discharge. The ease with which the mains can be led from the grand trunk, and the service pipes from the mains, at the same time that fire-plugs can be inserted with regularity and system, are prominent features of the syphon-pipe system. There is no change as in the aqueduct from channel to reservoir, and from reservoir to distribution pipe, but one compact and direct principle pervades the whole.

* We have evidence of this in the aqueduct of Mont Pila, the water of which was partly conveyed by leaden pipes, and partly by the usual stone channel-way. In one case the pipes (nine in number, and eight inches in diameter) were carried across a valley upon a range of low bridges, about 200 feet below the regular inclination of the aqueduct; and in crossing the Rhone, a series of similar pipes was laid down in the bed of the river. Towards the end of last century a portion of these pipes was dragged up by an anchor. The fragment is preserved in the museum of Lyons; it is soldered at the joints by the same material, and on each joint are the words in relief, C. CANTIUS POTHINUS, F., which is apparently the name of the maker.

With respect to the material for the conducting tubes or pipes, there can be no doubt of the superiority of cast-iron. It can be cast of any size, shape, or strength; can be jointed, laid, and re-laid with facility; and admits of being pierced for the insertion of plugs or service-pipes. Various concretes have been proposed, and may answer well on a small scale, though totally unfit for large mains under a high pressure. Earthenware tubes internally glazed, when carefully laid and puddled, are very sweet and cleanly; but they cannot be used on a large scale, nor are they well fitted for the insertion of plugs or branch pipes. The same remark applies to glass tubes, which have recently been much spoken of, and which, coated with asphalte, are now employed to some extent in France. As to lead, the great rival and auxiliary of cast-iron, its pliability, the readiness with which it can be cut, jointed, and soldered, and its comparative cheapness, must ever recommend it for small junction and service-pipes; but its inferior tenacity unfits it for a high pressure, while the deleterious qualities which it is apt to impart to certain waters must ever render its adoption a matter of dread and caution. On the latter point, the researches of Professor Christison have proved that water which is exposed to the action of lead by continually running through pipes of that metal, becomes impregnated with the carbonate of lead, to an excess which, when the water is habitually made use of, exposes the drinker to a disease called the lead colic. If it be asked how it is that so many persons are daily partaking of the so-called 'harmless beverage,' without experiencing any ill effects? the answer is, that it is only very pure water which is liable to deteriorate; that the impure water, which is decidedly in most frequent use, generally carries a protection in certain neutral salts containing saline matter, which prevents the lead from impregnating the water in proportion to the quantity of acid contained in the salts. Thus the greater the original purity of the water—such as rain and distilled waters—the greater its danger of developing carbonate of lead.

Pump-Works.

In all places where there is a deficiency of level to carry the water naturally to the highest parts of a town, there is no resource but in the employment of machinery. A steam-engine or other agent is applied to the working of pumps, which first draw the water from rivers or wells, and then force it through a train of pipes to all the different points of consumption. This mode is adopted in some of the densest centres of our population—as in London, Liverpool, Glasgow, Aberdeen, Perth, &c.: as with us fuel is cheap, and steam-engines of unrivalled power and construction, pumping as a system is not without its advantages. The water-works of Glasgow, which are compact, and systematically constructed, may be taken as an illustration:—They are situated on the banks of the Clyde (which yields the supply) about two miles above the city, and occupy both sides of the river, the motive power being on one side, and the aqueducts and filters on the other. 'The works on the northern bank,' we quote from a description in Chambers's Journal for October 1842, 'consist of a series of buildings occupied by nine large steam-engines, two of which, called Goliath and Samson, are of great magnitude and power, and well merit the names which have been given them. They were made in 1839 by the Neath Abbey Iron Company, Glamorganshire, and have each a 72-inch cylinder, with a 10-feet stroke. They are kept in excellent order, and present the finest and most elegant specimens of workmanship of the kind we have ever had the pleasure of inspecting. The room in which they perform their Herculanean labours is tastefully painted and papered, and entirely free from disagreeable effluvia. The erection of these magnificent machines, with their appurtenances, cost the Company £20,000. Four of the other engines, possessing 54-inch cylinders, with an 8-feet stroke, have received the appropriate names of Jupiter, Saturn, Achilles, and Ajax. At Cranston-hill works, which we did not visit, there are also four steam-engines in constant operation. The aggregate amount of motive force thus at the disposal of the Company is estimated at about 700 horse-power. Attached to the working-beam of each engine is a very ingenious piece of mechanism, with seven dials, resembling clockwork, and furnished with a pendulum, which vibrates in unison with every stroke of the engine, and registers, with amazing accuracy and precision, the number of strokes given in the course of an hour, a week, a month, &c. The superintendent has only to consult this self-acting index to ascertain the quantity of water thrown into the city by each engine during any given period. Connected with the water-pipes we observed mercurial pressure-gauges, of very fine workmanship, for indicating the height to which the water is raised in the city, where corresponding gauges are kept in the engineer's office, by which it can be known at a glance how the supply is maintained by the engines, though in operation at the distance of nearly three miles. The quantity of water furnished by the works daily amounts to upwards of 8,000,000 gallons, besides about 600,000 gallons of unfiltered water, raised directly from the river for the use of several public works.

Having examined the varied and ingenious means and appliances on the northern bank for propelling and conducting the water through the city, we were carried across the stream in a boat, to inspect the aqueducts and filters on the other side. These occupy a triangular peninsula, of a honeycomb-like structure, washed on two sides by the Clyde, and perforated in various directions by water-channels. The principal aqueduct or filter consists of an elliptical tunnel 7½ feet in diameter, and upwards of 600 yards in length, sunk ten feet lower than the level of low water, in a bed of sand and gravel, through which the water filters naturally. This tunnel forms a curve parallel with the bed of the river, at about fifty feet from its margin. There are, besides, about eight acres of meadow land, and nearly two of sand-filter, on which the water is raised by steam power. The whole water produced by these filters is conveyed through a gravelly subsoil into the tunnel above-mentioned. The water thus purified is brought across the stream through four suction-pipes, laid in the bed of the river, and connected with the engines on the northern side. It is worthy of remark, that two of these pipes were designed and laid under the direction of the celebrated James Watt, whose genius and skill triumphed over the first difficulty which presented itself, arising from the bend or curve in the bed of the river, by devising a flexible main or tube, constructed of iron pipes, and so connected by movable joints and hinges as to adapt its form to the bottom of the Clyde. The water is conveyed into the city through the medium of four principal pipes or mains, as they are called, respectively of 14, 21, 25, and 36 inches diameter. As the ground on which Glasgow is built is of great variation of elevation, four intermediate stations or reservoirs have been formed, into which water is raised to the elevation requisite to supply the several districts, and no more; thus economising the power required to be exerted by the steam-engines, and furnishing at the same time an abundant supply to those who occupy the highest houses. Besides these reservoirs, there are two others now in course of erection at the west end, to meet the increased demand arising from the rapid extension of the city in that direction. One of these is an extremely handsome massive structure, and harmonises admirably with the elegant buildings by which it is surrounded. It is lined throughout with cast-iron plates, and is 123 feet in length by 84 in breadth, and 10 in depth. The whole extent of pipes, with their varied ramifications throughout the city, amounts to upwards of 140 miles.

The supply to the inhabitants, we were informed, begins about six in the morning, and is continued without intermission throughout all the pipes till from eight to ten in the evening. The population of Glasgow, according to the last census, is nearly 300,000; and these works pour unceasingly, like the heart in the human system, the life-blood of a city—WATER—through a thousand channels, until it reaches the most distant and obscure member of the community. One has only to witness, for a brief period, the effect of a partial suspension of the works, to be convinced of the incalculable benefits they confer.'

As it is our wish to present principles rather than descriptive details, our space will not permit of any account of the Companies' water-works which supply the Metropolis. These companies are eight in number, and obtain their water partly from the Thames and partly from wells—employing a system of pumping-engines, filters, and reservoirs, aided, as in the case of the 'New River,' by the principle of the open conduit. By these means, the supply of water to the inhabitants of London has been brought to a considerable degree of purity and efficiency, though still wanting that sparkling transparency and coolness which give to water its most valuable properties as a beverage, and that overflowing abundance without which the great sanitary projects of the day can never be carried into full effect.

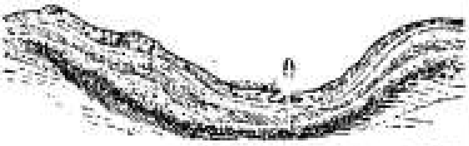
Artesian Wells.

Common wells, of whatever depth or construction, require no detailed notice. If the water rise to the surface, it may be led away either by syphon-pipes or by conduits; if it rise only to a certain height in the shaft, then it must be lifted by pumping, or other kindred apparatus. Wells of this kind are common all over the world; in Britain they are found in every locality, from the solitary farm-house to the crowded city. At one time they formed the sole source of supply for our towns, and are still to a great extent available; more, however, by private parties than by the general community. Being fed by subterranean springs, their water is frequently impregnated with mineral substances; and many of the springs being intermittent, the supply is often deficient during the droughts of summer. Laying aside these objections, which are less or more applicable to every other source of water, the common well, if carefully built with stone (bricks are objectionable), and fitted with an improved pump, is an invention by no means to be despised, though of course not for a moment to be compared with the full-pressure system of the aqueduct or syphon-pipe.

Artesian wells—so called from Artois, a province in the north of France, where it appears the greatest attention has been paid to the discovery of subterranean springs—are distinguished from common wells by the circumstance of their waters rising above the surface, often to a considerable height, and with considerable violence. This fact, that water will rise spontaneously to and above the surface, in certain localities, when bores of various depths are made into the earth, seems to have been long known to mankind. An Alexandrian writer of the sixth century narrates that 'when wells are sunk in the oasis of the desert, to a depth varying from 100 to 500 ells, water springs from the orifices, so as to form rivers, of which the farmers avail themselves to irrigate their fields.' In more modern times, travellers relate that, in some parts of the Desert of Sahara, the natives sometimes bore the earth to the depth of 200 fathoms, and always succeed in finding water, which flows often up the bores with such force, as to drown those engaged in making the excavations. In China also, and in European countries, there are proofs of wells of this nature having been early formed. In many cases the water of these wells not only spouts to the height of several feet above the surface, but might be conveyed with ease in pipes to the tops of the highest houses.

Artesian wells are common on the continent, particularly in France, which consequently furnishes the finest examples. That of Grenelle, near Paris, is, we believe, the most gigantic, the borings being carried through tertiary and chalk strata to a depth of 1798 feet, or one-third of an English mile. The bore is 20 inches in diameter at the orifice, but is contracted by stages, till at the bottom it is only 7 inches. The bore is lined with iron tubing; and the current, which discharges between 500 and 600 gallons per minute, rises to a height of 100 feet above the surface—thus forming an inexhaustible supply of excellent water, running from such an elevation as to be easily distributed to the loftiest situations in the city. The work was commenced under the superintendence of M. Mulot in November 1833, and finished in February 1844 at an expense of 303,000 francs. In Britain, as well as in France, there are others of large dimensions; several of them, however, discharging their supply partly upon the Artesian principle, and partly by pumps. The Polytechnic Magazine notices the following:—'The fountain at Cheswick, belonging to the Duke of Northumberland, is 584 feet deep, and throws the water 4 or 5 feet above the surface. An Artesian fountain in the monastery of St André, half a league from Aire, ascends 11 feet above the surface-level, and discharges two tuns per minute. At Gouchem, near Bethune, the waters from four borings turn the millstones, and churns, and serve for other purposes. At St Pol, a mill is turned by similar means. At Fontes, near Aire, the waters from ten borings turn some large millstones, and also works the hammers and bellows of a forge. All the machinery of the silk manufactory of M. Champoiseau, at Tours, is kept in motion by water from a similar well, 273 feet deep; and at Tooting, near London, the water from an Artesian fountain belonging to a druggist, works a pump, by which water is forced three storeys high in his house.' To these we may add the recently-sunk well at Southampton, which is 1300 feet deep, 600 of which is a built shaft, the remainder a bore of large diameter. The water rises within forty feet of the surface, and is then pumped by steam-engines at the rate of 55,000 gallons per day! Another at Hanwell, 290 feet deep, partly shaft and partly a bore of 14 inches diameter, discharges 100 gallons per minute, and rises upwards of 26 feet above the surface. In consequence of the law of increasing temperature as we descend into the earth, the waters of Artesian wells are frequently five, six, and eight degrees above that at the surface; and calculating upon the uniformity of this increase, it has been gravely proposed to sink at Paris to such a depth as to obtain the water at a temperature of thirty-two degrees Centigrade—this thermal current to be economically applied in heating the hothouses of the Jardin des Plantes, and the hospitals of La Pitie and La Salpetrière.

The geological and hydrostatic principles upon which the forcible discharge of Artesian fountains depend are sufficiently obvious. The greater portion of the earth's crust consists of stratified formations, which are variously broken up and inclined; here thrown into ridges, there into basin-shaped hollows, and again into long gradual slopes. The rain, percolating through the loose soils and subsoils, makes its way into and between the various rocky strata—those that are soft and porous imbibing the greatest quantity. Naturally seeking the lowest level, this water again makes its escape to the surface in the form of springs—these springs appearing in valleys, at the bases of hills, and other low-lying situations. Any rent, or fissure, or dike (see GEOLOGY), breaking the continuity of the strata, must also interfere with the passage of the contained water; and thus it is that natural springs are most frequent along the line of these interruptions. It must be obvious then, that among the hard and impervious strata of the primary formations, in broad flat districts, and in districts where the continuity of the strata is much broken up by igneous rocks, that the springs will be comparatively few and small; while among the softer and more porous strata of the secondary and tertiary formations, and in districts where these strata are variously inclined, and thrown into large basins or hollows, that the springs will be numerous and abundant. It is thus that the finest Artesian wells are found in secondary and tertiary basins, the principle being as follows:—Let the annexed section represent a tertiary basin, composed of alternating strata of sand, clay, gravel, and loose sandstones. It is clear that the thick bed of sand and gravel *a*, lying between two layers of impervious clay *b* and *c*, can have no outlet for the water with which it is saturated by percolation. It is, in fact, a great subterraneous sheet or reservoir of water, whose



maximum pressure is at the bottom of the basin. Let a well or bore be sunk in the valley, and the result will be, so soon as the bore strikes the bed of gravel, a rush or jet of water, forcible in proportion to the extent of the bed, and the height to which its sides rise above the surface of the valley. Of course the friction in passing up the bore, the weight of the atmosphere, and the self-weight of the ascending column, will all tend to prevent the jet from rising to precisely the same height as the water in the stratum; but these allowed for, a uniform column will be obtained so long as the bed of gravel holds the same quantity. Summer droughts will necessarily lessen that amount, and winter rains increase it—influences which are felt on shallow Artesian bores, but which are altogether imperceptible in those of immense depth. Depending upon these principles, no Artesian well should be attempted without consulting the geologist or mining-engineer. A deflexion of the strata, the occurrence of a dike, or some such phenomena, which the geologist alone can interpret, may render abortive years of the most assiduous and expensive labour.

The mode of executing Artesian fountains, though laborious and expensive, requires less ingenuity and knowledge than the determination of the site and depth. In the case of shafts, digging, hewing, and blasting, as in the case of coal-pits, are the means resorted to; and where the strata are soft and yielding, the shaft must be cradled—that is, lined with stone or iron—as the work proceeds. Where boring is resorted to, it is done after the ordinary methods, only with much greater expense, as the bore is frequently required to be of large diameter. Boring, as the reader may be aware, is performed by a cutting chisel, whose edge corresponds with the diameter of bore demanded. This chisel is at first worked by hand, and supplied with water much in the same way as the quarryman bores for blasting. As the bore deepens, lengths with alternate male and female screws are attached, so as to form a rod; and when this rod becomes of great weight, a windlass or other machinery is necessary to work it. The débris is removed from the bore by unscrewing the chisel, and attaching a cylindrical auger or gouge, fitted with a valve so as to prevent the return of the sand or clay, which is in a state of pulp or paste. This is one of the most troublesome parts of the operation; but is necessary not only to clear the hole, but to show the superintendent the nature of the strata passed through. Removing the débris, and attaching fresh chisels, are duties which consume much of the borer's time, and this just in proportion as the depth increases. Instead of working by rod, a heavy chisel worked by rope is sometimes substituted—the rope being lighter and more manageable, while torsion can be readily given to it so as to shift the edge of the chisel. By whatever means the bore is made, whether sunk of the desired width at once, or widened by degrees, it is customary in a soft strata to line the bore with iron tubing, let down by lengths soldered together. This casing prevents the filling up of the bore by lateral percolation, and prevents also the main spring from being rendered impure by discharges from intermediate beds of clay and shale. Fitted with a perforated cover, this tubing may be said to complete the operation.

Fountains—Jets-d'Eau.

Fountains or jets-d'eau are contrivances by which water is violently spouted or projected upwards in a continuous stream, so as to become at once ornamental, refreshing, and salubrious to the locality in which they are situated. The projecting force is acquired either from the hydraulic pressure of the water at the fountain-head, by the spring and elasticity of a confined volume of air, or by mechanical appliance; but generally by the former power. (See HYDRAULICS and PNEUMATICS, No. 15.) The water is conveyed from the reservoir to the fountain in pipes, and if the orifice from which it issues be directed upwards, it will spout to a height approaching that of the reservoir. It will always, however, fall short of this height, for the following reasons:—namely, the resistance of the atmosphere, the friction of the discharging orifice, and the resistance or weight which the first propelled particles of water offer to those which follow.

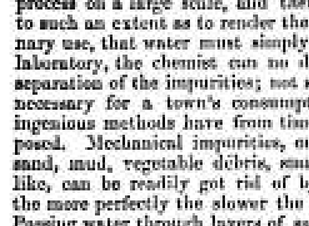
Decorated fountains of this kind were much in request among the Greeks and Romans, not only in their streets and gardens, but also in the courts of their houses. The 'Pirene,' a fountain at Corinth, was encircled by an enclosure of white marble, which was sculptured into various grottos, from which the water ran into a splendid basin of the same material. Another fountain in Corinth, called 'Lerna,' was encircled by a beautiful portico, under which were seats for the public to sit upon during the extreme heats of summer, to enjoy the cool air from the falling waters. We read of many others in both Greek and Roman authors; and this fondness for fountains still exists in Italy and the East, where there are numerous elaborate and fanciful designs. The French are also celebrated for their fountains, those at the Tuileries, Versailles, and St Cloud being superb structures; and indeed, with the exception of our own, most of the large towns of Europe are adorned and refreshed by these contrivances. The most remarkable jet-d'eau in the world is said to be that at Cassel in Germany, where the waters rise from an orifice of 12 inches diameter to a perpendicular height of 250 feet. The source from which it is supplied is at the top of a mountain near by, being about 500 feet above the level of the town.

Viewing jets as auxiliaries to health, as well as ornaments, we are inclined to advocate their erection wherever it is practicable. In our public gardens and squares, along promenades, and at the crossing of streets, nothing could be more appropriate and ornamental, independent of the cooling effect which they must exert over the surrounding atmosphere in summer. Where the supply of water is abundant, there is every scope for the ingenuity of the artist and engineer in the designing of fountains—from the most grotesque and fanciful, to the most severely classical conception. Nor is there any reason why small, permanent, or portable fountains should not be more generally introduced into our market-places, shops, and public buildings, where the atmosphere is apt to become heated and contaminated, producing oppression, listlessness, and languor.

Reservoirs—Filters.

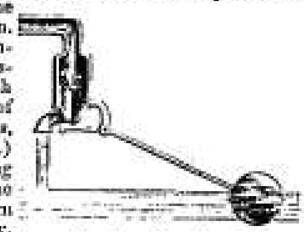
Reservoirs or tanks are necessary appendages to most water-works, and require to be constructed with skill and care. Occasionally, they are little more than simple excavations, the excavated earth forming the retaining banks; but in general they are puddled with clay, or lined with masonry; and if of considerable depth and size, the embankments should be strongly constructed, as serious accidents may arise from their breaking down under the pressure of the water. As the pressure of any given amount of liquid can be calculated with precision, there is no excuse for the engineer who blunders either as to the proper slope or weight of a retaining embankment. Besides the regulating sluices, large reservoirs should be furnished with waste outlets, to prevent damage to the banks in cases of freshets or land-floods. For small domestic or covered tanks, cast-iron plating securely rivetted, hewn stone, common masonry lined with some of the patent cements, glazed bricks, Welsh slate, or the like, form excellent materials, and are preferable to wood, which requires to be lined with lead or other metal. In all cases, large or small, there is necessity for regular cleaning, as the purest of our waters will in time give rise to offensive sediment.

As already stated, all natural waters are less or more contaminated with chemical or mechanical impurities. To get rid of the former, there is no cheap available process on a large scale, and therefore if they prevail to such an extent as to render the water unfit for ordinary use, that water must simply be avoided. In the laboratory, the chemist can no doubt readily effect a separation of the impurities; not so in the large supply necessary for a town's consumption, though several ingenious methods have from time to time been proposed. Mechanical impurities, on the other hand, as sand, mud, vegetable débris, small animals, and the like, can be readily got rid of by filtering, and that the more perfectly the slower the process of filtration. Passing water through layers of sand and gravel is the simplest perhaps of all methods: to these are sometimes added potsherds and charcoal—the latter ingredient exercising an antiseptic power, and destroying all fetor and putrefaction. Whether on a large or small scale, the materials most in use are those we have mentioned, together with porous earthenware and certain sandstones. As the intercepted slime and sediment will in all cases tend to clog and fill up the pores of the filter, considerable ingenuity has been displayed by various parties in arranging the materials so as to retard this clogging, and in the construction of what are termed 'self-cleaning' filters. That invented and used by Mr Thom at Greenock, Paisley, Ayr, &c. is one of the most effective, and may be taken in illustration:—In the accompanying transverse section, *a* is the conduit for supplying the water to the filter; *c* a sluice for regulating the flow; *b* a valve which admits the water above or below the filtering material at pleasure; *e* a floor of perforated tiles resting on a puddled basis; *f* the filter, composed of layers of gravel and sand, gradually increasing in fineness towards the surface, the top layer consisting of fine sand and grained animal charcoal. The whole apparatus being completed, the water is allowed to enter the filter at the top, and passing through the different layers, it issues quite pure and free from taint. When the filter becomes foul, which is shown by the decreased quality of water passing through, the valve *b* is reversed, and the current made to enter from below, carrying the particles of mud to the surface of the top layer, whence they can be readily removed. The cost of the Paisley filter was £600, and the quantity of pure water produced regularly every twenty-four hours is on an average 100,632 cubic feet. There are a number of other filters in use, but the same principle pervades the whole—namely, the passing of the water through successive layers of porous, and occasionally antiseptic, materials.



Modes of Distribution.

The manner of distributing water in towns by the ordinary mains and service-pipes, may be either 'intermittent' or 'constant.' The intermittent or periodical system consists in *laying on* the water, as it is termed, at regular or irregular intervals—once a day, or once in two days, as the case may be. Of course in the interval no water can be drawn from the service-pipes in the interior of the houses, so that means must be adopted for storing a sufficiency for domestic requirements during the time the supply is withdrawn. This necessarily involves the use of cisterns or tanks, with all their apparatus of pipes and ball-cocks, the latter (see fig.) ingeniously shutting off or admitting the supply as the cistern may be full or empty. The constant system, on the other hand, affords a supply at all times, to be drawn directly from the service-pipe, without the intervention of cisterns. Constant supply at high pressure is obtained by having the source from which the supply is obtained at a considerable height above the town, so that by the force of gravitation the water may be delivered at the highest house; or failing this, steam power must be applied to raise it to reservoirs at such a height, or to force it at once into the pipes. Of the two systems, the latter is the more advantageous both in a sanitary and economical point of view. In the constant high-pressure system, the mains and service-pipes may be reduced one-third in size; all the expensive and ever-failing apparatus of cisterns and ball-cocks is done away with; the casualties by fire are materially lessened; and the constant flushing of the drains and sewers is sanitarily of vital importance. Though the consumption of water be much greater, yet none of its efficacy can be said to be lost; and indeed until our towns and cities be in possession of a constant high-pressure system, they cannot be said to be adequately supplied.



BATHS—WASH-HOUSES.

Referring the reader to our article on the Preservation of Health for the sanitary value of personal ablution, we shall here treat of baths as a social arrangement, and of the various mechanical appliances requisite for the establishment of a system.

Baths of the Ancients.

The use of the bath has existed, in all probability, from the beginning of the world, since it is founded in the most natural wants of man. In barbarous ages, however, in which art had as yet accomplished nothing for the conveniences of life, men merely plunged into rivers, streams, fountains, and other natural reservoirs of water. They were far from dreaming of the erection of apparatus by means of which they might be enabled, as at a later period, to take their baths at any time, season, or place, and of an agreeable and salutary temperature. Doubtless the discovery of hot springs, which must have existed then as in our own times, at various parts of the earth's surface, suggested to them the happy idea of communicating different degrees of heat to the water they employed, and of erecting more commodious and less dangerous receptacles. It was amongst the nations of the East, the earliest reapers of the benefits of civilisation, that industry and the arts made the first efforts to satisfy the wants of men, and perpetuate the taste for, and employment of, warm baths. The custom was carried from Asia to Europe by the colonists, who successively established themselves in Greece, Italy, Iberia, and Gaul.

Greece knew the use of warm baths in the time of Homer, for mention is made of them in several passages of the writings of that poet. Among the Greeks, the Lacedæmonians were the first who adopted the custom, borrowed from Asiatic nations, of appearing naked at the public games; anointing themselves with oil, and covering themselves with sand prior to the contest, and then plunging into hot baths. But the employment of baths in private families was not even yet very general in the time of Hippocrates. This prevented his recommending the bath in many diseases which called for its adoption. As to the public establishments, they formed part of the *gymnasia* to which they were attached.

The Romans were accustomed, in the early period of the republic, after a day employed in labour in the fields, to wash only the arms and legs; and every ninth day, when they came to the city, to be present in the assemblies for state business, they bathed the entire body. At that period the Tiber or neighbouring streams formed their bathing resorts, vapour and hot-water baths being scarcely known to them. It was only at a late period they thought of establishing public or private baths. The city, by reason of its situation on hills, presented great difficulties for the conveyance of water. As already stated, it was not until about 441 years after the foundation of Rome that water was brought, for the first time, from Tusculum by means of an aqueduct. These structures were multiplied afterwards; and baths, or *thermæ*, were erected in various parts of the city, characterised as yet by the ancient Roman simplicity.

The new custom which the Romans adopted towards the last years of the republic, of attaching baths to the gymnasia, rendered them indispensably necessary; and the frequent application which physicians, from this period, made of them in the treatment of disease, powerfully contributed to the increase and embellishment of these salutary and useful structures. But it was not until the reign of Augustus that they began to give to their warm baths that air of grandeur and magnificence which is yet to be observed in the ruins which remain. To conceive a just idea of them, we should examine the plans of the principal edifices as traced by Palladio. In beholding his designs of the bas-reliefs and pictures which adorned the walls and ceilings, we are at once astonished at the perfection of the objects they represent, and at the exquisite purity of taste which then prevailed in the arts. The rarest marbles, precious vases, bronzes, columns, statues from the chisel of the greatest masters, and gildings skilfully applied, contributed to the brilliancy of the interior of these gigantic monuments.

It is difficult to enumerate the immense number of uses they were devoted to. Besides the vast basins, and the thousands of recesses (the thermæ of Diocletian contained three thousand) appropriated to the different baths, there were found there theatres, temples, amphitheatres, palaces, festive halls, vast open promenades planted with trees, schools frequented by youth, academies where learned persons assembled for discussion, and libraries, to which every one might freely resort.

The most complete establishments contained numerous apartments devoted to the various processes connected with an elaborate system of bathing. The bather, after having undressed in the *apodyterium*, was conducted into the *unctuarium*, where his body was freely anointed with strong oils; afterwards, in an adjoining apartment, it was covered with fine sand or powder. He now repaired to the *sphæristerium*, an immense hall or rotunda, in which he engaged in wrestling, or other gymnastic exercises calculated to develop physical power. When the locality admitted of it, the sphæristerium was uncovered and exposed to the sun; or rather, in the best-appointed baths, there were two sphæristeria. The various games were continued until the sound of a bell announced that the vapour and hot-water baths were ready. To these the crowd of bathers now proceeded, each person taking his seat on a marble bench, placed below the surface of the water, around immense basins, wherein swimming might be executed when agreeable. While here, they diligently scraped the skin with a species of ivory or metal knife, termed a *strigilis*, by which they detached all impurities from the surface. The *tepidarium*, or tepid bath, and *frigidarium*, or cold bath, were finally employed for a short time, for the purpose of bracing the pores of the skin, relaxed by so long a proximity of moist heat. Before dressing, those who desired to employ perfumes—latterly a numerous party—again repaired to the unctuarium.

The baths of the ancients, although usually built after a similar plan, yet offered a notable difference. At Rome, even in the most splendid establishments, the greater portion of the extent of the edifice was appropriated to baths, properly so-called, which obtained for them the name of thermæ, from the Greek word *thermos*, heat. But with the Greeks the gymnasium occupied almost the entire structure, the bath itself being but of very limited dimensions. This difference exhibits the passion for bathing which seized the Romans towards the end of the republic, and continued to possess them until the fall of the Empire. With regard to the mechanical arrangements—the heating, ventilating, and supplying of the Roman baths—little is known with certainty, though the remains of Pompeii has thrown some light on the subject. It would appear that the water was conveyed from the aqueduct to a reservoir, and from this directly to the cold baths by lead or earthen pipes. The hot baths were supplied from a copper or boiler, the furnace of which also furnished hot air for the flues which heated the pavement and walls of the vapour baths, the tepidarium, and other apartments. The light was admitted from the roof, and the ventilation regulated by openings furnished with ornamental valves. Of course their comparative ignorance of the metals prevented them from arriving at that nicety and rapidity of heating known in modern times; still their architects were sufficiently acquainted with the laws of caloric to make arrangements by which as little as possible of the heating power should be dissipated and lost.

At first, the public baths were only opened at two o'clock in the afternoon, and closed at five: the sick alone having a right to enter them at any time. Latterly, the emperors, wishing to conciliate the people by their favourite amusement, ordered the doors to be opened sooner, and closed later. Nero had them opened at twelve; Alexander Severus allowed the baths to be entered from the break of day, and even furnished at his own expense lamps and oil for lighting them. From that time the Romans may be said to have passed their lives at the baths. They frequently bathed twice a day; and hot water constituted one of the indispensable elements of their existence. We must not, however, attribute this singular passion exclusively to fondness of bathing. The desire and hope of meeting with friends, of discussing the topics of the day, and passing the time agreeably, were no less powerful motives.

Of all the Grecian people, the Lacedæmonians were the only ones in whom the gymnasia and baths were common to both sexes. The ancient Romans were far from following such an example, and carried modesty so far as to consider it improper that a father should appear at the same bath with his son, or even son-in-law. Later, however, the corruption of manners made such progress, that in the reign of Domitian, women and men bathed pell-mell together. This custom, then generally adopted, was afterwards prohibited by Hadrian and Marcus Aurelius; again tolerated by Heliogabalus; and finally abolished by Alexander Severus. The baths were, however, frequented indiscriminately by individuals of all ranks. The noblest and richest persons there found themselves mingled with the poorest plebeians.

It was not only the Roman metropolis which contained public and private baths. They existed in all the towns of Italy, and in the palaces of nobles and freedmen. They were found also in all the Roman provinces. In our time even, it is easy to perceive the vestiges of the Roman thermæ in every country which formed a portion of their extensive empire.

The greater number of these magnificent edifices, which, during the most illustrious period of the Empire, had constituted the pride and delight of Rome, were destroyed by the Vandalism of the barbarian hordes. Those which were not pulled down were otherwise employed, or, being no longer repaired, gradually fell into ruin. Baths, which formed one of the requisites for the effeminate and luxurious life of the Romans, were, for the warrior and invading nations, mere means for the preservation of cleanliness. Utility and cleanliness were the only objects held in view in the construction of the thermæ, which were henceforth erected in Italy or the other countries of Europe. Baths were much frequented, however, during the whole of the middle ages, until the sixteenth century—the epoch at which the use of linen became general. 'The barbarism of the middle ages,' says Grosley, 'not being able to attain magnificence, confined itself to the convenience of the public baths, and other establishments, which were erected in Europe. The idea was due to the Arabs, among whom the arts and sciences had found an asylum. The Crusades and commerce had opened up to Europeans the countries which flourished under the rule of this people, and the natural taste for imitation did the rest. The vapour and public baths were, for a long period, as much frequented in Europe as they are at the present day in the Levant. People were attracted to them for the sake of health and cleanliness; but, above all, from the want of society felt by persons who saw little of each other except in these places. Some took water baths, others vapour baths; while several came only to gossip, comfortably protected from the cold. For these last, the baths were what the stoves of Germany, the *estaminets* of Holland, and the cafés of Paris, are to this day.'

Modern Baths

Although the increasing use of linen has much diminished the hygienic necessity of the bath, and has occasioned the ruin and neglect of the establishments of the middle ages, yet public attention has not ceased to be directed to the advantages of such establishments—thanks to the salutary counsels of medicine, the progress of civilisation, and the amelioration of the material comforts of the masses. 'Eminent physicians,' says Dr Clarke, lamenting our inferiority in this respect to continental nations, 'have endeavoured to draw the attention of the British government to the importance of public baths, and of countenancing their use by every aid of example and encouragement. While we wonder at their prevalence among all the eastern and northern nations, may we not lament that they are so little used in our own country! We might, perhaps, find reason to allow that erysipelas, surfeit, rheumatism, colds, and a hundred other evils, particularly all sorts of cutaneous and nervous disorders, might be alleviated, if not prevented, by a proper attention to bathing. The inhabitants of countries in which the bath is constantly used, anxiously seek it, in full confidence of getting rid of all such complaints; and they are rarely disappointed. I may add my testimony to theirs, having not only upon the occasion which gave rise to these remarks, but in cases of obstructed perspiration much more alarming, during my travels, experienced their good effect. I hardly know any act of benevolence more essential to the comfort of the community, than that of establishing, by public benefaction, the use of baths for the poor in all our cities and manufacturing towns. The lives of many might be saved by them. In England they are considered only as articles of luxury; yet throughout the vast empire of Russia, through all Finland, Lapland, Sweden, and Norway, there is no cottage so poor, no hut so destitute, but it possesses its vapour bath, in which all its inhabitants, every Saturday at least, and every day in cases of sickness, experience comfort and salubrity. Lady Mary Wortley Montagu, in spite of all the prejudices which prevailed in England against inoculation, introduced it from Turkey. If another person of equal influence would endeavour to establish throughout Great Britain the use of warm and vapour baths, the inconveniences of our climate would be done away. Perhaps at some future period they may become general; and statues may perpetuate the memory of the patriot, the statesman, or the sovereign, to whom society will be indebted for their institution.'

Since this sensible and energetic appeal was made, a better state of things seems to be approaching; and for some years past the institution of baths has much engaged the public attention. The houses of our higher classes are now invariably fitted up with accommodation for hot and cold bathing; portable baths on the sponge, shower, or plunge principle are common in the dwellings of the middle classes;* and deficient as we yet are, the last ten years has witnessed the erection of a number of private and public establishments, at which the masses may enjoy a bath for the merest trifle of their weekly earnings. It were greatly to be wished that these establishments were increased tenfold, and that some public fund were raised for their establishment and partial maintenance. We have abundance of fuel for heating; in general, a fair supply of water; and as fine architecture and expensive fittings are not required, it is difficult to account for the tardy progress we make in this department of social economics. Without entering minutely upon the *mécanique* of baths, which may be varied almost to infinity, the following points seem to require consideration in the organising of such establishments:—

1. An abundant supply of soft fresh water. The quantity desirable for a single bath is from forty to fifty gallons. Whether for single or public plunge-baths, the number of bathers per day may be multiplied by forty, and the quantity of water to be consumed will thus be ascertained. There is nothing so unpleasant as the idea of laving in the water that has been used by others, and we know that in many instances the dread of doing so has deterred from the use of the bath, where there was otherwise a wish and a willingness. The practice of using the same water in succession, even though filtered, is highly objectionable, and ought never to be resorted to.

2. The water should flow into a large tank, from the tank to the boiler, and the boiler to the baths, the waste escaping by a conduit. If the tank is placed in a lower situation than the boiler, steam power will be required to pump it. In most situations it is desirable to be as economical of space as possible, and for this purpose it is generally contrived to have the reservoirs underground; the plunge-bath, shower, and douche baths, heating apparatus, and waiting-rooms on the ground-floor; the private baths in the upper storey; and the hot-water tank above all. In planning and laying out the apartments, the greatest attention ought to be paid to privacy and decorum; for whatever may have been the customs of the ancients, or what may now be the practice of continental nations, our countrymen have in general the keenest sense of delicacy in this respect—a feeling which ought never to be offended through any mal-arrangement or mistaken parsimony.

3. The establishment should possess washing-rooms, single private bath-rooms, a large plunge bath-room, and waiting-rooms for the several classes of bathers; also a separate apartment for the washing and properly drying of the towels and hand-cloths.

4. In the washing-room or rooms there should be basins, at which all persons proposing to use the plunge-bath ought, in the first place, to wash their hands, face, arms, and neck. If a regulation of this kind is not enforced, the water in the plunge-bath will very shortly become unendurable.

5. The plunge-bath may be made of a circular or

* In absence of *permanent* baths, which ought to form part of every modern house of any pretensions, just as much as its kitchen or laundry, *portable* baths, now procurable at the ironmongers in every variety, will be found to be no indifferent substitutes. Among the most approved are Read's 'Universal Bath,' which comprises in one the cold, warm, shower, douche, and vapour bath; the 'Omnidirection Bath,' which allows the stream to be directed against any particular part of the body; and the 'Portable Shower Bath,' which has the merit of going into very little space, and may be used in any apartment. For a permanent hot bath, the kitchen range may be constructed so as to have a supply of from ten to twenty gallons of warm water always in readiness, and this, after the original outlay, at a cost almost inappreciable.

oblong form. That generally recommended is oblong, measuring 40 feet in length by 30 feet in breadth; the depth, by means of a sloping bottom, to be from 4 to 6 feet, but never more. Within the bath there may be a step to assist in descending and ascending. At one end, near the surface of the water, there should be several inlets, to be kept constantly running, and at the opposite extremity outlets for escape. By the careful adjustment of these orifices, the water may be kept in a state of considerable purity, notwithstanding its continual use. Besides this, the whole volume of water should be discharged twice a week, and the bottom of the bath well scrubbed. The number of persons admitted at one time will require to be regulated according to circumstances. Over the bath there should be the means of ventilation for the watery vapour and heated air.

6. Where possible, the whole suite of baths should be lighted from above; and each room should be furnished with hot-water pipes, so as to raise its atmosphere to any desired temperature. We have spoken of a boiler, but this is only one means of heating that may be adopted. Steam-pipes, or a circulation of hot water, may be employed to keep the swimming bath at the proper temperature; and the hot-water tank may also be heated by steam, which will be found in most cases to be the most effectual and economical method. These, as well as other matters of detail, ought in each case to be intrusted to an experienced architect and plumber. So far as experience has gone, it has been found that, at the rate of 100 bathers per day, a single cold bath may be furnished for 2d., a single hot or tepid bath for 3½d., and a swimming bath for 2d., and that these charges may be made remunerative.

7. Another important requisite is, that the situation be as central as possible for the great body of those for whose use it is intended. A short walk one would suppose to be rather agreeable than otherwise to the working-classes; but experience has found that unless a bathing establishment be in their immediate vicinity, and be continually before their eyes, they are apt to seize every trifling accident—as a little unusual fatigue, a wet night, or the like—as an excuse for abandoning the ablution.

Such ought to be the leading characteristics of a bathing establishment suited to the wants and requirements of our population. With us the bath is a necessity, not a luxury. The great majority of our artisans and factory workers are engaged in labour of a kind by no means cleanly, and without daily ablution of some sort or other, disease, injured constitutions, and debased moral sentiments, are certain sooner or later to be engendered. What we desiderate is means for thorough, regular, and cheap ablution; the effeminacy of anointing, shampooing, and other kindred practices being wholly unsuited to, as they are unneeded under, our northern climate.

We have spoken above of public baths; but where steam engines are employed in connection with cotton factories or other works, there is usually a certain quantity of waste steam or waste hot water at disposal, which could at an insignificant cost be directed into baths for the use of the workmen of the establishment; and we hope this will be done wherever it is practicable. The improved health and cheerfulness of the parties benefited will be more than compensatory for the necessary outlay. We are aware of one instance where seven baths were comfortably fitted up at the small expense of £30, in which the men and women bathe on alternate days, to the number of from thirty to eighty a week—paying a mere trifle to the keeper, who attends an hour and a half each evening, and finds towels, soap, &c. nothing being charged by the proprietors for the original outlay.

Wash-houses.

These are recent inventions, forced upon us by the exigencies of our peculiar social condition. In a country where the labouring classes are in a comparatively easy condition, and thinly scattered, the house is at once the domestic brewery, bakehouse, and laundry, as it is the family sanctuary. But where the masses are densely packed in lanes and alleys, where house accommodation is dear and limited, where the necessaries of life have to be continually struggled for, and these conventional evils increased, in too many instances, by improvidence, the house is but a night shelter, affording little or no convenience for the necessary operations of the housewife. Independent of this, in point of economy, a public wash-house is preferable to any number of isolated efforts. By co-operation, superior accommodation, better apparatus, and a cheaper and more satisfactory result can be obtained; and thus the public wash-house, where self-paying and self-supported, may be classed among the co-operative arrangements which characterise the social features of the age. Several establishments of this kind, partly of a charitable and partly of a self-supporting kind, are now in existence in the metropolis, in Liverpool, and we believe in other of our populous towns.

As in the case of baths, wash-houses primarily depend upon a liberal supply of soft water, and upon economical modes of heating and drying. As only the needier classes are likely to make use of them, everything should be upon the cheapest possible scale—hot water, tubs, soap, soda, drying, smoothing-irons, and mangles. The establishment should consist, at the least, of a washing-room, furnished with tubs having stopcocks for hot and cold water; of a drying-room, fitted up with hot-air or other rapidly-desiccating apparatus; and of an ironing and mangling apartment. Seeing that hot water is always on the premises, a few baths may be conveniently attached—the persons of the occupants generally requiring ablution as much as their clothes. By using one furnace, and a system of steam-pipes, hot water for the tubs and baths may be cheaply procured; and by very little additional mechanism, the same source may be made to propel a current of heated air to the drying-room. When we consider the amount of fuel required for a kitchen fire on a washing-day, the time wasted by imperfect arrangements, the inconvenience experienced where the housewife has to wash, dry, and iron her clothes in the one sole room where she has to cook the family meals, and where that family has perhaps to eat, sleep, dress and undress, and perform all the minor offices of life, we can then appreciate the boon which a public wash-house is calculated to confer. Without dwelling longer on the arrangements of such establishments, which are so simple and intelligible, we shall present the practical results of one of the humblest of the kind—namely, that of East Smithfield, London, which is chiefly supported by charitable donations. It combines very properly bathing and washing, and provides every requisite, even to a change of clothing, to those who come to cleanse their solitary suit:—

The arrangements of the baths, which are six in number, though destitute of everything like ornament, and in some respects somewhat rudely constructed, are unexceptionable as respects privacy and decorum. The writer himself took a warm bath on the premises, and had soap and a clean towel allowed him, for all which accommodation he was expected to pay only a penny. The bath was certainly not so neatly or commodiously constructed, nor contained in so comfortable an apartment, as the second-class baths at the public baths and wash-houses in George Street, Marylebone, near Euston Square; but it ought to be taken into account, in instituting the comparison, that the charge for a warm bath at the latter place is fourpence, and that the establishment is a self-supporting one, and conducted on a much more extensive and pretending scale than that at East Smithfield.

As regards the other department of the institution, a large, lofty room, being the principal one in the house, is set apart for the washing and drying of clothes. There is always a number of women engaged in this work, superintended by the matron, amongst whom the greatest decorum and order are observable.

They are uniformly civil in their behaviour towards the matron and to one another, and all of them express themselves grateful for the privileges afforded. In this room there is a large steam boiler, used for the purpose of heating the water; not by *boiling* it in the ordinary way, but by pouring steam into wooden tubs filled with cold water, until it becomes heated. With the view of economising fuel, this boiler is used not only for heating the water in the wash-tubs, but also that in the baths placed in adjacent apartments; and what is more remarkable, it is likewise made available for the drying of the clothes when washed, through the medium of Davison and Symington's ingenious process:—A chamber, about the size, and having the appearance, of a large cupboard, is placed at the distance of a few yards from the boiler, with which it is made to communicate by a pipe of about eight inches in diameter, through which, by means of a revolving fan turned by hand, a column of heated air is sent into the drying chamber through the floor, which is of iron, and closely perforated. The clothes intended to be dried are suspended from horizontal poles placed within the drying chamber; and by the agency of the heated air ascending through the perforated floor, they are effectually dried in the short interval of a quarter of an hour.—This novel contrivance not only dries the clothes rapidly, but likewise ventilates and frees them from the peculiar smell that generally clings to long-worn garments; and thus, it is believed, all noxious and contagious matters that may lurk in the habiliments are effectively dissipated. The ironing and mending are carried on in adjoining apartments.

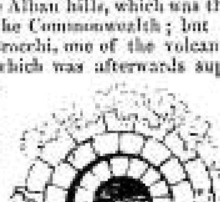
The institution is open from eight in the morning till eight at night. During part of the day—namely, from eight until four o'clock—women are exclusively admitted to wash their clothes and bathe; and on the women retiring, from four until eight in the evening men are admitted to these privileges.

The reader may be curious to know to what extent the class of people for whom these baths and wash-houses were more especially intended have availed themselves of the advantages which they offer. We are happy to mention that the result of the first year's essay was 27,662 bathers, 35,480 washers and dryers, and 4522 ironers—an abundant proof of the desire of the poor to be neat, clean, and wholesome when they can obtain the necessary means. The second year showed an increase of 16,920 bathers, washers, and ironers, and a decrease in the working cost, from improved arrangements, of £60, 15s. 4d. In the first year, the expenses contracted by supplying 63,142 bathers and washers amounted to £377, 17s. 9d., or less than three-halfpence each; in the second year, 73,288 cost in the aggregate only £305, 7s. 1d., or about one penny for each. In the first year, the cost of 4522 ironers was £4, 5s., less than one farthing each; in the second year, 11,296 cost £11, 15s. 4d. 'At the cost of one penny each,' says the official report, '34,615 warm baths were given in the second year, every bather having an ample supply of water, a clean towel, and a piece of soap; and 38,445 persons had a sufficiency of hot and cold water, of soda and soap, to wash more than a quarter of a million articles, the greater part of which, when washed, were dried and ventilated. The working expenses did not include rent or taxes or any water-rate for six months, or any charges for coal for seventeen weeks; but if the association had paid rent and taxes, and for water and coal, during the whole year, but had not given soap or soda, these expenses would have been £25 less than they were; so that, for the purposes of ascertaining how economically a bathing and washing establishment at which soap and soda are not given can be conducted, the experience of the association may be confidently appealed to.' While deprecating in the strongest possible terms any interference with a healthy and legitimate self-dependence, we think these gratifying results might induce corporations and others to direct themselves with some degree of zeal towards this department of our social economics.

DRAINAGE—SEWERS.

As efficient means should be taken to secure for our towns and cities a regular and abundant supply of pure water, so ought there to be a regular system of emission for that which is foul and waste. The rain which fall on our roofs and streets, and the waste water of our houses and public works, with all the animal and vegetable matter wherewith they are impregnated, must be regularly and speedily carried off, otherwise stagnation and putridity ensue, deleterious effluvia arise and are inhaled by the inhabitants, and disease, suffering, and death are the inevitable consequences. The most obvious method of discharge is by open gutters; but as these are offensive and unsightly, the great object both in ancient and modern times has been to establish a system of underground sewerage.

Among ancient nations, the Romans carried underground sewerage to the greatest perfection; and it is worth while in those days of sanitary preachments briefly to glance at their *cloacæ*. 'This term is generally used in reference only to those spacious subterraneous vaults, either of stone or brick, through which the foul waters of the city, as well as all the streams brought to Rome by the aqueducts, finally discharged themselves into the Tiber; but it also includes,' says Mr Rich, 'within its meaning any smaller drain, either wooden pipes or clay tubes, with which almost every house in the city was furnished to carry off its impurities into the main conduit. The whole city was thus intersected by subterranean passages. The most celebrated of these drains was the *Cloaca Maxima*, the construction of which is ascribed to Tarquinius Priscus, and which was formed to carry off the waters brought down from the adjacent hills into the Velabrum and valley of the Forum. The stone of which it is built is a mark of the great antiquity of the work; it is not the "peperino" of Gabii and the Alban hills, which was the common building stone of the Commonwealth; but it is the "tufa litoide" of Brocchi, one of the volcanic formations of Rome, and which was afterwards supplanted by the finer quality of the peperino. The arch of this cloaca is semicircular, and formed of three rings of voussoirs, as shown in the annexed cut, being 14 feet in width and 32 in height. The blocks are hewn, and joined together



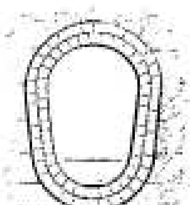
without cement. The passages in Strabo and Pliny which state that a cart loaded with hay could pass down the Cloaca Maxima, will no longer appear incredible, from the dimensions given of this stupendous work; though it must still be borne in mind that the vehicles of the Romans were much smaller than ours. Dion Cassius also states that Agrippa, when he cleansed the sewers, passed through them in a boat. The great sewer formed by Tarquin was only from the Forum to the river, but was subsequently continued as far up as the Suburra, of which branch some vestiges were discovered in 1742. When the habitations of the Romans were mere huts in comparison, it seems extraordinary that so costly a construction for the purpose of drainage should have been executed; but it shows that in the early history of their city, all that was undertaken for public utility was carried out with a spirit and magnificence surpassing anything done by other nations who have advanced more in civilisation and refinement. The expense of repairing and cleaning these cloacæ was defrayed partly by the treasury and partly by assessment. Under the Republic, the administration of the sewers was intrusted to the censors; but under the Empire, particular officers were appointed for that purpose, and who employed condemned criminals in the task.'

Notwithstanding the obvious and pressing necessity there exists for such a system of drainage in our large and populous towns, it is well known that there is scarcely one of them that is not notoriously deficient in this respect. What drain-courses do exist are either badly constructed or out of the districts most requiring them; while whole sections are entirely without a single underground channel. Such a state of matters is by no means creditable to British intelligence, and can only be palliated on the ground of the rapid increase of many of our towns, which were founded and arranged on plans of a very simple and primitive description, bearing no reference whatever to the probability of increase. Attention, however, is now energetically turned to this as well as other sanitary reforms, and the revelations made by the several recent Parliamentary Commissions are of too startling a nature to be readily forgotten.

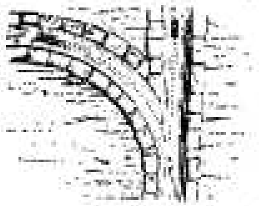
Setting out, then, with the axiom, that underground sewage is preferable both in point of health and convenience to open gutters, the first requisite is a plan of the district to be drained, with all its levels and facilities of discharge. Nothing, in fact, can be done without a descent for the sewage, and it is this want which occasions that stagnation and putridity so much complained of in many of our populous districts. Where natural descent is deficient, it is the duty of the civil-engineer to effect a remedy by carrying the tail or outlet to a greater distance, by inserting steps or falls at certain parts of the sewers, and by contracting and curving the drains occasionally, so as to increase the scour of the current. All these are remedies of a permanent kind; and where they cannot be obtained with full effect, it becomes necessary to adopt the system of flushing—that is, to insert sluices or traps at certain distances, which, being closed for a while, are suddenly withdrawn, and the dammed-up waters allowed to escape with a rush. These and such-like means being adopted to carry off the sewage with rapidity, the next point to be considered is the laying down of the mains and branches, so that no section of the town may be beyond the scope of the system.

According to the most eminent authorities, the network of sewers should consist of drains or pipes from every house or block of houses, these discharging themselves into branches or mains running under the principal streets and thoroughfares, and these mains again conveying their contents to one or more grand trunks or channels, as the levels of the district may allow. One great cloaca would be preferable to two or three, and should always be adhered to where practicable, as it not only concentrates the evil, and allows the solid contents to be collected and manufactured into manure with greater ease, but increases the flush of water, and thereby exerts a more thorough cleansing power. One main channel, however fetid and turbid, may roll its contents along comparatively harmless, but disperse these contents through several channels, and they creep lazily along, emitting in their course the most noxious effluvia. Connected with the main trunk is the regulation of the point of discharge—a subject of vital importance in any densely-peopled country. If discharged *en masse*, with sufficient descent in the ocean, for example, little or nothing requires to be done; but if on a low level, subject to tidal obstructions, then self-acting sluices are necessary, to prevent the influx of the tide, which is apt not only to injure the buildings, but to repel the confined air in the conduits, and send its deadly miasma through every pipe and grating in the city. The same remarks are applicable to low-lying towns situated on rivers; with this additional precaution, that no sewage ought to be discharged above any portion of the stream whence water may be drawn for domestic or other economical purposes. Of late years, instead of discharging sewage water as waste, attempts have been made to use it for the purposes of irrigation, or to collect its solid contents as manure. To the first of these practices there can be no objection, if sufficiently removed from the town; but if in the neighbourhood, nothing can be more prejudicial or offensive than the spreading of the fetid waters to the evaporating influence of the atmosphere. As to the collecting, desiccating, disinfecting, &c. of the solid contents, much absurdity has been promulgated. It is true that thousands of tons of valuable manure are annually swept away to the ocean by simple discharge; but it is equally certain that any system of tanks would in most cases but increase the evils complained of, or be conducted at such an expense as to render the project unprofitable. There can be no question as to the efficacy of sewage manure, and in all cases where it can be collected cheaply, and without danger, the attempt ought to be made; but for our own parts, we would rather forego any saving than run the risk of a system of open tanks and reservoirs steaming with poison and putrefaction.

The next points to be attended to are the materials, shape, and construction of the conduits and drains. The materials ought to be hard, durable, and impervious; everything of a soft crumbling nature being liable to break down in course of time, and obstruct the current; and if porous, percolation of the fetid contents is apt to take place, and affect wells, cellars, and other subterranean conveniences. As to the form, the egg-shaped sewer (see fig.) is allowed on all hands to be the most efficient. In the first place, it is stronger than either the common square conduit with flagged top, or the upright-sided conduit with arched top and levelled bottom. If the arch stones are well formed and jointed, no weight or side-pressure can break it down; and if the ground is soft and yielding, the arched structure sinks as a whole. Again, when formed of two rings or courses, as shown in the section, it is quite impervious either to moisture or effluvia, and requires less concreting and puddling than any other form. Further, the egg-shaped bottom gives to the minimum of water the greatest scouring effect; and while over a flat bottom the sewage might not exceed an inch in depth, it would amount to three or four in the egg-shaped; thus preventing, as far as possible, the lodging of slime and sediment. It is stated by Mr Roe, whose name is well known in connection with this subject, that with the same flow of water, the liability of the egg-shaped sewer to accumulate solid deposits is diminished one-half compared with the old upright-sided and flat-bottomed conduit. Lastly, as the oval sewer combines the greatest strength with the smallest consumption of material, a very considerable saving is effected in construction, amounting from two to five shillings per lineal foot over the ordinary upright sewers with footing. Mr Williams has shown that the saving in the Westminster district by the construction of the egg-shaped instead of the upright-sided, in ten years would have been upwards of £66,000; 'a sum,' says he, 'sufficiently startling to cause the inquirer to scrutinise with care the reasons that are advanced in favour of the adoption of a form theoretically imperfect, and found practically not to answer so well in some cases as the more perfect shape which could produce such a saving.' While such ought to be the form and construction of the mains, in the house-drains, bricks, stones, and mortar should be avoided, and cast-iron or glazed earthenware pipes adopted. These are more durable and impermeable, and are not so apt to be choked up if made of moderate dimensions. The chief fault in house-drains is their great width, the quantity of water sent through them never being able to flush or scour them sufficiently. Mr Dyce Guthrie, the able advocate for the adoption of earthen tubes, gives the following rule to ascertain the size of a house drain:—To the caliber necessary to carry off the water admitted into the house, add that required for the reception of rain or surface water, which is easily calculated by reference to the rain-gauges of the locality.



A very prevalent error in sewage is the joining of the house-pipes with the mains, and the mains with the grand channels at right angles. It is well known that if one current meet another at right angles, an obstruction or eddy is formed, which has the effect of interfering with the sluicing power of the receiving current, and thus solid deposits are gradually accumulated, often to the complete choking up of the system. There is nothing more common than to find such accumulations in our present sewers—accumulations which no flush of sewage can sweep away, and which has therefore to be removed by the offensive and dangerous process of hand-labour and cartage. This imperfection also involves considerable expense, as the pavement has frequently to be broken up and relaid, and this independent of the obstruction and annoyance to the public through the blocking up of the thoroughfare by one of the most disgusting operations. Science at once points out the remedy, by directing the entering channel with a sweep or curve, as shown in the accompanying diagram.



Acting upon this principle, the commissioners of the Holborn and Finsbury district (London) agreed to require that the curves in sewers passing from one street to another shall be formed with a radius not less than twenty feet. It is also required by them that the inclination or fall shall be increased at the junctions, in order to preserve an equal capacity for the passage of water, and of effect in scouring.

An important point in the construction of sewers is their internal dimensions, which, while sufficient for all ordinary contingencies, should never be so large as to diminish materially the scouring effect of the water. According to Dr Kebbell, to whose 'Lectures on the Diseases of Towns' we are indebted for several suggestions, the great size of existing sewers is one of their main faults. 'During even the heaviest thunder-storms, not one half of the internal capacity of the main sewers is occupied by the run of water; while the flow of water when there is no rain is a mere dribble compared with the size of the sewer. In the secondary sewers the run of water to the size of the sewer is still less. Now the general effect of this great disproportion between the size of the sewers and the run of water through them is, to impede the stream, and create deposits. The object of making the sewers of this large internal capacity is, to enable men to get into them and remove the accumulations. The above fault in the present system of sewage has been pointed out in the Report of the Metropolitan Commissioners, who strongly recommend the substitution of a much smaller system of sewers, to be kept in action by regular supplies of water. The general principle they advance is, that the size of the sewers should be so adjusted as to keep them as full of water as possible; and it is contended by men of experience and science, in accordance with this principle, that the drainage and sewage of a city might, and should be so constructed as to give rise to as little occasion for men to go through the main drains, as there is for men to go through the main pipes for conveying supplies of water. What is wanted are conduits through which the refuse matter may be carried away, not receptacles for its deposition and detention. The extent of diminution recommended is—for the main sewer, from 4 feet 9 inches by 3 feet, to 3 feet 9 inches by 2 feet 5 inches; for the second-class sewers, from 4 feet by 2 feet 5 inches, to 3 feet 4 inches by 2 feet. But while a more efficient sewer will be thus introduced, another considerable advantage will be gained in the reduction of the cost. The expense will be reduced from 14s. 2d. per foot run for the first-class sewers, to 7s. per foot run; and in the second-class sewers, from 12s. per foot run to 6s.'

Supposing that all these points were gained in the laying down of our sewers—that there was sufficient inclination, a regular system of ramification, a faultless construction as to size, shape, and material—still there is one great requisite, without which all others would be only partially successful; we mean an abundant supply of water, whereby these sewers might be kept always pretty full, and occasionally thoroughly scoured, from the remotest branch to the general embouchure. If we had such a supply always at command, the open gutter would in many situations be preferable to the underground sewer; and there would be no necessity for those abominations known as 'cesspools.' An overflowing supply of water is therefore necessary not only for the ordinary purposes of consumption, but for facilitating the removal of that portion which has been used, and become impregnated with filth and garbage. 'The drains,' says Captain Vetch, 'but furnish the ways or vehicles for transportation; the water is the moving power or carrier, and it is the cheapest that can be procured. In fact the supply of water to a town, and the discharge of refuse, are two branches of the same subject; and unless the water is abundant enough, and distributed enough to cleanse the drains, these last would be more offensive than useful.' Where artificial supplies of water cannot be obtained, the principle of flushing may be advantageously introduced. This consists, as already stated, in fixing in the sewers cast-iron gates or sluices, which, when closed, cause the ordinary flow of water to accumulate above them; and when a sufficient quantity is collected, they are thrown open, and the rush of water so caused is sufficient to sweep off the deposits. This plan was invented by Mr Roe, surveyor to the Holborn and Finsbury division, where it has been in operation for several years with marked benefit both as regards expense, and in keeping the sewers free from accumulations. Mr Roe has stated in evidence that the annual cost of cleansing the portions of the Holborn and Finsbury district, now supplied by flushing apparatus, by the old mode would be £326, 17s., and by the present system of flushing, £106—making a saving of £220.

Such are the requisites for a regular system of drainage, from which it will be seen that underground sewers are preferable in most instances to open gutters, and that neither can be efficient without a liberal and steady supply of water. We have said nothing of those chemical modes of destroying noxious smells and effluvia known technically as 'deodorising' and 'disinfecting'—leaving their merits to be discussed in the article devoted to the 'Preservation of Animal and Vegetable Substances.' Neither have we adverted to those numerous mechanical contrivances now in vogue for the prevention of effluvia from drains, water-closets, and cesspools. These, like the chemical deodorisers and disinfectants, may be all very good and ingenious in their way, but they do not apply themselves to the root of the evil: what our towns and cities desiderate is, a system of sewage that would render all such secondary remedies uncalled-for and unnecessary. And this brings us to speak of cesspools—a mode too frequently adopted to get rid of the refuse liquid from houses. In no case, and under no plea whatever, should these pits of poison and pestilence be permitted. Let them lie open in any degree—and it is impossible to have them hermetically sealed—and they are for ever giving off their noisome and noxious exhalations: they saturate the adjacent soil with their offensive contents; and there is no possibility of preventing the evil without the constantly recurring expense and annoyance of emptying them.* The rudest open gutter is preferable in comparison; for it is

* 'In one court,' says Dr Reid, 'the whole products of waste cabbage, water, &c. from the public kitchen, evaporated from a cesspool under it, which had not been cleaned for twenty years. When the cesspool was examined, I found that it had no communication whatever with any external discharge; and that, during the long period mentioned, there was abundant evidence to prove that all the liquid products it had received had no escape, except by evaporation into the atmosphere that supplied the courts above.' This is no solitary instance: we could cite hundreds equally startling and aggravated.

sure to force itself upon the attention, while the cess-pool, 'out of sight, out of mind,' is steaming and fermenting with the most subtile and deadly gases. So detrimental and barbarous is this system, that no opportunity should be lost of interdicting its application, or of indicting its continuance, as an insufferable nuisance. And here it may be remarked, in conclusion, that without clear and available powers of law on the part of Corporations, the most perfect system of drainage will often be unavailing. So much ignorance has to be dispelled, so many selfish interests have to be encountered, that we firmly believe there are thousands who would not take advantage of a remedial system though it were gratuitously offered them.

ABATTOIRS—MARKETS.

The situation and construction of abattoirs or slaughter-houses, and market-places, are intimately connected with the supply and emission of water, and deserve somewhat more than a passing notice.

Abattoirs.—Presuming that every one is less or more acquainted with the operations of the common slaughter-house, it must be evident that these establishments ought to be situated at a distance not only from the denser portions of our towns, but also from the markets or stalls where the meat is exposed for sale; and that they ought, beyond every other place, to be liberally supplied with water. So much filth and garbage of a rapidly-decomposing kind is necessarily associated with them, that without an absolute flush of water, and stringent regulations as to its application, they are apt to become centres of the most noisome nuisance and disease. Notwithstanding these facts, which are but too lamentably apparent in all our large towns, yet as a country have we done almost absolutely nothing towards the establishment of abattoirs, to which the animals might be led quietly, and without danger to the inhabitants, where their carcases might be dressed with regard to cleanliness, and where the offal might be sluiced away, and collected in such a manner as to become of value to the agriculturist. Our neighbours on the continent are infinitely before us in this respect; and with a view to convey some idea of their arrangements, we transcribe the following account of the abattoirs of the French metropolis:—

'The Emperor Napoleon, about the year 1810, ordered five of these establishments to be commenced at Paris, and they were executed at the cost of the city. A commission was formed of five architects, assisted by the vice-president of the Council of Public Works, the secretary, and a retired master butcher, who were instructed to examine several plans that had been presented, and to report upon their efficiency; but eventually M. Gauché, one of the five architects, was commissioned to furnish the designs which were adopted. The five abattoirs are those of Roule, Villejuif, Grenelle, Menilmontant, and Montmartre. Their dimensions were defined by the number of persons that each district contained. The two first had each 32 slaughter-houses, that of Grenelle 48, Menilmontant and Montmartre each 64, making in all 240. To each of the abattoirs are attached houses for the melting of tallow; reservoirs, and water laid on by lead pipes wherever required, every means for cleansing, stables and sheds for the use of the butchers, enclosures for the cattle, and apartments for the superintendents. A vaulted sewer receives and carries away all superfluous water; there are also buildings for preparing tripe, trotters, &c.' Of these sectional arrangements, Mr Cresy, from whom we quote, gives the annexed details:—'1. *Scalding-house*, used by the butchers for slaughtering. All the abattoirs have two or more ranges of these, each composed of two buildings divided by a yard. The stalls where the beasts are knocked down are formed of walls of wrought stone, and are 16 feet wide and 32 feet in length. Each has two entrances: one in the yard, by which the animal enters; the other in the outer side, to permit the removal of the meat, &c. Each stall is provided with a supply of water for cleansing, with a drain, and a windlass and pulleys, by which the carcase can be drawn up to be flayed. Two pieces of timber are placed across the building, at seven feet of height, fixed into the wall at one end, and carried or supported at the other by a stirrup of iron. On these, seven or eight carcases may be suspended, exposed to the air, previous to their being taken to their several destinations. There are pegs and hooks around for the calves, sheep, and lambs. The stalls, as well as the yard, are flagged with thick stones, the joints of which are filled with cement, that nothing offensive may pass through them. The bottom of the doors are cut, so that the air passes under them freely. The roofs project three feet beyond the external walls, which has the double advantage of sheltering the stalls from the sun's rays, and forming a cover for the carts which remove the meat. 2. *Sheds*, for the oxen and sheep on their arrival, where they are housed previous to slaughtering: these are 9 feet in width in the interior—one side being occupied by oxen, the other by sheep, calves, &c. Large stone arches support a floor above, over which are separate divisions for the butchers to stow away the forage which belongs to them. Water is laid on for the use of the cattle. 3. *Melting-houses*, where the fat is converted into tallow. 4. *Reservoirs.*—An abundant supply of water, and facilities for distributing it, is most essential in such establishments. In the five abattoirs, 75,000 oxen are slaughtered in a year, and the mean quantity of water for the service is from 240 to 300 cubic metres per day, to provide which there are two reservoirs to each—each containing 100 cubic metres, formed in masonry, and lined with cement. 5. *Keepers' Apartments.*—At the entrance of each abattoir are two small houses for the persons who have charge of the establishment. 6. *Stables, Sheds, &c.* are provided for the horses and carts, all commodiously arranged. 7. *Sewers* are most carefully constructed of hard gritty sandstone, their dimensions being 3 feet in width and 6 feet in height. To prevent any smell from escaping, a trap is introduced, which answers admirably well. There are also pits for the ordure, which is removed every day.' Such are the abattoirs of Paris; and no town of any importance on the continent is without some similar establishment—as at Nantua, Lyons, Blois, Rochefort, La Rochelle, Brussels, Orleans, Marseilles, Strasburg, &c.

It is much to be wished that some general arrangement like the above were adopted in all our large towns and cities, which at present, so far as the slaughtering of animals and the exposing of their carcases are concerned, are deficient in the extreme. With the finest animals in the world, the largest consumption of butcher-meat, and every facility for the construction of proper shambles, this department of our economy is conducted in a manner at once obnoxious to health, humanity, and decency. Attention is no doubt being directed to the matter, but so many contending interests have to be satisfied, so much ignorance and idleness to be moved, that years must pass by with all the danger, filth, pestilence, and inhumanity of the present non-system. What is desiderated are abattoirs or shambles sufficiently removed from the towns; fitted with the necessary accompaniments, like those of Paris; abundantly provided with water and sewerage; and stringently regulated, as the class to be dealt with are by no means among the most orderly or enlightened of the community.

Markets.—Leaving it for others to decide whether the existing shop-system of our large towns or that of the Oriental bazaar be the more convenient, there can be little doubt that concentrated and commodious market-places for the sale of butcher-meat, fish, poultry, vegetables, fruit, and the like, are highly advantageous for the bulk of the population. Legitimate competition is encouraged, fraud more easily detected, a better choice afforded, and a uniform system of inspection and regulation obtained, which would be utterly impracticable were each country supplier of the raw produce and each town-retailer to follow his own isolated plan. Market-places have accordingly been established in all our large towns; but in most cases they are little better than a collection of open stalls, with little regard to arrangement, supply of water, sewerage, shelter, or ventilation. It is true that London, Liverpool, Newcastle, and Aberdeen can boast of commodious, we were about to say magnificent markets; but these are the exceptions, not the rule of the United Kingdom. 'The great points,' says the authority above quoted, 'to be considered in these establishments, are central position, solidity and strength, convenience, health, and command of water. The strength requisite for an edifice is particularly required in one intended for the public service, and where the slightest accident might be of great importance. Convenience and salubrity require that all who attend should be sheltered from the inclemency of the weather; that the arrangements should be suitable for the provisions bought and sold; every possible means adopted for ventilation; and every precaution taken to insure the most perfect cleanliness. The walls of a market should be carried up a certain height in masonry or brickwork; the lower openings should be provided with Louvre boards, to exclude the sun, rain, and wind, without too much shutting out the light and air. Other openings must be provided under and in the roof to afford light and air. A certain width should be given to the markets, so as not to increase the extent of the outer walls; and pillars internally should not be introduced, as they obstruct and occupy room. Where they are indispensable, they should be of stone or iron, and placed as distant from each other as possible. The width of the building depends upon the number of stalls, which should be in pairs, so that one walk approaches two rows. Experience proves six feet and a half a sufficient width for the walk, and the same for the stalls. A public fountain is indispensable, and constitutes one of the chief ornaments. The architecture should be simple, yet imposing, from the mass, the arrangement, and the proportions. The divisions should be so arranged that all parts should be equally eligible, without any just grounds for preference; nothing should be sold out of the enclosure, that the entrances and streets leading to it may be free from all obstructions. The whole should be cleaned out daily, and shut in at night. When the market is of any extent, certain accessories are necessary—as stores, vaults, &c.—for warehousing unsold goods.'

Market-places possessing these requisites are common on the continent. Those of Italy—Naples, Florence, Bologna, &c.—are highly spoken of. They are in general lofty airy structures, with light roofs supported on colonnades; have paved areas, are well supplied with water, adorned with fountains, and are easily cleaned. The markets of France are also set down as models, especially the new ones of Paris, in which thorough cleanliness, and a systematic arrangement of the articles exposed, are rigidly enforced. Of our own markets, we have instanced those of London, Newcastle, Liverpool, and Aberdeen, as the most unique and systematic. Those of London are Covent Garden for the supply of vegetable produce; Smithfield for bestial; Leadenhall for poultry and game; Mark Lane for corn; Billingsgate for fish, and the minor depôts of Whitechapel, Newgate, Farringdon, and Hungerford. In illustration of these busy centres, that of Covent Garden may be taken as the most systematic:—It derives its name from the circumstance of there having once been a convent, with its garden, on the spot which it now occupies. The site of the market, which is spread over two acres of ground, as well as the ground in its neighbourhood, are the property of the Russell or Bedford family, as is indicated by the number of streets, hotels, &c. which are called from these and kindred names. Previously to 1830, the booths or stands in the market consisted of rough-looking, slightly-built sheds; but in 1828 the legislature took the matter up, and seeing the great public advantage, as well as ornament, to the part of London in which the market is situated, which would result from a suitable stone erection, an act of parliament was passed on the subject, which rendered it necessary that the Duke of Bedford should construct the present building, authorising at the same time the collection of such tolls on the goods sent thither for sale as should, in conjunction with the rents which would be derived from the different shops, and stands, or stalls, insure the noble proprietor a sufficient return for the money expended in the erection. The place was built at an expense of about £50,000, and most ample has been the return received by the duke for his money. It is understood that, reckoning rents, and tolls on articles sent to the market, his yearly revenue from Covent Garden market is from £12,000 to £15,000. The rents vary according to the situation of the different shops and stands. Shops in the middle or best part of the market, possessing a little accommodation in the storey above, individually bring rents of from £60 to £110 a year. And yet such shops are but small; they do not, judging from a glance of the eye, measure more than fourteen or fifteen feet, by about twelve feet. On all wagons, carts, and other vehicles bringing goods to the market, there is a toll, varying according to the nature of the articles brought.

The buildings are handsome, and at the east and west ends, and in several parts of the interior are supported by massy pillars of granite. There are three ranges of shops; the middle, or most handsome range, being double. Between the first and second, and second and third range, there is a large open space, which is occupied by various persons, and with various sorts of vegetables, the parties paying a certain rental per day. This rental varies, according to circumstances and according to situation, from one shilling to fourpence per square foot. The most southern range of shops is exclusively appropriated for the sale of potatoes. In the wide space between this range and the middle range of shops, you see hundreds of persons offering every variety of vegetables used in London for sale. The middle range of shops, which, as already stated, is double—that is to say, there are shops on each side of the thoroughfare—are chiefly used for the sale of all the finer varieties of fruits and vegetables. The remaining, or northern range of shops, is appropriated for the sale of oranges, apples, nuts, and for the sale of gooseberries, cherries, peas, &c. in their seasons.

That of Newcastle, which is still more unique, consists of a quadrangular area of upwards of two acres, all under one roof, and surrounded by the houses of four new streets. It has entrances from the different sides; and on entering it, we perceive that it consists of four principal arcades, crossed at right angles by four equally spacious avenues, the whole lined with open shops or booths, and well lighted from the roof. The length of the arcades is respectively 338 feet. The entire length and breadth has a remarkably neat and clean appearance, expressive of correct taste. In the long and broad arcade devoted to the sale of garden and dairy produce, there are placed at the cross avenues two handsome stone fountains or jets-d'eau, with basins capable of holding three thousand gallons each. It were matter for proud congratulation that all our larger towns had market-places one-half so elegant, so substantial, and commodious.

On the subject of *interment in towns*, which is generally treated in connection with the preceding sanitary arrangements, we need only remark that in no case, and under no pretence, ought the practice to be tolerated, whether by common burial or by the still more objectionable mode of entombment in vaults. It is, however, a gratifying feature of the times, that extra-mural cemeteries of an ornamental kind are every year becoming more numerous; and it would be still more gratifying that these were more frequently constructed upon principles of correct and becoming taste, and that the vault system, which they all less or more endeavour to perpetuate, were thoroughly and for ever abandoned.

AGRICULTURE.

Agriculture may be defined as the art of disposing the soil in such a manner as to make it produce, in the greatest abundance and perfection, those vegetables which are useful to man and the animals depending on him for subsistence. The earth, in a state of nature, unless where chilled by an ungenial climate, possesses a degree of fertility sufficient to produce plants more or less suitable for the subsistence of man and beast; but its spontaneous productions are small in amount compared with what can be drawn from it by industry and intelligence. Savage nations usually rest content with the natural produce, and they are accordingly found to be few in proportion to the surface which they possess, and generally in the lowest state of misery. But wherever man has arrived at a certain stage of civilisation, he has applied himself to cultivate the earth, so as to make it capable of supporting in comparative comfort a larger amount of population.

The earliest efforts in agriculture appear to have everywhere been simple, and limited in their object. The surface was ploughed, the cereals (wheat, barley, oats, &c.) were sown, and such a crop as nature gave was contentedly reaped. It cannot be said that by such a system more was done than merely to take advantage of the natural fertility, in order to raise farinaceous grains instead of the spontaneous herbage. Here, however, agriculture seems to have in every country taken its stand for many ages. It has only been in recent times that men thought of cultivating the soil on anything approaching to scientific principles, so as to *increase the natural productiveness*, and consequently render a given extent of country capable of supporting an increased population.

The rise and progress of agriculture amongst us have unavoidably been much affected by the natural peculiarities of the country. Great Britain and Ireland are islands, having the vast expanse of the Atlantic on the west, and German Ocean on the east, and lie within the 50th and 59th degrees of north latitude. Both from relative situation and latitude, therefore, they are exposed to a variable, and upon the whole ungenial climate. For about five months in the year, or from November till March, the ground is liable to be covered less or more with snow, or to be frozen in its surface; and herbage in either case is so scanty, that unless for sheep, and not always for them either, the open field does not afford nourishment for the stock of pasturing animals required in husbandry, or for the dairy and markets. In a word, vegetable food must be produced in sufficient variety and quantity during the seven milder months, to store up as a provision for the remaining five. This necessarily gives a peculiar character to the husbandry of the British islands, or of any other country similarly situated. Independently of this circumstance, the natural character of the soil throughout is far from being uniformly suitable for agriculture. Some land is good, some is of a medium quality, and a large proportion is positively bad, being in a state of nature no better than an unproductive morass or waste. Hence, under an unskilful system of agriculture, only the good land was cultivated, and a large proportion of the country was totally useless in an economical point of view. In former times, live-stock were either kept in such limited numbers, as to render their amount of winter provender attainable, or they were half-starved for several months while the inclement season lasted.

The improvements which were in time effected to remedy these deficiencies consisted of a series of moves, each depending on the other. Two things were desirable—to increase the extent of culturable soil for grain crops, and to raise sufficient food for bestial all the year round. Now these desirable points involved a thorough change in the practice of husbandry. How was it possible to break up and profitably cultivate indifferent soils, much of which had hitherto been considered beyond all hope of improvement, without an abundant supply of manure? And how could this manure be procured without keeping a large stock of cattle, for which there was evidently no means of subsistence? To overcome these difficulties, it was found necessary, in the first place, to introduce what are called *green crops*—that is, crops of artificial grasses, including clover, turnips, and other roots and plants; for by having a proper supply of these substances two important ends were gained—the support of cattle for manure, and the alternation or rotation of green with *white crops*; thus at once enriching the land, and relieving it from the scourging obligation to raise corn successively. On these main points then, along with plans for thorough drainage, subsoiling, and the application of specific manures, hang the great agricultural improvements of modern times. This course of improvement has been greatly assisted by rearing plantations for shelter, by laying down smooth and accessible roads, and by the general increase of machinery, whereby every process is facilitated, and much waste of time and strength avoided. It is to a brief exposition of agriculture so improved that we intend to devote the present sheet, referring the reader for certain general facts concerning the atmosphere, climate, soils, and vegetation, to Meteorology, Geology, Physical Geography, and Vegetable Physiology.

CHOICE OF A FARM.

In the choice of a farm, attention should in the first place be directed to the nature of the climate; after which the principal object of examination ought to be the quality and character of the soil. From want of attention to this matter, much labour and capital have been spent in vain attempts to grow crops not suited to the soil; and manure has been as improperly applied. This ignorance has also prevented many from improving their lands, though the expense would have been trifling, and the means within their reach. Under Vegetable Physiology (p. 67) we treated of soils generally, and touched upon their chemical properties; we shall now notice them in the order of cultivation.

Soils.

Agriculturally, soils may be classified under the following general heads; namely, sandy, gravelly or stony, clayey, chalky, alluvial, and loamy:—

Sandy soils, or those containing more than 80 per cent. of sand, are not naturally of much value, being liable to be scorched during warm weather, and incapable of affording sufficient nourishment for the heavier varieties of crop. When very sandy, the farmer should be exceedingly cautious in breaking up the natural herbage which ages may have collected on their surface, as the sand is liable to be blown up by the winds, and is long in rearing an artificial herbage of any value. So impressed with the importance of this fact have been the legislators of most countries possessing extensive tracts of sand downs, that laws have been enacted to prevent the pulling up or otherwise injuring the native covering, which is chiefly composed of bent, white clover, bird's-foot, and creeping trefoil. These form a sweet and early pasture; the value of which may be greatly enhanced by an occasional top-dressing of peat-moss and clay. In the vicinity of the sea, sand downs are open during winter, and form a dry, warm, and healthy sheep-walk. Light sandy soils may be permanently improved for tillage by an admixture of clay, marl, silt from pools and rivers, or of vegetable earth.

Sandy loams, or such soils as contain a greater proportion of vegetable and clayey matter than the above, have, since the general introduction of green-cropping and sheep-farming, greatly increased in value. If containing only 50 or 60 per cent. of sand, they are reckoned of good quality; and under a regular course of husbandry, are invaluable. At all seasons they are cheaply cultivated, are not liable to injury from the vicissitudes of weather, and being in general deep, when under liberal cultivation, they retain moisture well. The crops which can be raised on sandy loams are the following:—Turnips, potatoes, carrots, barley, rye, buck-wheat, peas, clover, saintfoin, and all the other grasses. If rather light, potatoes may be a hazardous crop in dry seasons; but for the other green crops and grasses, sandy loams can scarcely be excelled; their yield being clean, nutritious, and healthy. Beans, wheat, Swedish turnips, and other heavy crops, are never attempted on soils of this description.

Gravelly soils are in general called hungry soils, and being of an open porous character, the moisture sinks easily through them. Their fertility depends upon frequent falls of rain, as well as upon a due administration of nourishing manure. They are fitted for the production of potatoes, turnips, barley, rye, and grasses, and where dry and irregular in surface, form excellent sheep-pasture, whether natural or artificial.

Clayey soils present innumerable varieties—those being reckoned *strong clays* which contain from 85 to 95 per cent. of clay, and those *clay loams* which contain from 70 to 85 per cent. Strong clays are of so adhesive a nature, that they often continue moist throughout the driest summer. The plough turns up the earth in huge clods, which are broken with difficulty by the roller; and thus, generally speaking, their cultivation is attended with considerable labour and expense, and requires constant watching for a proper working season. Unless situated in a good climate, and under the care of a judicious farmer with sufficient capital, it is seldom that they produce remunerating returns. After being thorough-drained, turned up to the frosts of winter, and manured with proper composts, they generally assume the character of clay loams, and it is now chiefly in this character that the farmer is called to operate upon them. These soils are well adapted for beans, peas, wheat, oats, Swedish and yellow turnips, clover, tares, teasel, hops, &c.; but are not suited for barley, unless after summer-fallow. Formerly, potatoes and turnips were seldom cultivated on clay soils; but under the modern system of furrow-draining, these crops can now be raised with advantage. Clay soils produce good artificial hay-crops, but seldom good pasture after the second or third year: they are generally unsuitable for the grazing of heavy cattle.

Chalky soils consist chiefly of calcareous matter, mixed with various other substances in greater or less proportion. When clayey or earthy substances are found in chalky soils in considerable quantities, the composition is heavy and productive; when sand and gravel abound, it is light and not very fertile. The crops chiefly cultivated on these soils are peas, turnips, barley, clover, and wheat; and however much the land may seem exhausted, it will produce saintfoin. Chalky soils are in general fitter for tillage than for grazing; for without the plough, the great and peculiar advantages derived from them by saintfoin could not be obtained. English writers on agriculture assert that the plough ought not to be used on the fine chalky downs of Dorset, which, by very attentive management during a number of years, have been brought to a high degree of fertility as grazing-lands, and are extremely suitable for sheep in winter. Chalky soils which have been in tillage allow water to pass through them in winter, and reflect the sun's rays in summer, so that it is the work of an age to bring them into good pasture, more especially if the chalk lies near the surface.

Alluvial soils, produced by slow depositions from water, are generally called *marshes* in England, and *carses* in Scotland. They are composed of the finest particles of soil washed off by running waters, and deposited in low-lying situations, or on the shores of estuaries, where they are formed by the flowings of the tide, and enriched by marine productions. They have generally a rich level surface, and being deep, yield abundant crops of wheat, oats, barley, beans, peas, clover, and tares. Their fertility may be said to be nearly inexhaustible; but from their low and damp situations, they are not easily managed, and require considerable applications of lime. From the peculiar uniformity of the soil of such farms, and the crops grown thereon, their profitable cultivation requires a special training on the part of the farmer; and from the amount of heavy crops, such as wheat, potatoes, &c. grown, the quantity of manure is always much more than can be raised from the farm. Hence, for want of due training, and an adequate amount of capital, arise the numerous failures which have taken place among the occupiers of such land. The tenant of a mixed farm has, let the season be what it may, always some portion of his crop to fall back upon; not so with the carse farmer, for on one or two species of crop his whole success or ruin depends.

Loamy soils present innumerable varieties, and the term *loam* is perhaps the most indefinite in agricultural language. Loam may be generally described as an admixture of sand, clay, and vegetable mould—as moderately cohesive, less tenacious than clay, and more so than sand. Loams are the most desirable of all soils to occupy, being easily pulverised, and except in frost, can be cultivated at any season of the year. They are ploughed with greater facility than clay, bear better the vicissitudes of season, and seldom require any change in the rotations adopted. Above all, they are peculiarly fitted for convertible husbandry, for they can be changed not only without injury, but generally with benefit, from grass to tillage, and from tillage to grass. They are too valuable to lay out in sheep-walks; but for black cattle pasturage they are unequalled, as also for fattening the finer varieties of sheep for the shambles. According to their quality, they will bear any species of crop, and form by far the safest field for the application of specific manures.

In the selection of lands composed of any of the foregoing soils, that should be chosen which is the best of its kind, and most suitable for the crops required in the district. But before coming to a determination, the examination should be extended to the *subsoil*, the nature of which has a powerful influence on the productive properties of that which lies above it. If the land be dry and porous, and the climate also rather dry, the subsoil should be firm, so as to preserve the soil in as moist a condition as possible; but if the land and climate be wet, a porous subsoil is desirable. If the soil be as much as three or four feet deep, the nature of the subsoil is of little or no consequence.

Situation.

The degree of elevation of lands above the level of the sea has a material influence on the kind and quality of their produce. Land in the same parallel of latitude, other circumstances being nearly similar, is always more valuable in proportion to the comparative lowness of its situation. When in grass, the herbage of high districts is less succulent and nourishing, and the growth slower; when in grain, the head is smaller, the plant runs more to straw, is less perfectly ripened, and the harvest is later. In considering the crops to be raised on any particular farm, attention ought therefore to be paid to its height above the level of the sea, as well as to its latitude. It is considered that in latitude 54 degrees and 55 degrees (or about that of Edinburgh), an elevation of 500 feet above the sea is the greatest height at which wheat can be cultivated with any chance of profit. The ordinary height at which common grain-crops can be raised in Britain is from 600 to 800 feet; but in some situations, from particularly favourable circumstances, average crops of barley and oats may be produced at 900 feet, and even higher. In proportion as the climate is improved by sheltering plantations and drainage, the height at which grain-crops may be realised becomes the greater. In general, it is most appropriate to devote high grounds to sheep-pasturage than to tillage; and a consideration of this circumstance should regulate the selection and rent of land.

In making choice of land for farming, it should be a rule to prefer a gently sloping, or level, to a hilly and irregular surface. The labour of working land of irregular surface is very great, independently of other disadvantages; and if taken, it ought to be at a proportionably low rental. If possible, land which lies with an easy slope to the south should be preferred; though, if well sheltered, the inclination in other directions is of little consequence. If the land require drainage, or be exposed to heavy rains, observe if there be sufficient inclination to carry off the water. If there be no lower point to which the water may be conveniently drawn, avoid the risk of taking the land, for this defect in its character will prove a frequent source of trouble and loss. In the case of dry calcareous soils, and in moderately rainy districts, the inclination of the surface and means of drainage are immaterial.

Land on the banks of a running stream is likely to be more salubrious for crops than that which is near sluggish brooks or dull sedgy lakes. From stagnant waters there arise, in certain conditions of the atmosphere, dense pernicious vapours, which steal along the surface of the adjacent grounds, and tend to blight and otherwise injure the crops; and this generally in the summer and autumn months, when the crops are most valuable. Running waters purify the air, and are of great advantage for cattle. See, however, that the land is not liable to be flooded in winter, for a contingency of that nature should cause a diminution in value.

All these considerations respecting climate, soil, elevation, &c. sink into insignificance in comparison with the very important matter of *distance from markets and roads*. A long carriage to market, particularly if the roads be indifferent, is one of the greatest drawbacks which the agriculturist can possibly encounter. Where bad roads interpose, a distance of a few miles is practically as bad as a distance of hundreds where the carriage is easy. Goodness of roads to markets, or to seaports, should therefore form a very important matter of consideration to all intending purchasers and tenants of land. In fact, the best land in the world, without the means of disposing of its produce, or of hiring labourers to work it, is not worth the having.

Size of Farms.

Farms, as to size, are usually divided into—small farms under 100 acres; moderate-sized farms from 100 to 250 acres; and large farms of from 250 to 1000 acres and upwards, of land fit for cultivation. Each of these sizes is adapted to particular districts and other circumstances—especially to the degree of fertility and the amount of capital employed. It is a common but injurious mistake to suppose that the more land a farmer holds, the greater must be his profits. The profit does not arise from the land itself, but from the manner of using it; the best soil may be made unproductive by bad management, and the worst may be rendered profitable by an opposite course. 'Assuming always,' says a competent authority, 'that the expenditure on a farm be directed with judgment, it will be found that the profit upon the outlay increases in more than a proportionate degree to its amount. Thus, suppose that five pounds be the lowest, and ten the highest sum that can be employed in the common culture of the same acre of land, it is more than probable that if the five pounds return at the rate of five per cent., the ten will yield twenty, or any intermediate sum at the same progressive ratio. Now admitting this to be true—and it is presumed that no experienced agriculturist will doubt it—it follows that £1000 expended in the cultivation of 200 acres will only yield a profit of £100, while, if applied to no more than 100 acres, it would produce £200. For this reason, although a farmer of limited capital may not be driven to the extremity we have already supposed, and although he may be able to carry on his business with a certain degree of advantage, it is yet evident that his profit would be increased by diminishing the quantity of his land.'

It is impossible, however, to lay down any precise standard regarding the size of farms, as so much depends on the nature and situation of the soil, the character, skill, and capital of the farmer. In Ayrshire, where dairy husbandry is well understood, and has arrived at greater perfection than in any other part of Scotland, the farms are of moderate size, being in general from 60 to 160 English acres. A farm of about 127 acres is reckoned a good size, and on this from ten to twelve cows are kept. Sir John Sinclair recommends that a clay-land farm should not exceed 380 English acres; and he justly remarks, 'that those who grasp at having farms of a greater extent, where servants are not immediately under the master's eye, lose rather than gain by extending their land. Such a farm as 380 acres may be divided into six, seven, or eight fields, and they may be laid out so as not to extend beyond a reasonable distance from the farm offices. Where the soil is of a light description, a larger extent is necessary, as in such soils sheep and cattle are frequently fed in large numbers; and a farm of this description, of from 600 to 1000 Scotch acres, or 762 to 1270 English, is not considered too large. Where farms are almost entirely employed in pasturage, or in the breeding of sheep or cattle, as is usually the case in hilly districts, there can be no precise limits to their extent; some in the Highlands of Scotland, devoted to sheep-pasture, reach 25,000 English acres.'

The selection of a farm requires the whole ability and experience of the farmer. He must attend to all the advantages and disadvantages regarding it, so that he may fully make up his mind as to the amount of rent he considers it worth, taking care neither to be too cautious nor too rash. There is one common but very erroneous rule which guides the choice of a farm—namely, the success of the outgoing tenant. If he has made money in it, or is leaving it for a larger one, numbers will flock after it, and offer a high rent, without even inspecting it. But if the tenant be unsuccessful, all his misfortunes are attributed to the badness of the land, not to his own mismanagement; and few will be found willing to take the farm even at a reduced rent. These notions are very absurd; for the management of various farmers is so essentially different, that success or misfortune may be said to depend more on that than on either rent or quality of land.

The last advice which may be offered in reference to selecting and also managing land, is not heedlessly to carry prepossessions of what is right in one country to another country in which he may chance to settle. Agriculturists have commonly the reputation of being bigotedly devoted to their early opinions and usages, and this has an unfortunate effect in retarding their success in almost all cases in which they change their locality. Every country, and indeed almost every district of a country, has its own peculiar fashions in agriculture as in everything else, and the meaning of these should always be carefully studied before pronouncing on their error or inutility.

Leases and Rents.

A farm cannot be conducted properly, for the legitimate advantage of either landlord or tenant, except a lease of considerable duration be granted; for if the tenant be at all times liable to be dispossessed at the mere will of the proprietor, he can have no interest in improving the land, and therefore cannot afford to pay a sum suitable to the actual capabilities of the soil. According to the modern practice of agriculture, the profits of a farm are frequently prospective; a number of years must sometimes elapse before the ground repays the farmer for his sunk capital, and his trouble in effecting improvements. The duration of a lease consequently depends on the nature and condition of the soil, as well as some other minor circumstances. It is understood that a long lease is a much greater stimulus to spirited farming than a low rent. If the lease be long, and the rent high, great exertion is used by the farmer; but if the lease be long, and the rent low, a slovenly mode of farming, such as is found under the 'life-leases' of Ireland, may in general be expected. It appears, from all experience in Scotland, that a lease should neither be too long nor too short, but of a moderate duration, as nineteen or twenty years.

The connection between landlord and tenant is that of a disjunctive copartnery. The tenant trades upon a certain sunk capital of the landlord. The question, then, as to what is to be paid in the form of rent, is determined by the value of this capital, and what return it will produce annually on an average of years. From this return the tenant is supposed to draw one share, while the other is handed to the proprietor of the ground. 'The exact extent of these shares respectively is a matter of delicate consideration.' We find it stated in the 'Code of Agriculture,' that where land produces £10, 10s. per annum per English acre, the rent should be £3, 10s.; where it produces £6, 12s., the rent should be £1, 13s.; and where the produce is only £4, 5s. per acre, the rent should be 17s. It will be understood that these estimates are to be made on the aggregate produce of a farm, not on particular fields. With respect to grazing farms, they are let on the principle of how much stock they can regularly maintain; and not being liable to the same expenses for management, both landlord and tenant receive larger shares out of the general product. In some instances, proprietors, from negligence or a wish to retain an undue power over their tenants, delay the renewal of the farmer's lease till the period is almost expired. This is highly injurious to both parties; as, while uncertain if he is to continue on the land, the tenant will naturally be slack in his exertions to improve it, or even to maintain it in a fair condition. This evil might be easily avoided by the proprietor renewing the lease of his tenant a few years before the expiration of the time. In those districts where agriculture is in its infancy, through the ignorance, indolence, or obstinacy of the farmers in general, or of any particular tenant, or where a want of capital will not allow them to improve, it may be necessary for the proprietor to part with some of his tenants. When, on the other hand, a landlord has an intelligent and industrious tenantry, with capital sufficient to cultivate their farms to advantage, he ought to be very cautious of parting with them. Should the land have materially increased in value during the lease about to expire, it will be found most advantageous for the landlord to nominate a judicious valuator, and to offer the farm at the declared rental to the existing tenant, without bringing it to public competition.

In drawing up leases, it is customary to introduce clauses restricting the tenant to certain rotations of crops, manuring, &c. applicable to the few years which precede the termination of the contract. These clauses, and also others respecting the keeping of fences and roads in repair, are sufficient in all ordinary cases. Some landlords may be desirous of prescribing the exact mode of management of their farms; but this has a discouraging and injurious effect, and should therefore be avoided, except in what may be called improving leases, or engagements to improve the land in a certain manner. With regard to the form of a lease, it should commence, says Sir J. Sinclair, 'with the necessary preamble, stating the parties contracting, the situation of the property to be leased, the extent of the farm, a plan of which ought to be subscribed by the contracting parties, the duration of the lease, and the time of entry: it is then proper to enumerate, *1st*, The powers and privileges reserved to the landlord; *2d*, The obligations incumbent on the tenant; and *3d*, The stipulations obligatory upon both. Leases thus drawn up would not be liable to much uncertainty or dispute; and lest any should occur, it is expedient that a mutual obligation for settling by arbiters should be inserted.'

In modern farming, rent is altogether payable in money, or partly in money and partly in grain. The system of grain rents is yearly extending in Scotland, and is highly popular with the tenants, as it equalises in a great measure the risk of bad seasons and low prices between farmer and landlord—not requiring from the former a fixed amount of rental from an uncertain and fluctuating source. Thus, for example, a farm at the nominal rental of £500 a year would be let for £250 or £300 in money, the remainder being payable in so many quarters of wheat, barley, and oats, at the fiars' prices* of the county. When the rental is estimated at so many quarters of these grains, the average of the three is taken, under the title of the *Triple Quarter*; but frequently wheat alone is taken as the convertible grain, and then, as the case may be, nine or ten bushels are given per acre. In order still more to equalise the fluctuations in price—that is, to prevent the rents from rising too high in scarce years, and falling too low in plentiful harvests—it is becoming usual to fix a maximum and minimum price, at which the grain shall be convertible into money when the fiars' prices exceed or fall below them. Thus if the maximum for wheat be fixed at £3, 16s., and the minimum at £2, 10s., it will prevent a ten-bushel rent from falling below £3, 2s. 6d., or rising above £4, 7s. 6d. per acre.

The periods of the year at which tenants remove from and enter farms are very various. In many parts of England, Michaelmas, or 29th of September, is the period for both grazing and arable farms, that being the most suitable on account of the number of great stock fairs at that time, and other circumstances. In Scotland, Martinmas, or 11th of November, is the usual period. It is considered to be a most advantageous rule, that in all cases the removal of an outgoing tenant should be entire, not partial, as bit by bit removals too often lead to disputes between the retiring and entering individuals.

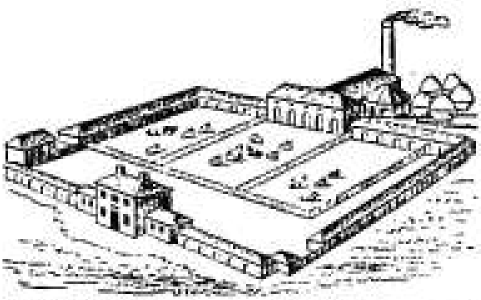
Farm-house and Offices.

Each farm must possess a residence for the farmer, offices adjoining for horses, cattle-feeding, preparation of grain for market, and other necessary purposes; also cottages for the married out-door servants. The whole, for convenience, ought to lie as nearly in the centre of the farm as possible. The comfort of the farmer and his family requires of course particular attention; but one of the chief objects of regard, along with this, is to make arrangements for housing and feeding the cattle, and causing all the liquid refuse to flow into a common centre. To gain this desirable end, offices for a mixed farm—that is, a farm in which both grain-cultivation and grazing are conducted—are now usually constructed on four sides of a square, the farmer's residence either making part of the quadrangle, or, as more frequently happens, standing a little apart.

The following engraving represents the appearance of one of the largest suite of farm-offices, including a dwelling for the farmer. The whole, it will be observed, form a quadrangle, with the farmer's residence in front; feeding-houses for calves and cattle on the left; cattle-sheds in the rear, over which is a straw-room connected with the edifices behind for the thrashing-mill, for which steam or horse power is employed; and on the right, stables, saddle-room, &c. In the centre are three fold-yards, open to cattle from the sheds behind, and into which straw may be thrown from the straw-room. The edifices on each side of the farm-house in front are for cart-lodges, boiling food, lodgings for unmarried male servants, or other pur-

* Fiars' prices in Scotland are the average prices for each county, as fixed by the sheriff with a jury, upon the evidence of the principal buyers of grain within the district. The average is usually struck about the beginning of March for the crop of the preceding year.

poses. A granary is supposed to be connected with the thrashing department. To this brief account of what constitutes a regular farm establishment, such as is



found in the best agricultural districts, we may add the following general observations:—

The size of the stables, cow-houses, feeding-houses, and cart-sheds, will depend on the extent of the farm; but it is proper in all cases to afford ample accommodation in every department. Where there is any danger of fire, the houses should be separated, from above the roof downwards, with strong dividing-walls. Each stall in the stable should be constructed for but one horse; and there should be a small separate stable into which a sick horse might be removed.

It is convenient to place the hay-stack so near the stable as to admit of the hay being thrown at once into the loft, which will save both hay and seed. Where there is no loft, the hay should be stored as near the stable as possible. Feeding-houses are required where either the turnip-husbandry or soiling is practised. These houses should be well aired, and constructed so as to occasion the least possible trouble in feeding, and in being kept clean and dry. Stakes for tying up cattle are placed at a distance of from three to four feet apart, according to the size of the cattle kept. The best way is to fasten the cattle to a chain, attached to a ring which moves up and down on the stake. This prevents them from throwing their heads too high, and incurring the risk of choking upon small turnips. Milch cows require warmth, and the greatest attention should be paid to the paving, draining, lighting, and ventilating their houses. The best constructed cow-houses are those in which the animals are arranged in stalls, with their heads opposite each other, with passages between for feeding, and access to the stalls from behind. Calf-houses, or pens, are usually placed at some distance from the cow-houses, to prevent the calves being heard by the cows. The chief object to be attended to is to keep the calves warm and dry.

A tight drain should be made along and under the passage behind the cattle, having branches at short distances to the gutter, with gratings to let off the urine. The dairy will be described minutely when we come to treat of that important subject (No. 30); and in connection with the brief sketch given of farm-offices, it may merely be mentioned that, of whatever dimensions, they should embrace a boiling and steaming-house, a cart-shed, and house for implements, and a root-house; also stack-yard, granary, straw-yard or pen, dunghill, and a covered tank for the preservation of the liquid manure. The size of the farmer's house will be regulated according to his means and family; and it will be found advantageous to have the houses of the married servants at no great distance.

Arrangement and Management.

With respect to the arrangement and management of a farm, we cannot do better than extract the excellent digest of rules from the 'Code of Agriculture:'—

'1. The farmer ought to rise early, and see that others do so. In the winter season, breakfast should be taken by candle-light, for by this means an hour is gained, which many farmers indolently lose, though six hours so lost are nearly equal to the working-part of a winter day. This is a material object where a number of servants are employed. It is also particularly necessary for farmers to insist on the punctual performance of their orders.

2. The whole farm should be regularly inspected, and not only every field examined, but every beast seen at least once a-day, either by the occupier himself or by some intelligent servant.

3. In a considerable farm, it is of the utmost consequence to have servants specially appropriated for each of the most important departments of labour; for there is often a great loss of time where persons are frequently changing their employments. Besides, where the division of labour is introduced, work is executed not only more expeditiously, but also much better, in consequence of the same hands being constantly employed on some particular department. For that purpose, the ploughmen ought never to be employed in manual labour, but regularly kept at work with their horses when the weather will admit of it.

4. To arrange the operation of ploughing, according to the soils cultivated, is an object of essential importance. On many farms there are fields which are soon rendered unfit to be ploughed, either by much rain or severe drought. In such cases, the prudent farmer, before the wet season commences, should plough such land as is in the greatest danger of being injured by too much wet; and before the dry period of the year sets in, he should till such land as is in the greatest danger of being rendered unfit for ploughing by too much drought. The season between seed-time and winter may be well occupied in ploughing heavy soils, intended to be laid down with beans, oats, barley, and other spring crops, by means of the scarifier. On farms where these rules are attended to, there is always some land in a proper condition to be ploughed.

5. Every means should be thought of to diminish labour, or to increase its power. For instance, by proper arrangement, five horses may perform as much labour as six, according to the usual mode of employing them. One horse may be employed in carting turnips during winter, or in other necessary farm-work at other seasons, without the necessity of reducing the number of ploughs. When driving dung from the farm-yard, three carts may be used, one always filling in the yard, another going to the field, and a third returning. By extending the same management to other farm operations, a considerable saving of labour may be effected.'

To this digest it may be added, that the farmer should habituate himself to keep regular accounts of his affairs, which may be done by means of a cash-book for all outlays and receipts as they take place; a labour-book, in which to mark the commencement and time of work of every individual employed; a journal for entering daily transactions and memorandums; and a ledger, in which a special debtor and creditor account is kept of every department, as well as a general account of the whole concern.

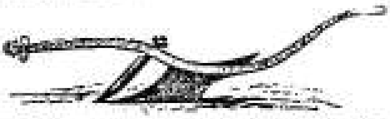
TILLAGE—IMPLEMENTS.

Tillage comprehends the ploughing, cleaning, and fallowing of the fields, with a view to their proper culture and improvement. The object of ploughing is to delve and turn over the soil in the ridges, to destroy the surface vegetation by burying it underground, where it rots and becomes a kind of manure; to bury the dung spread on the land; to form furrows for different purposes; and, generally speaking, to prepare the soil for the processes of cropping.

Ploughing.

Ploughs in old times were exceedingly clumsy in construction, and were dragged with much difficulty. This great defect was at length removed by the invention of the swing plough, about seventy years since, by James Small, a Scotch plough-wright. Small's plough, which is an elegantly shaped instrument formed on scientific principles, was originally composed of wood and iron, and did not weigh altogether above seventy-six pounds; it was afterwards made of malleable iron, and of a light appearance; but latterly the practice of making it of wood and iron has again become pretty general. The chief merit of this plough consists in the fore part being formed in such a slender and tapering wedge-like manner, as to cut the land with the least possible resistance. The mould-board for turning over the furrow is beautifully curved from the point of the sock to the heel of the wrest, so that it turns over the mould fully and with a small degree of friction.

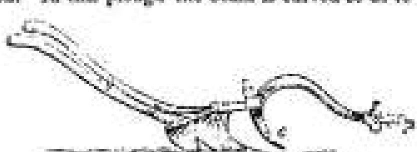
A sketch is here presented of the profile or side appearance of this valuable instrument. The degree



of bend in the mould-board is observed in the next figure, which represents the lower part or sole turned up to view. Small's plough, under different modifica-

tions, is adapted for every species of tillage which the plough is required to perform. In its own proper form it is particularly well suited for light soils, and proceeds actively through the ground, cutting to a depth of from seven to nine inches; but it may be made to go much deeper, if additional power be attached to it. In Scotland, and other countries in which it has come into use, it is almost invariably drawn by two horses, yoked abreast, and is guided and tended only by the ploughman, the reins coming to each handle of the plough. Considerable skill is required to steady and guide this sharp instrument as it advances through the ground; but this is a point on which properly-bred ploughmen pride themselves, and strive to acquire.

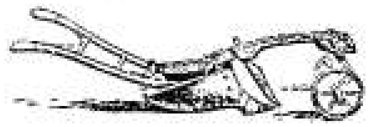
Small's plough may be said to be the parent of all those modern improved ploughs which are strictly adapted to peculiar kinds of work. In its ordinary form it is not very well suited for ploughing up moor or heathy land from a state of nature, as the heath and other tough vegetable matter is liable to collect upon the coulter, and so choke and retard the instrument. To remedy this deficiency, Mr Finlayson, an Ayrshire farmer, about twenty years ago contrived an instrument called the rid-plough, a representation of which is here given. In this plough the beam is curved so as to ter-



minate in the coulter (*c*); and when the heathy matter collects, it is pushed up as the plough advances, and falls off, so as to rid or clear itself of all kinds of loose fibrous rubbish. The sock and mould-board are also so contrived as to cut and lay over the slice, without the power of its springing back to its old position.

There are various kinds of ploughs with one or two wheels, and adapted to particular purposes, but chiefly designed to suit an unskilful class of ploughmen. Wherever agriculture is in an antiquated, backward condition, there wheel-ploughs are in use.

With Small's or Finlayson's plough, a skilful ploughman and a couple of active horses will make excellent work. 'It is not the man who makes the greatest ado with the horses,' we quote Mr Finlayson, 'who opens his ridges best, but more commonly he who goes steadily and directly forward himself, and keeps such a command by the reins, as to prevent them from deviating far from the right path, yet without laying *too much stress to their precision*, or checking them suddenly from one side to the other; and he who can take a straight



furrow at first, and continue so to the last, even on a ridge of fifteen feet, will finish with one, two, or three bouts less than one who is all along undoing and overdoing, and that too independently of the ease to himself and his team, and the preference of the work in every respect. If broadcast ridges are of unequal breadth, bent, or zigzag, the work cannot be so uniform, and in the turnings much time is lost, and harm done to the land which is ploughed; and with crooked drills there is a loss of ground, an unequal distribution of manure, if such has been applied, and the hoeings cannot be so effectually done where they are far distant, or done at all, without suddening the mould and injuring the crop, where they are narrower.

In fine, the grand criterion of ease and proficiency is that of the ploughman walking between the stilts, and in the furrow, with a free step and erect body; for thus he is more convenient for himself, has the horses and the plough better at command, and increases not the friction by his weight; for thus *he cannot go*, excepting the horses and the plough are properly adjusted, and proceeding with the least possible obstruction; and thus too he is more graceful to look on, than when wriggling with one foot foremost, or moving as if part of his muscles were under the domination of some violent spasmodic contraction.

It would perhaps be impossible to give anything like *a system of rules* for the most proper and convenient make, size, weight, turn, &c. of a plough for all the varieties of soil, or of diversity to be met with, even in the same ridge; but a few rules may be laid down, and observed as axioms in all ordinary circumstances—namely, 1. The horses should be yoked as near to the plough as possible, without too much confining, or preventing them from taking a free step. 2. When at work, they should be kept going at a good pace. 3. The chains or theets should, from where they are suspended over the backs of the horses, point in a direction leading through the muzzle to the centre of the cutting surfaces of the coulter and share. 4. The implement, when taking the form of the dimensions required, should stand upright, and glide onwards in the line of progression, without swerving in any particular way. 5. The ploughman should walk with his body upright, and without using his force to one point, or showing appearance of inclination. 6. The untamed and liveliest, or most forward horse, should be put in the furrow, and only bound back to the right or off theet of the land-horse, or at near the place where the back-band joins it, at such length, when stretched at the width required, as to prevent his end of the beam or double-tree from being before the other. And further, the heads of the two should be connected together by a small rope or chain, at the distance wanted, giving the furrow-horse power over the other—that is to say, if tender-mouthed, it must be fixed well up on his head, and in the rings of the bit or curb of the other, so that he may have the power of the head over that of the mouth of the land-horse.'

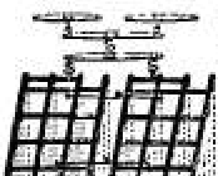
Let the draught of the horses go in a direct line to the plough or swingle-trees; for if the line be in any way bent, a portion of the power will be lost. Sometimes in England as many as five horses are yoked to a plough, two and two, with one in front; and in most cases of this kind the power of the foremost horses is partially thrown away, or probably distresses the hind pair of animals. Two horses will in general do more work yoked abreast to a plough, than four yoked before each other in single file; because some of the power of the foremost horses is always lost in its passage along the sides of the hind horses, and in turning, the whole draught is imposed upon the hindmost in the row. Where four horses must be employed, yoke them two and two abreast, and let the draught of the foremost pair proceed by a chain from their centre swingle-tree to the centre swingle-tree of the hindmost pair, thus passing between the hindmost and going in a direct line to the muzzle of the plough. Never on any account let the power of the foremost pair proceed by two chains along the sides of the hind horses to the outer ends of their swingle-trees, for this would only cause a needless expenditure of draught. In Scotland, where the economising of animal power has been carefully studied, all ploughing whatsoever, be the land light or heavy, except when exerted on the subsoil, is performed with but two horses, and these invariably yoked abreast.

It is a well-known maxim in tillage, that clay or tenacious soils should never be ploughed when either too wet or too dry. In ploughing the first time for fallow or green crops, it is of importance to begin immediately after harvest, or as soon after wheat-sowing as possible, in order that strong tenacious soils may have the full benefit of the frost. On wet stiff soils, frost acts as a most powerful agent in pulverising the earth. It expands the moisture, which, requiring more space, puts the particles of earth out of their place, and renders the soil loose and friable. On such soils there is no rule of husbandry more essential than to open them as early as possible before the winter frosts set in. If left till spring, clay soils may be too wet for ploughing, or if the season be dry, the earth, when turned up, will be in hard clods, very unfit for vegetation. Therefore, on farms having a proportion of clay and of light soils, it is necessary that the strong wet land should be ploughed first, provided the weather will allow.

Subsoil-ploughing is a new feature in husbandry. The object of it is to trench or loosen the soil beneath the ordinary ploughed surface, so as to allow of its gradual assimilation with the mould above, into which it may afterwards be brought. The process of subsoil-ploughing is effected by a powerful instrument, constructed according to the design of Mr Smith of Deanston. As subsoil-ploughing, however, is intimately connected with the 'Culture of Waste Lands,' we postpone any account of it till we treat of that subject in the following sheet. For an account of the proper steps to be taken to drain the land, if in a moist condition, we also refer to the same article.

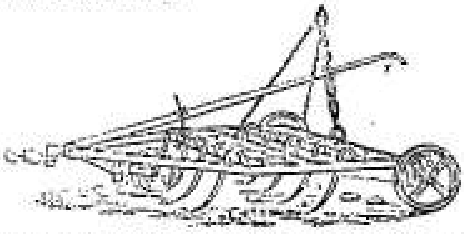
Harrows.—The plough leaves the land cut in longitudinal slices, and is therefore less intended to pulverise the soil than to turn up a fresh surface to the atmosphere. Another kind of instrument is required to break the upturned sward, reduce it to powder, and also to clear it of weeds or other foul substances. The harrow is the implement chiefly employed for this purpose, as well as for covering the seed. According to the diversity of soils, and the particular use to which the harrow is to be applied, its form undergoes considerable modification.

The common harrow is a frame of wood or iron, consisting of at least four bars lengthwise and crosswise, with iron teeth set on one side. Usually a pair of harrows is yoked and drawn together, as here represented.



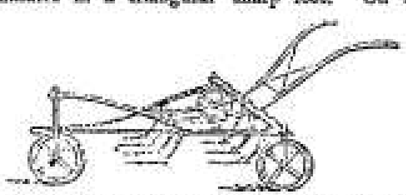
The teeth are set only on the long bars; and the harrows are drawn at such an angle as to preserve the tracks of the teeth in separate lines, and at regular distances from each other. Strong heavy lands require heavier harrows than those of a light nature. In some cases the teeth of the harrow are of different lengths, those forming the front row being half an inch longer than the second, the second a little longer than the third, and so on, diminishing backwards. In drilling crops, an implement called the drill-harrow is employed. A light single harrow is in most instances sufficient for drilling or harrowing over the young wheat in spring.

Where the land is very foul, and calculated to choke the teeth of the harrow, a powerful and effective instrument is now used, called Finlayson's Patent Harrow or Self-cleaning Cultivator. The annexed figure represents its usual construction;—



This instrument is now universally formed of iron, and has, according to the inventor, the following advantages:—1. From the position in which the tines are fixed, their points hanging nearly on a parallel with the surface of the land, the implement is drawn with the least possible waste of power; 2. From the curved form of the tines all stubble, couch, &c. is brought up to the surface and rolled over them—the instrument thus relieving itself in its progress; 3. The readiness with which the cultivator can be adjusted so as to work to any depth renders it of great value, inasmuch as the regulator or lever (*r*) can be moved up and down with the greatest ease, each notch upwards giving the tines an additional depth of 1½ or 2 inches. The axle-tree of the wheels is also capable of being moved up or down by a screw, as represented at *o*, so that the whole implement can be equally adjusted to work at any depth, from 4 to 10 inches; 4. In turning at the headlands, the lever is pressed down to the lowest notch, thereby elevating the front tines out of the soil, and allowing the implement to be easily moved round. There are various modifications of the self-cleaning cultivator in use, according to the taste of the farmer.

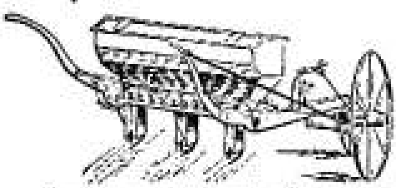
Grubbers, &c.—In certain conditions of the ground, a harrow is incompetent to cut up and clear it of its under-surface weedy matter. In such cases grubbers, eradicators, or scufflers, are used according as circumstances require. The common Scotch grubber resembles a strong harrow frame, running upon four wheels, and guided like a plough. On the lower side of the frame are placed eleven long prongs, each of which terminates in a triangular sharp foot. On being



dragged forward, the prongs scuttle the ground to a depth as great as that of the plough, effectually cutting the roots of weeds, and bringing all loose matter to the surface. The grubber or scarifier, according to the 'Code of Agriculture,' may be used to advantage in the following cases:—'1. Barley and turnip land, after being once ploughed, may be made both clean and fine by its means, and the harrowings and subsequent ploughings thereby rendered unnecessary. 2. Where lands have been ploughed in autumn, the objection to the sowing of spring crops on the winter furrow may be obviated by the use of the scarifier, as not only barley, but oats (if not grain after grass), beans, pease, and tares, may be sown without an additional ploughing. 3. Summer fallows may likewise be advantageously carried on with fewer ploughings, earlier in the season, and at less expense. 4. It may be effectually employed to forward operations in the preparation of land for potatoes or turnips, and afterwards for raising the potato crop; and 5. Its utility in mixing lime or compost with the soil is of the highest importance, as it not only incorporates these manures more effectually than the plough, but never places them beyond the proper depth.'

Sowing.

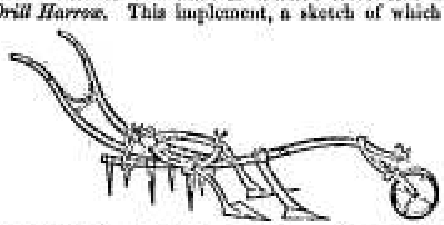
There are various machines for sowing grain, seed for turnips, &c. in drills or rows in the hollow of furrows, on ridges, or on a flat surface, as may be required. For sowing turnip-seed, a barrow on wheels, and pushed along by the hands, is generally used. For sowing grain, one of the best implements in use is *Morton's improved Grain-Drill Machine.*—This ma-



chine, as above represented, consists of a box or hopper supported on a frame with wheels, and is drawn by one horse, and guided behind by one man. The seed escapes from three conductors, the lower points of which act as coulters on the soil, making drills for the seed. In the inside of the box is an axle with projecting teeth, kept in motion by the axle of the machine, and preventing the seed from getting clogged. The seed passes into the conductors through holes, which can be made of any size by means of a sliding board. The width of the coulters admits of being regulated by means of a screw and other apparatus; and five coulters may be used if necessary. A rod projects from the handle half the breadth of the machine (not shown in the cut), to mark the ground, and by this mark the next advance of the machine is regulated.

There are other drill-sowing machines of greater breadth and size, likewise machines for dibbling beans; but they require no particular description. The rollers of wood, stone, or metal, employed to crush or press down the land which has been sown, are so common, that it is also unnecessary to describe them.

Hoes.—The light instrument called the hand-hoe is of use in cleaning turnips and other plants, but is altogether unsuitable for stirring the soil between the rows of extensive crops of turnips, potatoes, beans, &c. This heavy duty requires to be performed by animal labour by means of the horse-hoe. One of the best instruments of this kind is *Wilkie's Horse-Hoe and Drill Harrow.* This implement, a sketch of which is



here presented, is guided and drawn like a plough. As soon as the plants appear above the surface, it is drawn betwixt the rows, thoroughly scuffling or cleaning the land from its numerous weeds. The depth to which its prongs and feathered feet go in the soil, is regulated by elevating or depressing the wheel in front. It likewise answers as a rake, by dragging along with it the heaps of destroyed weeds. Some horse-hoes are fitted with a movable mould-board at each side, by which the earth is heaped up on rows of plants; this is also done by a variety of the plough.

Weeding.

All lands are less or more infested with weeds, which injure the crops by extracting the nourishment from the ground, and greatly impede cultivation by spreading their entangled roots beneath the surface. The manure deposited on the soil is destined exclusively for the support of what is meant to be raised, and every useless plant, therefore, which lives upon it, is so far noxious, and ought to be extirpated.

As prevention is always better than cure, the farmer should begin by preventing the growth of weeds. The seeds from which weeds spring are brought in some manner to the land from somewhere. Try to cut off this vicious produce at its source. Let all banks or natural embankments forming boundaries to fields, be cleared of every species of weeds, such as thistles, docks, ragweed, rank grasses, &c., and let all roadsides near the fields be similarly cleared of their gay but unprofitable vegetation. If this were done generally over the country, a fertile source of foulness in land would be in a great measure destroyed. It is also desirable to sow clean seed for grain or other crops, and to use, if possible, those manures only which are free of the seeds of noxious vegetables.

Notwithstanding all ordinary precautions, lands, it is acknowledged, will develop a crop of weeds, because some weeds will lie uninjured for centuries in the soil, and the winds will waft others from great distances; such, in fact, is one of nature's provisions for covering the earth with vegetation. It has been ascertained that upwards of fifty different weeds infest arable lands, some of which are annuals, others biennials, but the principal part perennials, whose seeds will lie for a long period in the soil. The more common of these various weeds are the wild-oat, the common thistle, dock, coltsfoot, ragweed, dent-de-leon, and charlock or wild mustard, the latter particularly. To these is to be added that most tormenting weed, couch-grass or quick, which spreads its long cord-like roots beneath the surface, weaving the soil into a kind of matting. Annuals and biennials may be partially extirpated by a well-wrought summer fallow, or if the soil be light, by the culture of potatoes or turnips, for the land in that case is well cleaned and dressed in spring, as well as hoed in summer. Hand-hoeing for this purpose is sometimes necessary. If, however, no ordinary process of teasing and cleaning the land extirpate the weeds, the more tedious and expensive operation of hand-pulling by women or children must be resorted to.

This process of weeding may be expensive, but it generally cleans the land, and repays itself by the increase of grain crop. According to experiments adduced by Sir John Sinclair, the increase of a wheat crop on a weeded over an unweeded land was four and a half bushels per acre, and of other crops much more. 'A six-acre field was sown with barley, in fine tilth, and well manured. The weeding, owing to a great abundance of charlock, cost twelve shillings per acre. The produce of an unweeded acre was only thirteen bushels; of the weeded twenty-eight bushels: difference in favour of weeding, fifteen bushels per acre, besides the land being so much cleaner for succeeding crops.' With regard to oats:—'Six acres were sown with oats; one acre ploughed but once, and unmanured, produced only seventeen bushels. Other six acres, ploughed three times, manured, and weeded, produced thirty-seven bushels. Ten bushels may be fairly attributed to the weeding, and the other ten to the manure.' It is justly observed by the same authority, that however anxious farmers may be to have their lands *tithe-free*, it is of greater importance to have them *weed-free.*

Fallowing.

Fallowing signifies leaving the land for a certain time in a bare unproductive condition, during which it receives a rest from the labour of cropping, and is subjected to various processes of ploughing and harrowing, to pulverise the soil, and destroy its noxious weeds, The value of fallowing for these purposes is a subject of considerable controversy; some ascribing to it numerous virtues, and others altogether condemning it, where green crops and good husbandry prevail. The truth seems to be, that fallowing is extremely useful for the purpose of pulverising, cleaning, and otherwise improving lands of a poor quality, after their first subjection to tillage; and that there its value rests.

The operations necessary for a well-wrought naked summer fallow commence after harvest. The first winter fallow ploughing is begun as soon as the hurry of harvest and wheat-sowing is over. If deferred till an advanced period of the season, and the weather sets in wet, the land becomes unfit for the operation. To prevent the bad consequences of too much rain at this period, that manner of ploughing and laying the ridges should be adopted which will best keep the land dry during the winter months, this being a most essential point. Strong retentive soils, to which a summer-fallow is more particularly applicable, should get an end-long ploughing, so deep as completely to turn up the soil from where it mingles with the subsoil or till.

When thoroughly pulverised, and freed from roots and weeds by the process just described, the fallow is ploughed end-long into gathered ridges, which are usually from fifteen to twenty feet broad. When the land is gathered into a furrow as deep as the soil will permit, the manure may be laid on. The manure is carted along the crown of the ridges, and is thrown out into heaps, of a size and at distances proportioned to the quantity intended to be applied; experienced workmen can generally measure both ground and manure accurately with the eye. People are now employed spreading the manure, and the plough immediately follows, in order that the dung may lie exposed as short a time as possible. The dung being covered, and the ridges raised, so as to admit the rain to run freely into the furrows, the land should remain untouched for a few weeks, that the manure may become thoroughly decomposed.

The land may now be considered as ready to receive the seed furrow, which is generally given to it previous to the sowing. The ridge is again gathered; but as this ploughing is very slight, it does not raise the ridge much higher. Lime is frequently applied to fallow as well as dung, sometimes before the dung is laid, and sometimes after. In the first case, the lime is laid on just before the land is formed into ridges, and, if possible, a calm dry day should be selected for the purpose. After the lime is laid, the land should be immediately harrowed, to incorporate it with the soil. The second mode is to lay the lime on just before the seed furrow is made; and if the ground be dry, and the dung decomposed, this will be found advantageous.

The system we have described is referable to the heavier soils; when those of a lighter nature are to be fallowed, the cleaning process is not so difficult, and there is not the same risk from wet weather. If summer fallowing be judiciously conducted in the manner described, strong soils may carry repeated alternate crops of grain and pulse, without any intervening naked fallow, for perhaps six or eight years. But to preserve the beneficial effects of fallow on ordinary farm land, which is manured alone from its own produce, it is certainly the best and most economical plan to lay it down to grass with the crop immediately succeeding the fallow. Afterwards, successive crops of grain and pulse may be taken as its condition will allow, when broken up from lea previous to next fallow. Sir John Sinclair says—'It may be foretold of every farmer on a strong soil, in such a climate as Scotland, that his affluence and prosperity will always be in proportion to the excellent state of his fallows, everything else being equally well conducted.' Indeed, if fallowing is negligently or imperfectly performed, no land, however cheaply rented, can yield much profit.

Carts and Miscellaneous Implements.

Two kinds of machines are in use for conveying produce to market and other purposes in husbandry—wagons and carts—and of these there are several varieties. Wagons with four wheels, and drawn by two or more horses, are acknowledged to be best adapted for conveying great loads to a great distance, and that is their principal merit. For all ordinary purposes connected with husbandry, the one-horse cart with two wheels is preferable.

The Scotch cart, as it is called, is a most convenient and useful machine; and to add to its uses it may be rendered serviceable for carting hay or straw by placing a moveable frame on its sides, as represented here.

The Scotch cart (without the frame) is suited for conveying any kind of material—dung, turnips, grain in sacks, &c.—and usually carries from eighteen to twenty-two hundredweight, when drawn by only one horse; with a horse in trace, the weight may be augmented. In Scotland, all grain for market is carried in these one-horse carts, and to any distance. On such occasions, one driver can take charge of two carts.

The following advantages of one-horse carts are well enumerated by Lord R. Seymour. 'A horse, when he acts singly, will do half as much more work as when he acts in conjunction with another; that is to say, that two horses will, separately, do as much work as three conjunctively: this arises, in the first place, from the single horse being so near the load he draws; and in the next place, from the point or line of draught being so much below his breast, it being usual to make the wheels of single-horse carts low. A horse harnessed singly has nothing but his load to contend with; whereas, when he draws in conjunction with another, he is generally embarrassed by some difference of rate, the horse behind or before him moving quicker or slower than himself; he is likewise frequently inconvenienced by the greater or less height of his neighbour: these considerations give a decided advantage to the single-horse cart. The very great ease with which a low cart is filled may be added; as a man may load it, with the help of a long-handled shovel or fork, by means of his hands only; whereas, in order to fill a higher cart, not only the man's back, but his arms and whole person, must be exerted.' To these just observations it need only be added, that in many parts of England there is a wasteful expenditure in horse power, a couple of horses being often set to draw a clumsy wagon to market, containing a load which could with the greatest ease be drawn by one horse in a less ponderous machine.

Every well-conducted farm establishment is now, or ought to be, provided with a variety of small but useful machines—for slicing turnips or potatoes, chopping hay or peas straw, bruising beans, peas, or oats, weighing-machine, &c.—all which, of the newest construction, are to be seen at the establishments of agricultural implement makers. Utensils for cooking food for cattle, dairy utensils, and tools for manual labour, need not here be particularised.

MANURES.

By repeated cropping, the best soils become exhausted of their fertile properties, while naturally indifferent soils require the administration of certain qualities, before they will yield a due return to the labours of the husbandman. There are, no doubt, soils so naturally rich in some parts of the world, that, though used for twenty or more years in growing successive grain crops, they show no indications of impoverishment; yet even these must in time be exhausted, and therefore, in all circumstances, manures, or artificial fertilisers, require the consideration of the husbandman.

Manures are of two classes, both of which have distinctive characters, and perform different offices in the economy of vegetation. The first of these comprehends all animal and vegetable decomposing matter, and is principally employed in feeding the plant, augmenting its size, and sustaining the vital energy. The second operates more on the soil and decomposing matter, and in this manner contributes to the support of the vegetable. The first kind has been called animal and vegetable, and the second fossil or mineral manures. Under this second class are ranked not only lime, marl, gypsum, sand, and clay, but the so-called *special* manures—nitrate of soda, sulphate of ammonia, phosphate of lime, &c.—which have recently come into use.

The animal and vegetable manures, which are putrescent in their nature, are foremost in importance and dignity. They consist of certain elementary parts of animal and vegetable substances, elaborated by a natural chemical process in the course of the decomposition or decay of the bodies. The excrementitious matter, or dung of all animals, is no other than the remains of the vegetable or animal food which has been received into the stomach, undergone there a partial dissolution, and been thrown out as unserviceable for the further nutrition of the system. From this universal decay of organised matter, and its conversion into fluids and gases, it would seem that animal and vegetable substances, and excrementitious matter, are resolvable into each other, and are only different parts of the same original principles. The essential elements of them all are hydrogen, carbon, and oxygen, either alone, or in some cases united with nitrogen. Conveyed by liquids or moist substances into the ground, these elements are sought for as nourishment by the roots of plants, and so form the constituent principles of a new vegetation. Inasmuch as flesh consists of a greater concentration of these original elements than vegetables, the manure produced by carnivorous animals (man included) is always more strong in proportion to its bulk than that discharged by animals who live only on herbage.

Whatever be the value of the elementary principles of manures, practically they are of no use as manure till they are disengaged by putrefaction. It may be further observed, that putrefaction is in every instance produced by the elementary principles being set at liberty either in a fluid or volatile state. If a quantity of stable dung be piled into a heap, and freely exposed to all varieties of weather, it soon heats and emits a stream of vapour, which is often visible as a cloud over it. These vapours, and also the odours sent forth, are gases escaping, and the heap is constantly diminishing in weight and volume; at the end of six months, if there have been alternate moisture and warmth, not above a fourth of the original essential material remains to be spread on the field; there may be in appearance nearly as much substance, but the fertilising principle is gone, and what remains is little better than a mass of worthless rubbish.

It may be safely averred, that no principle connected with agriculture is so little understood or thought of as that which has been now mentioned. Generally speaking, the excrementitious matters thrown to the dunghill are treated with perfect indifference as to the effects of exposure and drainage away in the form of liquids. It cannot be too strongly stated that this is a gross abuse in farming. The putrescent stream contains the very essence of the manure, and should either be scrupulously confined within the limits of the dunghill, or conveyed to fresh vegetable or earthy matter, that it may impart its nutritive qualities. A knowledge of this important truth has led to the practice of making compost dung-heaps, in which the valuable liquids and gases of different kinds of manure are absorbed by earth, or some other substance, and the whole brought into the condition of an active manure for the fields. Hitherto it has been customary to speak of dunghills, but there ought to be no such objects. The collection of manure from a farm-yard and offices should form a dung-*pit*, not a dung-*hill*; and the manner of managing the contents of this pit on the best method is well worthy of consideration.

Farm-yard Manure.—The situation of the dung-pit should be near the stables and cow-houses, and placed so low, that all streams of urine from them should flow at once into it, but no discharge of rain or spring water should be permitted to enter. It may be three or four feet deep, and of a size proportionate to the stock of cattle usually kept by the farmer. It is not necessary that it should be built round with a wall, or have a perpendicular descent, as it may slope gently inwards, and deepen gradually towards the centre. It may be covered with alternate layers of common soil or peat-moss, so that these may receive the evaporating principles from below, and also prevent the hurtful action of the sun and frosts. If the bottom be found firm, impervious, and capable of containing the juices, no further trouble is requisite, and the work is complete; in many instances, however, it will be necessary first to puddle with clay, and then line the bottom with flagstones. Into this pit earth, with refuse straw, should be brought, and strewed over the bottom and sloping sides, to the thickness of from nine to twelve inches, and this will form an inferior layer to absorb all that portion of the liquid manure which naturally runs to the bottom. The pit is now prepared to receive all kinds of animal and vegetable manure, which, when brought, should be always laid evenly over the surface. On well-conducted farms, such dung-pits are common, and in the course of accumulation, a young or wintering stock of cattle is allowed to go at large upon the whole; the animals being at the same time fed on a proper allowance of straw. Care is also taken to mix, in laying on, the dung brought from the cow-house, stable, and piggeries, so that the rich excrement of the well-fed animals may be incorporated with that of a poorer description. It is likewise of importance, though too frequently neglected, to convey to the pit the entire liquid refuse of the farm-yard, provided the quantity be not so great as to render it advisable to have a separate tank for its reception.

It is customary to cart away the material of the dung-pit at convenient opportunities (usually during the frosts in winter) to a place in the fields, near where it is to be used, and there pile it up in a quadrangular heap of about four feet in height. Dung, carted out in this manner, is ready for the turnip husbandry in June, and the practice is otherwise convenient. It may, however, be stated, that for want of attention to principles already explained, such dung-heaps, by exposure for months to the weather, must lose some of their valuable properties. In every instance, the dung heap in the fields should be placed in a hollow situation, with a substratum of earth, and should have a scattering of a few inches of earth over it, and around the sides, to keep in the volatile gases. When the dung-pit has been thus emptied, it may again be progressively filled as before; and when it is carted out in any of the spring months, it will be found necessary to turn it once, or oftener, for the purpose of accelerating the decomposition of the strawy part of the mass. It may be of use to know, however, that the dung required for fallows for wheat in autumn, may be less putrefied than that for turnip or potato crops.

Liquid Manure, Bone Dust, Guano, &c.—The urine of cattle is of great value as a manure; and this is so well known to the farmers of Belgium, that they use tanks for collecting the liquid from the cow-houses, and thence they pump it up, and pour it over the land at the proper season. When mixed with vegetable refuse, moss, or earth, it forms an excellent compost. It is deeply to be regretted that so little is known on this subject; and such is the carelessness of farmers and cottagers, that the urine from their cattle-stalls is in most cases suffered to go completely to waste. The value of night-soil and human urine as manures is equally great, but both are much neglected in British agriculture. Without entering minutely into details on this point, it may be stated that the offensive odour of all excrementitious matter may be neutralised by an intermixture of gypsum, or of lime and earth, and in this state be used as most valuable manure.—*Bone-dust* is now used as a highly nutritious manure on light soils; and it is reckoned that 100 bushels are equal to forty cart-loads of farm-yard manure. Common sea salt, when judiciously administered in moderate quantities on arable land at the time of fallowing, has been found of great value for its manuring and cleaning properties. It promotes fertility, is a remedy against smut and rust, preserves the seed from vermin, and is particularly useful in increasing the produce of grass lands. The sterile soils of South America are manured with a substance called *guano*, consisting of urate of ammonia and other ammoniacal salts, by the use of which a luxuriant vegetation and the richest crops are obtained. Guano is the excrement of sea-fowl, accumulated for centuries on the islets and rocky shores of arid climates. It is now imported from Peru, Africa, and other tropical regions, into Britain by merchants for the use of agriculturists. The increase of crops obtained by its application to land is said to be very remarkable. According to one authority, the crop of potatoes is increased forty times by it, and maize thirty times. This may be an exaggeration; but it is certain that guano contains ammoniacal salts in abundance, and other inorganic constituents which are indispensable for the development of plants.

Quicklime possesses the power of decomposing animal and vegetable matter, and enters as an element into the fabric of plants; in certain cases it only alters the constitution of the soil. Though occasionally of value on well-cultured soils, the great use of lime is to prepare newly broken-up land for successful cultivation; and on this account we shall reserve consideration of its efficacy for the subsequent number.

CROPPING—ROTATIONS.

Difference of crops successively on the same piece of land is essentially necessary in a right system of husbandry. Crops of the same kind have an exhausting effect, and experience proves that there must be a regular round or rotation, involving in particular a change from grain to green crops. Referring the reader to the article VEGETABLE PHYSIOLOGY for the theory of rotations, we shall merely transcribe the following practical synopsis, as given by Yvard and Pielet:—1. That every plant has a natural tendency to exhaust the soil; 2. That all plants do not exhaust the soil equally; 3. That all plants of different kinds do not exhaust the soil in the same manner; 4. That all plants do not restore to the soil the same quantity nor the same quality of manure; 5. That all plants differently affect the growth of weeds. From these fundamental principles the following conclusions are drawn:—1. However well a soil may be prepared, it cannot long nourish crops of the same kind in succession without becoming exhausted; 2. Every crop impoverishes a soil, in proportion as more or less nutritious matter is restored by the plant cultivated; 3. Perpendicular rooting plants, and such as shoot horizontally, ought to succeed each other; 4. Plants of the same kind should not return too frequently in a circle of cropping; 5. Two plants equally favourable to the growth of weeds ought not to succeed each other; 6. Such plants as greatly exhaust the soil, as grains, should only be sown when the land is in good heart; 7. In proportion as a soil is found to exhaust itself by successive crops, plants that are least exhausting should be cultivated. It may be added, that a change of crops has a tendency to destroy noxious insects, as those which are produced by one crop cannot, in most cases, be supported by another.

Special Rotations.

On Clay Soils.—These soils are of various depths and fertility, and, like all others, differ materially according to the climate in which they are situated. All other circumstances being favourable, good clay soils are particularly adapted for the production of wheat and beans, and may be continued under these crops alternately, as long as the land can be kept free from weeds by drilling the bean crops. This is the most profitable course of cropping that can be followed, providing a sufficiency of manure be procured, and the drilled beans be alternately horse and hand hoed. The nature of the soil or other circumstances may render a crop of clover or rye-grass necessary occasionally for one year, and this can be succeeded by oats. This course may continue for six or eight years, or even longer, and will run thus:—1. Fallow; 2. Wheat; 3. Clover and rye-grass; 4. Oats; 5. Drilled beans; 6. Wheat. In this rotation, to procure full fertility and luxuriant crops, the soil ought to be recruited with manure every third or fourth year, the dung being first applied in the fallow year, and next to the bean crop. Whenever the soil gets foul with root weeds, which it will sooner or later do, another naked fallow must in most cases be resorted to; and this begins a new rotation.

Where circumstances are not favourable to the above rotation, the following may be advantageously substituted. It contains a variety of the crops usually cultivated, and by dividing the labour more equally throughout the year, may be carried on with a smaller number of horses, and consequently at less expense:—1. Fallow; 2. Wheat; 3. Drilled beans; 4. Barley; 5. Clover and rye-grass; 6. Oats; 7. Drilled beans; 8. Wheat; after which a new fallow begins a new rotation. In this rotation, it is absolutely necessary that the land should have dung twice or thrice if possible, to insure abundant crops throughout the course; and the proper periods of its application are—on the fallow before the first crop of wheat, on the clover stubble in the fifth year, and to the beans the seventh year.

A favourite rotation on the strong lands of Essex is —1. Summer fallow, limed; 2. Barley; 3. Clover, first fed and afterwards kept for seed; 4. Wheat; 5. Beans, dunged; 6. Wheat; 7. Oats. It is a rule in Essex never to put in wheat in a fallow. Although two successive crops of white corn are justly objected to, on the best principles of cultivation, yet upon land of this nature both wheat and oats are frequently taken either before or after each other, without doing material injury to the soil. On the strong soils in the neighbourhood of Edinburgh, clover is found not to succeed when sown along with wheat, on which account barley is taken after wheat, and the grass sown along with it succeeds well. In the colder parts of Scotland, beans will not ripen in some seasons, and in these districts the clay soils are uniformly thin and sterile. On such soils and situations, the following rotation may be found to answer:—1. Fallow, with dung; 2. Barley, beans, or oats; 3. Clover, cut in the first year, and depastured for two or three years; 4. Oats; and a new rotation begins. By this method, the rotation is kept up for six or seven years—a period quite long enough, as the pasture on these cold and meagre soils, after the second or third year, will be found of little value; and after this, the soil will rather fall back than improve in fertility. But, as already mentioned, from the practice of furrow-draining, to which, even in exposed situations, these soils are subjected, a fallow crop of turnips is now superseding the naked fallow.

In the south of England, the farmers consider that a clover ley is the best preparation for a crop of wheat; while in the north of England, and in Scotland, clover is more commonly sown with wheat or barley, and followed by oats, both because the oats are almost invariably found to produce a large return after clover, and from the wheat being better placed in the succession immediately after the fallow.

On Loams.—Clayey loam, and loamy soils, in the rotation of crops, may be ranked as clay soils, and cropped exactly in the manner already explained, even though they should approach to the nature of light lands, from which they only differ in degrees of quality. The mode of managing rich loam depends upon the nature of the subsoil. If this be retentive, and not furrow-drained, the soil will require to be subjected to a naked summer fallow every six or eight years, to free it from root weeds; and in this case, the steps of the rotation will be similar to those already described as suitable for the best clay soils. When completely furrow-drained, or if the soil lies on a porous bottom, a fallow crop of drilled turnips or potatoes will be found an effectual cleaning; and from the great value of these roots, they are in every way preferable to naked fallow. The rotation may then be as follows:—1. Turnip fallow; 2. Wheat, on such parts of the land as are freed from the turnips in time for that crop, and barley or oats on the rest: 3. Clover and rye-grass; 4. Oats after grass; 5. Drilled beans; 6. Barley; 7. Clover and rye-grass; 8. Oats; and this to be succeeded by turnips, or other green crop, to begin a new rotation. Some stop at the sixth crop, and make it wheat instead of barley, and then commence with turnips. Where beans are not wished to be grown, the following have been found to be advantageous rotations:—1. Potatoes, with manure; 2. Wheat; 3. Turnips, with manure; 4. Barley; 5. Clover and rye-grass for hay: or, 1. Potatoes, with manure; 2. Turnips, with manure; 3. Wheat; 4. Barley; 5. Clover and rye-grass for hay and pasture: or, lastly, 1. Potatoes, with manure; 2. Turnips, with manure; 3. Wheat; 4. Barley; 5. Clover and rye-grass for hay; 6. Oats. Comparing the returns of these three rotations, they stand in relative value to the farmer as 21, 23½ and 16.

On Light Lands.—The general principles of management for this description of soil are precisely the same as those already described, and every rotation should be established on a well-wrought and well-dunged turnip fallow. The course of crops best suited for these light soils is—1. Turnips in drills; 2. Wheat or barley; 3. Clover and rye-grass; 4. Oats; and round again to a new rotation. On good turnip soils this rotation may be repeated indefinitely, providing the turnip crop be eaten on the ground, that the grass crop be pastured, or that the manure derived from the hay be returned to the ground. It will be necessary, however, to introduce occasionally the alternate system of pasturage; for without this, even with the most liberal treatment, it will scarcely be possible to keep up the fertility of the soil.

On good turnip soils, when what is produced on the farm is the only manure used, the following rotation may be found advisable:—1. Turnips; 2. Wheat or barley; 3. Clover and rye-grass; 4. 5. and, if necessary, 6. Pasture; 7. Oats; and round again. When manure is within reach, alternate white and green crops may be followed for a number of years, in this rotation:—1. Potatoes or turnips; 2. Wheat; 3. Drilled beans or peas; 4. Wheat or barley; 5. Potatoes or turnips; 6. Wheat or barley; 7. Clover and rye-grass; 8. Oats. The advantage of this course is, that it secures a good crop of clover; but wheat occurs too often.

In the vicinity of London, Edinburgh, and Glasgow, the rotations are frequently:—1. Potatoes; 2. Wheat; 3. Clover and rye-grass. By some, the clover is followed by oats, and the rotation again begins; others end the rotation with clover. Even with the manure which these short rotations secure to the soil, occasional pasturage must be had recourse to, if the soil appear in any way exhausted.

On Sandy Soils.—These soils require the most liberal cultivation to produce either grain or green crops; for in the event of dry weather they become so parched as to be unfit for the growth of almost any species of plant. When well manured, sandy soils produce good crops of potatoes or turnips; if possible the latter should be consumed on the ground by sheep or cattle. It is difficult to make these soils too rich, and from their nature, all the manure given them is soon consumed. Wheat, beans, or peas, do not succeed; barley, oats, and rye, are the only grain crops which yield a profitable return on these soils; and pasturage for a term of years is absolutely necessary. The following six years' rotation has been recommended for these soils:—1. Turnips, with dung, which are to be consumed on the ground by sheep; 2. Barley or oats; 3. 4. 5. Grass pastured by sheep; 5. Rye or oats.

On land situated in exposed and remote districts, the only grains which are cultivated are early varieties of oats, bere or bigg, and potatoes, as a change of seed for the more genial and fertile grounds. The following course of crops, proportioning the quantity sown to the manure supplied to the turnips and potatoes, may be followed in such situations:—1. Oats from old ley; 2. Turnips and potatoes; 3. Oats, barley, or bigg, sown with clover or grass seeds; 4. Hay; and then restored to pasture. The rotations *on peat and moorish soils* will be treated in the subsequent number.

White Crops.

By white crops are meant those which, like wheat, barley, oats, and rye, assume a whitish appearance as they approach to maturity. They are called *white* in contradistinction to clover, rye-grass, turnips, &c. which are made use of in a green state, and therefore known as *green crops*. Wheat, barley, oats, rye, and other bread corns, are also known by the name of *cereals*, from the Latin *ceres*, corn; and this term is used to distinguish them from beans, peas, vetches, and the like, which rank under the appellation *leguminous*.

Seed-Sowing.—In choosing seeds, there are three rules which should be attended to:—1. That the variety to be sown is suited to the soil and climate; 2. The propriety of occasionally changing the seed; 3. That the seed has the appearance of being sound. All seed should be allowed to arrive at full maturity before being sown, for the nourishment which the seed must yield to the plant in the first stage of growth can never be so great when this is not the case. The best cultivators choose the finest qualities of each species for seed; sowing them on the land best adapted for their growth. Some varieties are remarkably attached to particular soils, and certain degrees of fertility and moisture seem to suit them best. Others require a greater degree and duration of heat, and frequently take four or five weeks longer to ripen. Early sowing of these sorts ought to be resorted to. Too sudden a change in climate and situation is hurtful; hence Yorkshire seed has been found to answer better in Scotland than that brought from Essex. Many varieties may be introduced gradually, which would not answer if their habits were not a little consulted.

The oldest established mode of sowing is by *broadcast*, or scattering the grain from the hand over the land which has been prepared for it. But this plan is not so economical, or otherwise so valuable, as sowing in drills by machines. In Scotland, the usual method of sowing broadcast consists in the sower walking along the ridges, and at very regular intervals, so as to keep time with his steps, throwing a handful of grain before him by a wide sweep of the arm. He carries the grain in a sheet, which is slung round his neck, and is open to the hand in front. A servant attends, to afford fresh supplies at the end of the ridges.

Wheat is the most important of all the grains, and its varieties are numerous. Among those now in cultivation, the following may be enumerated:—The bearded, the Dunglass, the golden ear, the velvet ear, the egg-shell, the hedge-wheat, the Essex dun, the Kentish yellow, the white and red Essex, the Mungoswell's, the Burwell red, the Hunter's, and the Georgian. A general division of wheats is made into white and red, with several shades between, and summer and winter. Winter wheat may be brought into the nature of summer, by altering the time of sowing. If winter wheat be sown at the period for putting summer wheat into the ground, in the course of two seasons the winter will become of a similar habit as the summer, and the same process will bring a summer wheat to be a winter one. In general, the fine white wheats are preferred to the brown and red; but the latter is most profitable for wet adhesive soils and unfavourable climates, on account of its hardiness and ripening early. The variety of wheat most profitable to be produced must depend upon the nature of the soil, as land which has produced an indifferent crop of one may yield an abundant crop of another kind; and land is frequently found to yield better crops if the varieties be alternately changed. The richer description of clays and strong loams are the best adapted for the production of wheat; but if properly cultivated and well manured, any variety of these two soils will produce excellent crops of this grain. Good wheat land ought always to possess a large quantity of clay, and little sand; for although light soils may be made to produce good crops, yet the strong clay lands in general yield the heaviest grain.

'The season for sowing wheat'—we quote the General Report of Scotland—' is necessarily regulated by the state of the land, as well as of the season; on which account it is not always in the farmer's power to choose the moment he would prefer. After fallow, as the season allows, it may be sown from the end of August till the middle of November. On wet clays, it is proper to sow as early as possible, as such soils, when thoroughly drenched with moisture in autumn, are seldom in a proper state for harrowing till the succeeding spring. In the opinion of many experienced husbandmen, the best season for sowing wheat, whether on fallow, rag-fallow, or ploughed clover stubble, is from the beginning of September to the 20th of October; but this must depend upon the state of the soil and weather. On dry gravelly loams, in good condition, after a clover crop, and well prepared, wheat may be sown till the end of November. After turnips, when the crop is consumed or led off, and the ground can be properly ploughed, wheat may be sown any time betwixt the 1st of February and the middle of March; and it is customary to plough and sow the land in successive portions as fast as the turnips are consumed. It is only on turnip soil of a good quality, verging towards loam, and in high condition, that winter wheat, sown in spring, can be cultivated with success. When circumstances are favourable, however, it will generally happen that such lands, when wheat is not too often repeated, will nearly produce as many bushels of wheat as of barley. The wheat crops, therefore, on an average of seasons, will exceed the value of the barley crop considerably; hence its culture is an object which ought not to be neglected.'

Wheat is liable to certain fungous diseases, as, for example, smut, mildew, or rust, &c. With the view of preserving the grain from these most injurious disorders, it is customary to prepare the seed by steeping or pickling it in a kind of saline brine, or diluted urine. Steeping or pickling is performed after the seed has been washed, by allowing it to lie for a time amongst stale urine, diluted with water, or salt brine, of sufficient strength to float an egg. The seed is put into tubs, containing as much liquid as will cover the grain a few inches, and allow it to be well stirred, so as to bring all the light grains to the surface, which are skimmed off as long as they continue to rise. Another way is to put the seed into baskets, which are immersed in the water, are easily taken out, and can be conveniently placed over an empty tub to drain. The seed is left for three or four hours in the chamber lye, or full six hours in the pickle, after which the liquor is drawn off, and the wheat spread thinly on the floor of the granary, where it is well sprinkled over with quicklime slaked in the liquid. About half a peck of lime is sufficient for a bushel of wheat, and it should be well stirred, so that every grain may get a portion. If the seed is to be drilled, it should be passed through a coarse sieve after being limed, which will facilitate its progress through the machine. The grain will thus be quickly dried; and it should not lie more than six hours in the heap, then be spread out, and sown on the following day.

Some caution should be used in having the lime properly slaked, for if this is not done, too great a heat may be raised, which will destroy the vegetative principle. Doubts have been expressed of the efficacy of lime, and a solution of copperas is used on the Continent instead. Dry powdered lime would certainly have no effect, but when newly slaked it is very efficacious, as has been proved from experiment. It was found that a steep of lime-water alone, in which wheat was immersed for four-and-twenty hours, proved a powerful preventive of disease, while the good effects of unmixed brine were very inconsiderable.

Of the two kinds of steeps mentioned, urine is thought the most efficient, and it should be used neither too fresh nor too stale, as in the first state it is ineffectual, and in the second injurious. The seed should be sown as soon as dry; for if allowed to lie in sacks or heaps beyond a day or two, the lime may be very hurtful. Another steep, which is recommended by Sir John Sinclair, and is much used in Flanders, France, and Switzerland, is a weak solution of the sulphate of copper, or blue vitriol. The modes of using it are as follow:—Into eight quarts of boiling water put one pound of blue vitriol, and while quite hot, three bushels of wheat are wetted with five quarts of the liquid; in three hours the remaining three quarts are added, and the wheat is suffered to remain three hours longer in the solution. The whole should be stirred three or four times during the six hours, and the light grains skimmed off. After the wheat is drained, slaked lime is thrown on it to facilitate the drying.

Rye is usually sown on light soils, and does not require so much care as wheat; it suffers less by being sown on the stubble of another corn crop, or upon its own, and it is not unusual to grow it on the same land two years in succession. This grain is frequently sown to be cut for soiling instead of winter tares, and in England it is frequently used for early sheep-feeding, cut green, without obtaining a grain crop from it. It is extremely useful to breeding flocks, as it comes forward earlier than tares, and affords good food when other sustenance is scarce.

Barley is a much hardier grain than either wheat or rye. There are six varieties of this grain, distinguished by the number of rows in the ear, four of which are cultivated in Britain. The kinds which have been recently introduced into Scotland are the Chevalier, Annat, and other sorts; but the two-rowed and four-rowed, called *berè* or *bigg*, have been most extensively cultivated. In its culture, barley requires a clean, rich, mellow loam, moderately retentive; and on clays, tempered with sandy mould, or containing a certain portion of chalk and sand, it is found to succeed well. On poor wet soils it is never successful; and every kind of land on which it is cultivated should be well wrought and thoroughly pulverised. If the preceding crop has been wheat, the land should undergo three ploughings before barley is put into the soil. Barley usually follows turnips in the rotation, but it is found to grow very well after potatoes. It is thought best to have the turnips eaten on the ground when this can be accomplished; and if the preceding crop has been potatoes, the land should be well ridged up, in order to have it as dry as possible. The application of lime and earth, earth and dung, or urine, is thought of great advantage to the barley crop, and even to plough in the turnip leaves is beneficial. If the plough is not sufficient to pulverise the land properly, the harrow and roller ought to be used to accomplish this. In most cases, more than one ploughing is given, but after a winter furrow the grubber may be used instead. When turnips have been consumed on the ground, it is much trodden down, and will require two ploughings; if this is not given, the soil should be well harrowed and rolled. Barley should be sown as soon after ploughing as possible, when the land is fresh and moist, in order to obtain equal and speedy vegetation. The best season for sowing barley is from the beginning of April to the middle of May; but it has been sown a month after this with success. The bere or bigg sort is sometimes sown in October, and called winter barley.

In Scotland, clover and rye-grass are sown immediately after barley, and the seeds are covered by the last harrowing; a light grass harrow being sometimes used for the purpose. Rolling is practised by some immediately after, while others prefer allowing the plants to come above ground; the small clods in this case act as a shelter to the plants, which is of great service in frosty weather.

The oat is suited to climates which are too cold for wheat or other grain crops, and therefore thrives in high regions better than in low-lying countries. When land is broken up, either from a state of nature or from pasture, oats form the first crop, as they may be repeated for a series of years without injuring the soil. They are also the best crop to follow clover, and are sometimes sown with clover and grass seeds. They often follow potatoes and green crops, and in either of these cases, the land should be well ridged up in the winter. When the seed is sown, the land should be completely harrowed, and then rolled across the ridges. A mixture of oats is generally sown along with tares, to prevent them from falling and rotting on the ground. In this state they are cut green, and form an excellent food for cattle and horses. A change of seed from hot to cold, and cold to hot, is always to be recommended; and the quantity of seed must depend on the nature of the soil and the variety to be sown. On poor soils, from the plants not spreading, oats should be sown thick. The Hopetoun, and many other varieties, do not tiller out, and therefore require more seed to be sown. The quantity of seed necessary varies from four to seven bushels per imperial acre, and broadcast sowing is that generally practised.

The usual time of sowing is from the beginning of March to the end of April; early sowing is to be preferred, as the grain is of better quality; but late sowing produces the greatest bulk of straw. The produce differs materially according to the soil, climate, and the fitness of the particular variety for the land. The maximum quantity, soil and climate being favourable, may be estimated at seventy bushels, and the minimum twenty bushels per acre; the average being about four quarters. Oat straw is preferred to any other as fodder for cattle, as it is considered more nutritive.

Green Crops.

No farming can be said to be perfect unless it involves a due alternation of *green* with *white* crops. The more foul the land is with weeds, green crops of the drill kind are the more necessary, because, in the course of cultivating green crops, we have an opportunity of hoeing and trenching the land, not only once, but repeatedly, and of thus exhausting the seeds of weeds lodged in the soil. By administering manure, and this mode of cleansing, the necessity for *fallowing* is in a great measure obviated. But green crops also fulfil the important purpose of feeding live-stock and producing manure. The constant exhaustion of the soil, be it even very fertile, demands a periodical nourishment, and this is best done by means of live animals. It is customary on the well-organised farms of Norfolk, East-Lothian, &c. to manufacture manure on a large scale by means of *soiling*; that is, feeding cattle in houses or an open yard with turnips, the cattle at the same time treading on the waste straw of the farm, and thus using up a material which would be otherwise lost. Sheep are also turned into pens on turnip-fields, to eat up the turnips from the drills, and the droppings greatly enrich the spot. It is customary in Scotland for low-country farmers to buy cattle lean at the end of autumn, and sell them fatted to a certain extent in spring; and all this trouble is taken principally for the sake of their manure.

Beans require the same sort of soil as wheat—namely, heavy clays—and should be sown in drills. Some suppose that beans exhaust the soil; but this is scarcely probable, from wheat always yielding a good crop after them. In preparing the ground for beans, it ought to be ploughed after harvest, or early in winter, that the soil may be mellowed with the winter frosts. The furrow should be deep, but before sowing the land should be drained of its superabundant moisture. Sow as soon as winter is over, or never later than the end of March in Scotland. Four bushels of seed to the acre are sufficient; but it is common, for the sake of improving the fodder, to mix peas with the beans, to the extent of one bushel of peas to six of beans. Beans require frequent weeding with the horse-hoe. The crop, if late, should be carried to another field to dry, and thus make way for the wheat crop.

Peas grow best when mixed with beans, as they by that means gain a support for their slender trailing stalks. They, however, grow on a poorer soil than beans, such as a sandy loam, and neither too moist nor too dry. They are improved by lime and marl manures. Drilling, as in the case of beans, is greatly preferable to broadcast; and from four to five bushels of seed per acre is reckoned a proper allowance. The early kind of peas may be sown at any time till the end of May, but the late must be sown in February or March.

Tares or vetch are a valuable crop, both for soiling and feeding cattle. Tares are of two sorts—winter and summer. The seed of the summer tares should be put into the ground at intervals, from the end of March to the end of May, so as to furnish successive cuttings. The winter tare requires to be sown in September or October; and in early spring it is a very valuable food for cattle and sheep.

Clover and *Rye-grass* are the most valuable artificial grasses that can be grown by the farmer. They should never be sown except when the land is in the best condition; if possible, with the crop immediately following a summer fallow, or after turnips or potatoes. Thus in all well-manured and well-dressed land, clover and rye-grass are mixed with the crop of grain, being either sown at the same time or at a suitable period after. When the grain crop is cut in harvest, the tops of the young clover are perhaps cut at the same time, but this is of little consequence; the great bulk of the grass crop comes into maturity among the remaining stubble, and is then either scythed for hay or for feeding animals in a green state. When sown on land on which grain has been sown, it is customary to roll the ground, to assist in covering the light seeds. Great care requires to be employed in choosing proper kinds of clover and grass seeds, as there are always many worthless sorts in the market.

Many farmers, on purpose to prolong the rotations, and prevent the too frequent repetitions of the clover crop, substitute a crop of peas or tares after the barley, sowing the clover after the wheat or barley in the next rotation, which makes the time between the two clover crops to be seven instead of four years. The crop of peas they consider as by no means remunerative, yet, from the additional crop of clover reaped in the second rotation, they find themselves compensated for the deficiency in the peas. Surface applications are now administered on an extensive scale in improved districts, for the sole purpose of procuring an abundant crop of clover and rye-grass. Soot is one of the ingredients which is applied, and has uniformly the effect of strengthening and forwarding the crop. Liquid manures are also extensively used, and are much more lasting in their effects, and seem better adapted for clover, than soot. Saltpetre is likewise much employed, and forms an excellent top-dressing for seedling grasses. It is by such means as these that the agriculturists of the Netherlands have been able to keep up the fertility of their lands, in the cultivation of clover, through time immemorial. The whole of the agriculture of the Netherlands rests upon the cultivation of clover, which not unfrequently yields a heavy crop the first year; two and even three abundant crops the second; and, if allowed to stand another year, will yield a good crop, and afterwards be excellent pasture for cattle, till ploughed up to receive wheat seed.

Turnips yield a most profitable crop for the maintenance of live-stock; and they are also useful as a green crop, by permitting an effectual cleansing of the land from weeds. The leaves being large and spreading, they afford a shade, which retains the moisture, and tends to decompose any vegetable matter in the ground. Turnips are divided into various classes, in each of which there are several varieties. The more common classes are the round or globe-shaped; the depressed or Norfolk; and the fusiform or oblong, the latter being better known by the name of Swedish. They are also sometimes known by their colour—as the white, the yellow (including the Swedish), and the purple-topped. The white, with the purple-topped, is early, particularly suited to those light soils where sheep are fed, and requires less manure. It must be consumed, however, as soon as possible, or is apt to run to seed, or to be injured by frost. Upon the whole, the Swedish is now preferred to most others, and yields the heaviest crop. It requires to be sown early, or from the beginning of April to the end of May; the seed should be given liberally, or at the rate of about three pounds per acre. In all cases the sowing ought to be in drills, to permit an effective hoeing when the crop is getting up. After being sown on a well-ploughed field, the roller must be employed to press all smooth on the ridges. The plants will in general make their appearance about ten days or a fortnight after they are sown, according to the quality of the soil and the state of the weather. When the leaves are about two inches high, a horse-hoeing is given between the ridgelets, to cut up the weeds close to the plants. The hand-hoe is then introduced to thin the crop, leaving plants standing at intervals of from eight to ten inches apart, the Swedish kind being somewhat wider. This distance is thought quite sufficient to insure plants neither too large nor too small in size. The soft turnip, when allowed too great a distance, is apt to become very large, and its nutritive juices are found to be quite lost. The Swedish and other hard turnips should be allowed sufficient room to become as large as possible, for their nature is such that there is no fear of their ever being over-bulky. The hand-hoeing and thinning are generally performed by women and boys, and three expert hoers will go over an acre a day. A few days after the hoeing, a small swing-plough is used to make small ridgelets between the rows; and when weeds are still in abundance, it will be necessary again to horse or hand-hoe the ground, which levels the intermediate ridgelet. After all weeds are thoroughly destroyed, and the thinning is accomplished, the earth is sometimes gathered up about the plants by means of a small plough with two mould-boards. This operation, however, is objected to, on the plea that the earth prevents the bulbs from growing, and also when the produce is to be consumed on the ground, the sheep may be injured by falling into the hollows between the rows. On wet soils, the earthing-up is very beneficial, as it allows the free discharge of superabundant moisture; and when the weather is frosty, the earth is an excellent protection to the plants.

Turnips may either be consumed on the fields where they grow, in grass fields, in fold-yards, or in feeding-houses; and in the vicinity of large towns they are sold to cowfeeders. *Mangel-wurzel* or field beet and carrots are both now introduced with advantage as a variety in green husbandry, and either in a raw or dressed state, afford a highly nutritive food for cattle and horses.

Potatoes usually enter into a course of husbandry, particularly in the neighbourhood of populous towns, where a ready market can be obtained. The usual period of planting in the British islands is the end of April or beginning of May, for the late and more common sorts. The early kinds, which are not kept for permanent stock, are planted in March. The potato harvest is in October or beginning of November. It has been customary to plant by sets or cut pieces of the potato, each having an eye or point of germination; but the numerous failures of the crops have introduced the practice of setting the whole tuber. In the large farms of Scotland, they are set in drill furrows (previously well manured), at a distance of eighteen inches apart, and six inches of earth is turned over upon them by the horse-hoe. When the plants appear above the surface, they are repeatedly earthed as may be required; this, with the weeding of them, is done by hand-hoeing. Potatoes are very susceptible of diseases, which cause failures of crop; but there is reason to believe that this arises from some kind of mismanagement or accident—as, for example, producing again and again without change of seed, lifting of seed after frost, rot from wet seasons, heating of heaps after lifting, &c. The preventives of disease, likely to be most successful, are—frequent changes of seed, bringing seed from quite a different soil, not too frequent cropping from the same land, spreading out to dry after lifting, and careful protection from frost during winter. They are best preserved in pits, a layer of potatoes and earth alternately to a height of four feet, and finally covered with earth on the top and sides.

Haymaking.—When the grass has arrived at or near its full growth, but before the seed is perfected, it should be cut down by the scythe for hay. A short time after being mown, it should be turned over in full swathes, without being scattered. If not in a fit state to be cocked the first day after cutting, it should be put into small handcocks as soon as its state of dryness will allow; from these it should be gathered into larger ones, and when its condition permits, put into tramp ricks. The gathering of the hay is generally performed by women and boys, some carrying, and others raking up what may remain. Let it be remembered that the less the hay is exposed to the sun, the better is its flavour and strength. In wet seasons, the utmost care will be required not to stack the hay while moist; for then, like moist sheaves of grain, it will heat, and either burst into a flame, or be seriously damaged in quality. The criterion for good hay is, that it should be greenish in colour, be perfectly dry, and possess a sweet odour and saccharine taste.

REAPING—HARVESTING.

The ripeness of grain is shown by the straw assuming a golden colour from the bottom of the stem nearly to the ear; or when the ear begins to droop gently, the corn may be cut. Although the straw may be green from the ear for some distance down the stem, yet if it be quite yellow at the bottom, and for some distance upwards, the grain requires no farther nourishment from the earth, and if properly harvested, will not shrink. These indications of ripeness may suffice for wheat, barley, and oats.

Reaping.—It was formerly the practice to cut grain with a saw-edged sickle; but this has given place to a larger instrument, with a smooth edge like a scythe. The reapers are usually divided into bands of six or seven, with a binder to each band. When the ridges are less than eighteen feet broad, three reapers are usually placed upon each ridge, the middle reaper making the bands with which the sheaves are bound up. When four reapers are placed upon one ridge, as is usually the case when the ridge is eighteen feet broad, two bands are laid upon one ridge; and two are enabled in this way to manage twelve reapers, placed on three ridges, stooking the corn all in one row upon the middle ridge. When the crop is very strong, however, it is often found necessary that each binder should stook by himself. In harvesting oats and barley, each shock or stook is formed of ten sheaves placed in two rows, the head of each sheaf leaning upon the opposite one, and a sheaf on the top at each end. They stand usually due north and south, so that each side may receive equal benefit from the sun. The straw of wheat being longer than that of oats and barley, the stooks of the former are made larger, having six sheaves in each row, and one on the top at each end. When the crop is thin, half stooks are frequently set up; and to forward the drying process, the end sheaves are now generally omitted when the weather is good; but this should never be done where the climate is uncertain, as it exposes the corn to rain.

Oats and barley are now frequently cut with a scythe, which is either plain or furnished with a bow or cradle, in order to lay the grain evenly in one direction. Wheat is almost universally cut with the sickle; and if the weather keep good after this operation is performed, it will be ready for stacking in the course of five or six days. Barley is frequently cut with the scythe in England, but the sickle is generally used in Scotland. Barley and oats require to lie ten or twelve days, as they are more or less mixed with clover, before being ready for stacking. The clover ought to be completely withered before the corn is stacked; and indeed it requires the greatest caution on the part of the farmer in ascertaining whether his crops are in a proper state for being carried to the stack-yard. The best way for judging of this is to take out a handful from the centre of the middle sheaf on the lee side of the stook, repeating this on several parts of the field; and if the knots or joints of this are dry and shrivelled, the crop may be led home in safety. All corn crops should be cut as low as possible, for by this a great addition is made to the straw, and consequently to the future manure.

Stacking.—When the crop is thoroughly dry, it is led home to the stack-yard on open spar-built carts, and built into stacks so constructed as to afford complete shelter from the weather. The stool or bottom upon which the stack stands was formerly made of loose straw or brushwood; but in the best-managed farms, it is now the practice to construct the stacks on stands made of stone or brick, or upon pillars made of stone or cast-iron, spurred across with wood or iron.

These stands are formed so as to prevent the access of vermin, which is calculated to effect a saving of two bolls in thirty; and many have funnels from the top to the bottom of stacks, to admit a free current of air. In Scotland, the stacks being mostly round, a sheaf is first placed on its butt-end, in the centre of the bottom or stand; around this others are placed, also upright, but with a slight inclination of the head inwards, until the stand is nearly filled. The stacker then places a layer of sheaves horizontally on the outside of these, lying on their sides, the ear-ends inwards; and pressing them together with considerable force, he continues to lay on rows until the outside sheaves are as high as those standing on end. The whole stack is filled up in nearly the same manner, the ear-ends of the sheaves being always inwards, with a regular inclination downwards and outwards to their butts, and the centre of the rick being higher, and not so compressed as the outside. Proper attention to the sloping of the sheaves is necessary from the foundation of the stack, but particularly so at the intake of the inner layers, that part being always left more open. When this is done, the stacker sets up an outside circular row of sheaves, having their butt-ends projecting a few inches beyond the body of the rick, after which the outside layers come gradually inwards, until the roof is drawn to a narrow circle, when two or three sheaves placed upright completely fill up the stack. The topmost sheaves are then firmly bound with a few turns from the middle of the straw rope, the two ends of which are fastened on opposite sides of the stack. When carefully built and thatched, a stack will completely keep out rain, and be quite secure from high winds. Materials for thatching, and straw ropes, should always be made before harvest, so that no delay may arise from this in the event of wet weather. The thatcher stands upon a ladder, placed on the sloping roof of the stack, and lays on the straw in handfuls from a quantity placed within his reach. One end of the straw he thrusts into the butt of a sheaf, and the other end hangs over the stack. He thus progresses upwards, making each handful overlap the other; and having drawn the top to a point, he binds the whole covering securely down with a series of tough oat-straw ropes.

Stacks are sometimes constructed in England on a timber platform raised upon stones, and over the stack the framework of a perfect barn is placed, which can be either tiled or thatched. This is said to afford greater security to the crop, and to be less expensive than annually thatching. The price of erection is said to be comparatively trifling, when the convenience of such buildings is considered; and they have been known, when well put up, to last for thirty years.

Thrashing is either performed with the flail or the thrashing-mill. The use of the latter we by all means recommend in preference on arable farms of above one hundred acres in extent. The machine may be driven by water, horse, or steam power, according to circumstances. Several improvements have been made on thrashing-mills since their first invention. The unthrashed corn is now made to pass through two revolving rollers, while it is acted on by beaters placed lengthwise upon a large cylinder or drum, which moves at the speed of 2500 feet in a minute. The great essential in thrashing is to have regularity of motion, and the grain to be equally fed into the rollers. One man should be employed to feed in the corn, one man, or two boys, to carry the sheaves, and a woman to untie and place them on a table near the feeder. Other persons are employed in raking and carrying the thrashed straw to the straw-house, where it is built. When the machine is driven by steam or water, it is generally the case that one or two winnowing-machines, according to the power employed, are attached to the thrashing-mill, and thus the expense of preparing the grain for market is considerably lessened. A powerful machine will thrash from two to three hundred bushels in nine hours; and allowing for wages and wear of machinery, the expense of thus preparing grain for the market is under one penny per bushel.

Winnowing is a process performed by the aid of wind, by which the chaff of corn is separated from the grain. Winnowing-machines, or fanners, as stated before, are sometimes attached to thrashing-mills, and they are a necessary appendage to every farm, either in conjunction with the thrashing-mill, or separately. Some farmers winnow their grain by hand-fanners, which are thought to be steadier in the motion than when driven by machinery, and consequently the grain is more thoroughly cleansed. After thrashing, the grain is regularly dressed in the clean corn room by means of fanners, riddles, and sieves; and this final dressing is regulated according to the state in which the grain comes from the thrashing-mill. By the process of winnowing, chaff, bits of straw, the seeds of weeds, and other refuse, are separated from the grain; and it is a wise precaution to boil the latter before putting them on the dunghill, which will effectually destroy their vegetative powers. The different qualities of grain are also separated from each other, by which it is rendered more valuable than when the good and bad are mixed together. The thorough cleaning and dressing of grain are of great importance to the farmer, and he will find it to add to his profit in the end to have this effectually done.

Barley undergoes a process called hummelling, by which the awns are broken off from the grain. The machine is composed of a vertical spindle enclosed in a cylinder, and furnished with arms which act upon the grain. It is sometimes attached to the thrashing-mill, and sometimes driven by a separate power. The grain is put in at the top of the cylinder, and as it passes through, the awns are broken off by being struck by the arms attached to the spindle. A more simple process is, after the barley is thrashed, to take off the head of the drum and put on another cover of tin, perforated with small holes about three-sixteenths of an inch wide. The barley is passed through the rollers, and by this the awns are rubbed off.

After being dressed and made ready for market, grain should be kept very dry, in a granary free from damp, and which is impervious to the incursions of vermin. It is, however, the best plan not to thrash grain till it be required for market, because it loses in weight, or shrivels in bulk, by keeping. It also loses in weight, though to a much less extent, by being kept long in ear in stacks; and therefore the sooner grain is thrashed and carried to market, the greater will be the return, supposing there be no rise in price.

CULTURE OF WASTE LANDS—SPADE HUSBANDRY.

According to the best authorities on the subject, it appears that the British islands contain about thirty millions of acres of waste lands. Much of this large proportion of our territory is situated at an altitude which places it beyond the possibility of improvement; but at least one-half is believed to be improvable, and capable of being rendered suitable, if not for tillage and grain crops, at least for the pasturage of cattle. The question as to the propriety of reclaiming the really improvable waste lands of the country is, in any particular case, to be satisfactorily answered by ascertaining at what expense, in relation to the probable profit, the process may be performed. A barren rocky desert may be rendered productive by covering it with soil and manures brought from a distance of miles, aided by years of skilful tillage; but will the cost of these operations be fairly returned by the profits of the produce? Gold itself may be purchased too highly, and so may agricultural improvements. We do not throw out this idea for the purpose of discouraging, but of cautioning proprietors and farmers of lands. In all projected improvements, they will require to ascertain in the first place what will be the probable return, within a moderate length of time, for their outlay—always keeping in view the prospective prices of rural produce during the period. Such at least is the principle of calculation which ought naturally to guide all owners of extensive tracts of waste ground, the outlay on which is to be strictly pecuniary. With reference to those who propose to reclaim wastes chiefly by an expenditure of time and personal labour, the calculation will take a similar turn; and the question will be, whether that time and labour could not have been employed more profitably in another line of pursuit. Leaving this, however, for further discussion in the sequel, we proceed to point out, *first*, to those whose situation in life and inclinations lead them that way, the means to be adopted, according to the best principles of science and lights of experience, for improving large or small portions of waste lands, and the results which may be expected to reward their enterprise; and *second*, the best plans which may be followed for improving patches of ground by spade husbandry, and establishing thereupon small cottage farms, suitable for the support of a comparatively humble class of families. In the treatment of these certainly not unimportant subjects, we shall of course refer chiefly to the condition of waste lands in the United Kingdom.

MORASS OR MOSS LANDS.

The greater proportion of what are usually called waste lands are stretches of peat-bog or moss, covered by a thin benty grass and tufts of heath. This remarkable species of land, though occurring in all parts of the country, is found to the greatest extent in Ireland and Scotland, often in the midst of productive tracts of country, but generally in high-lying districts, which are somewhat defective in point of climate.

Peat-mosses are supposed to be occasioned by the destruction of ancient forests, either by the hatchet or from natural decay. The trees found at the outskirts of these mosses appear to have been cut down, while those in the interior seem to have decayed by the gradual process of time. It is believed that the trees thus left upon the ground would soon become covered with moss, lichens, &c.; and the free drainage of the land being obstructed, aquatic plants, such as reeds, rushes, horsetail, and marsh trefoil, springing up and decaying, would leave a stratum of soft vegetable matter, which every succeeding year would increase. These plants grow in greater or less abundance, according to the quantity of moisture on the ground; and this may account for morasses being deeper in some parts than in others. The hollows would naturally retain moisture in larger quantities than the level ground, and here the aquatic plants would be most prolific, and the hollow gradually become filled up. The peat, which has been in this manner formed, is therefore a compound vegetable substance, which, although it has undergone a change, has not been entirely decomposed; probably the cellular tissue or transparent vegetable matter has decayed, while the woody fibre still remains. Water is indispensable to the formation of moss; and according as the ground is very wet, or only so to a certain extent, different plants will be produced. On ground completely saturated with water, various species of moss grow, to the almost total exclusion of other plants; but if the land should in any way become drier, reeds, rushes, marsh trefoil, horsetail, and the like, spring up in place of the moss. The quality of the peat may be judged of from the plants which grow upon it; all the moss tribe, the horsetail and the marsh trefoil, are fibrous, and difficult to decompose, while reeds, rushes, and sedge are comparatively easy of decomposition. Peat-moss possesses an astringent quality, which has the power of preserving bodies immersed in it, and even keeps itself from entirely decaying. This power is supposed to arise from the carbonic and gallic acids which issue from decayed wood; and vegetable gums and resins will also have the same effect. The tannin principle exists, as is well known, in the oak; and the pine contains much both of resinous and astringent matter. Many mosses are formed upon decayed trees, and the wood most commonly found is either pine, birch, hazel, or oak; and in these cases the presence of the tannin principle is easily accounted for. It is also highly probable that the plants themselves, by the action of natural agents, may have acquired an antiseptic or antiputrefactive quality. In some cases, lakes and pools of water have been filled up by the accumulation of moss; and it has been observed that fermentation occurs where this has taken place. Gaseous exhalations are evolved, and the neighbourhood of such a morass is generally unhealthy; but true peat soils are always salubrious.

The reasonable question has sometimes occurred to inquiring minds—Whence the substance of peat-mosses? for stagnant water alone could not have produced many feet deep of solid matter. This question is answered by chemistry. The vegetation which springs up in the form of aquatic plants, absorbs carbonic acid gas from the atmosphere, and a carbonaceous deposit is made in the condition of vegetable fibre, or dead vegetables in the state of mould. Mr Johnston, in his 'Lectures on Agricultural Chemistry,' makes the following observations on this subject:—'When lands are impoverished, you lay them down to grass, and the longer they lie undisturbed, the richer in vegetable matter does the soil become. When broken up, you find a black fertile mould where little trace of organic matter had previously existed. The same observation applies to lands long under wood. The vegetable matter increases, the soil improves, and when cleared and ploughed, it yields abundant crops of corn. Do grasses and trees derive their carbon from the soil? Then how, by their growth, do they increase the quantity of carbonaceous matter which the soil contains? It is obvious that, taken as a whole, they must draw from the air not only as much as is contained in their own substance, but an excess also, which they impart to the soil. But on this point the rapid growth of peat may be considered absolutely conclusive. A tree falls across a little running stream, dams up the water, and produces a marshy spot: rushes and reeds spring up, mosses take root and grow: year after year new shoots are sent forth, and the old plants die: vegetable matter accumulates; a bog, and finally a thick bed of peat, is formed. Nor does this peat form and accumulate at the expense of one species or genus of plants only. Latitude and local situation are the circumstances which chiefly affect this accumulation of vegetable matter on the soil. In our own country, the lowest layers of peat are formed of aquatic plants, the next of mosses, and the highest of heath. "In Terra del Fuego," says Darwin, "nearly every patch of level ground is covered by two species of plants, which, by their joint decay, compose a thick bed of elastic peat. In the Falkland Islands, almost every kind of plant, even the coarse grass which covers the whole surface of the islands, becomes converted into this substance." Whence have all these plants derived their carbon? The quantity originally contained in the soil is, after a lapse of years, increased ten thousand fold. Has the dead matter the power of reproducing itself? You will answer at once, that all these plants must have grown at the expense of the air—must have lived on the carbon it was capable of affording them—and as they died, must have left this carbon in a state unfit to nourish the succeeding race.' In other words, the substance of peat-mosses is a deposit from the atmosphere, which, as explained under VEGETABLE PHYSIOLOGY, p. 65, is a universal source of subsistence to vegetable life.

Though thus composed of a deposit of dead vegetable matter, which is a basis of fertility to new vegetation, peat-mosses are not in a condition to be actively useful till freed of superabundant moisture, and compounded with siliceous (sandy) materials. Where the subsoil, however, is composed of gravel or sand, it is necessary that the peat and these bodies should be mixed together, so as to form a soil. The first of these methods was planned by the late Lord Kames, and performed with distinguished success on his estate of Blair-Drummond, in the county of Perth. The first process performed by Lord Kames was to construct a ditch through the centre of the moss, through which a stream from the river Teith was directed. Branch ditches were cut in all directions from the main one, the water from which poured itself into the river Forth. The whole estate was divided into portions, and let to small occupiers of land, who received the most favourable terms from the proprietor, as an inducement to carry out his views. The peat earth was cut into small pieces, and cast into the running waters, by which they were carried into the Forth, and thence to the sea. After the moss was cleared away, the trees of the ancient forest appeared, and presented new difficulties to the workmen, which were only overcome with great labour and expense. The roots of these trees were firmly fixed in the earth, and the tanning process which they had undergone in the moss seemed to have added greater strength to their root-branches. They were completely eradicated, however; and in the year 1782, no fewer than 336 acres of ground were reclaimed and brought into cultivation. His son, who inherited his father's spirit of enterprise, pursued the same plan; and in ten years more, the population on the estate had increased to 764 persons, who cultivated 444 acres of land. In 1805, by survey, 577 acres were cleared; and in 1814, between 800 and 900 acres were under cultivation. Lately (1842), the whole has been cleared. Thus an extensive tract of country, which at one time was entirely useless, has been brought, by labour and perseverance, to bear rich crops; and the land is now worth from £3 to £5 per acre of annual rent. In this case the subsoil was good earth, and the operation necessary was the removal of the peat-moss, so that the subsoil might become the culturable surface soil.

Where the subsoil is gravel or sand, a very different operation must be performed; and this perhaps is the most common species of moss ground. Of whatever nature moss ground be, it is evident that, so long as the stagnant water remains, no useful crop can be cultivated; and to remove the superabundant moisture, by means of draining, must be the first operation of the improver. In some cases, where the moss is not too wet, a road may be run through the land, which will greatly facilitate the after-operations. Should such a road be cut, and a deep ditch on each side of it formed, the next operation is to open drains leading to some main channel, by which the water can be carried away. The moss land should be sounded in different places, to ascertain where the greatest depth lies; and when this is found, the main drain should be drawn as nearly in that tract as possible. Where there are beds of great depth, it does not appear expedient that the drain should be cut to the bottom at first; and indeed a difference of opinion exists as to whether moss land should be thoroughly drained at first, so as to render it perfectly dry. Mr Boroughs, the author of a treatise on waste land, is of opinion that the surface water only should be drained off at first; while Mr Blackadder of Stirling asserts that there is no danger of over-drying moss by draining. This may depend upon whether or not the moss be in a decomposed state. When moss is rendered too dry, it becomes a fibrous inert matter; and as is the case with all other lands, it will be easier to work afterwards when moderately moist. With regard to the size and form of drains, it was formerly the practice to make these wide and deep, and at about fifty yards apart. The lateral pressure of the water upon the sides of these drains, however, pressed them so much together, that in the course of years they were scarcely traceable. The depth of the main drain will depend in some measure upon the depth of the moss; and if the average depth of this be twelve feet, the drain may be seven or eight feet deep, and about the same width at the top. The sides should be made sloping, so that the bottom of the drain will not be above two or three feet wide; and this difference between the top and bottom will gradually diminish, in consequence of the lateral pressure. It may in some cases be necessary to perforate the main drain with holes, if any water appear to be coming up from below. The next operation is to form smaller drains leading into the main channel. Experience has shown that the most effectual way of draining deep moss is to insert drains at small distances from each other, and as deep as the nature of the moss will allow. They may be either of tile or stone, and guarded from choking by overlaying turf. Moss ground drained in this effectual way, will be, first, surrounded with the main drain which carries the water entirely away from the field; second, cut into divisions with open drains, at from forty to sixty yards apart, leading into the main drain; third, these divisions will be again divided into smaller portions by the covered drains at five yards' distance from each other.

In this manner the moss will be effectually relieved from its superabundant moisture, and the next operation is to level the surface with the spade. In cases of dry moss, of course the draining is needless, and may be omitted. The land being either naturally, or rendered artificially dry, should now be ploughed with a peculiar kind of plough, made of wood, and covered with sheet-iron, which can be freely used if the ground is free from rushes, heath, &c. If these plants be growing in profusion, however, it is thought better to burn them down to the surface before ploughing. After the ground is ploughed, some prefer rolling, and others burning, as the next operation. If a roller is used, it should be made of iron, with thin plates of iron six inches deep, five inches from each other, and placed at right angles to the cylinder. Repeated rollings from this will cut the sod fine enough to allow the mixing of it with sand or gravel. Instead of rolling, it has been found advantageous to burn the turf turned up, as a more effectual way of decomposing the roots of such plants as the cotton-grass, mat-grass, marsh, trefoil, &c. If the land is burned, it should be ploughed immediately after, preparatory to being mixed with other substances, The next step in the process is to cart sand or small gravel to the field, and spread it over the whole to the depth of three inches. Now plough all down, as the first regular dressing and culture. Thus prepared, the land is ready for cropping, and it is generally allowed that the best plan is to sow with grass seeds; the kinds recommended for this purpose are the timothy grass, cocksfoot-grass, and ribwort. Wheat, however, has been taken from newly-reclaimed moss land; and potatoes, if the moss is in the neighbourhood of cultivated ground, will be found a very valuable crop to be disposed of for seed. Italian rye-grass and rape have both been highly recommended for a virgin crop on bog land, to be followed by oats or barley.

One of the most remarkable experiments ever made in reclaiming peat land was performed some years ago in the neighbourhood of Edinburgh, and is mentioned at length in 'Jackson's Agriculture.' It was as follows:—'On the high and bleak grounds which lie on the boundaries of Mid-Lothian and Tweeddale, at the distance of twelve or thirteen miles south from Edinburgh, there existed, from time immemorial, an extensive tract of moss, which was dug for its fuel, and exhibited the appearance of precipices of peat rising from sour pools of water, the whole broken and disorderly, and of little or no value whatever for pasture. A portion of this dismal-looking land, which lies about 800 feet above the level of the sea, being purchased by Mr John Carstairs, a gentleman in Edinburgh, he commenced operations for reclaiming it. The purchase was made twenty-five years ago, at which time there was neither tree, house, nor road upon the whole moor; and a more hopeless attempt, to all appearance, than that of bringing such a tract of utterly waste land into cultivation could not well be conceived.

The first effort of Mr Carstairs was to gain access to the ground, by forming a road to it from the great road between Edinburgh and Dumfries. He extended the road at a great expense through the centre of the moss, and built a handsome suite of farm offices at the western extremity. The moss was then subdivided into fields of various sizes, by running stripes of plantation in squares, protected by ditches and turf dikes; and the fortunate formation of a new line of road between Edinburgh and Peebles, going through a corner of his property, gave energy to his exertions. Well-formed macadamised roads, made at his own expense, now intersect and cross each other all over the property, affording easy access to every part of it.

The extent of the land to be improved was from 500 to 600 acres; and this he partitioned into fields, protected by plantations and turf walls, as we have just described. The land was also effectually furrow-drained, and levelled on the surface by manual operations. The remainder of the process of reclamation consisted in the application of lime and sandy materials, and tillage. Year after year the land gradually assumed a better appearance, and yielded a better crop. At first, the oats which grew upon it were scanty in the extreme, but now the land is in heart, and yields good crops, and also excellent pasturage. To quote the words of Mr Carstairs himself upon the state of this moss when he got possession of it—"It was mostly composed of white foggy stuff, standing from two to twelve inches deep of water, and not worth sixpence an acre of rent, as it would carry neither man nor beast." In 1834, he commenced cutting sheep drains twelve inches wide and twelve inches deep across the whole moss, dividing it into regular riggs of from twelve to fourteen feet broad each, which has had the desired effect of drying the moss completely, the hollows being filled up with the sods taken from the drains. This drainage cost him £43, 11s. In the summer of 1836 and 1837, a great extent of it was top-dressed with earth and lime; and now it bears the horses and carts over its surface freely, although the moss is from ten to forty feet in depth.

The application of gravel and sand effects perhaps more improvement, in consolidating and decomposing the moss, than either lime or dung. This is shown to be the case from the circumstance, that moss land, when overflowed, is rendered fertile by the deposit of earthy matter from the water. In imitation of this operation, Mr Carstairs is in the habit, at every breaking up of the reclaimed moss land from pasturage, of giving a liberal application of clay, gravel, or sand. This he effects in an easy manner, by means of a portable railway. The application of the gravel, and the committing of the land to pasturage, or irrigated meadow, for a given number of years, have the effect of consolidating it so much, as in most cases to render it capable of being ploughed by horses; but when rather soft, broad wooden pattens are put upon their feet to prevent them from sinking.

By the means detailed, some very large fields of the moss ground have been so reduced in depth as to allow the subsoil, formed from the application of clay, gravel, &c. to be brought up by the plough, and incorporated with the moss. Complete furrow-drainage keeps the soil and subsoil always dry; and now this ground presents fields of as fine and as fertile vegetable loam as can be seen in the whole county, which nothing but their great elevation prevents from being equally valuable. The chick, the sorrel, the nettle, and other weeds, which usually infest moss land when first brought into cultivation, have entirely disappeared—a sure indication that in the above instance a complete melioration of the land has been effected.

When the depth of the moss is considerable, the under stratum, from being more decomposed and consolidated, is uniformly of a much better quality for agricultural purposes than that on or immediately below the surface. To get rid of this inferior soil, Mr Carstairs has frequently resorted to burning; and even in this operation the effects of lime and other earthy applications, some years previously put on, is singularly valuable. They not only make the moss burn more freely, and at a more uniform degree of depth, but the ashes are rendered highly valuable as a manure to the succeeding crops by being mixed with the lime. Thus by frequent applications of any earth or lime, but particularly clay, and occasional burning, the worthless moss soil becomes progressively reduced in depth, and fertilised.' One point in the process of burning requires especial attention—namely, that the moss do not burn unequally, thereby producing pits and hollows for the reception of water beneath the common drainage level. The safer mode is to collect the turf, &c. into heaps, which can be reduced to ashes without any risk, and then spread over the surface, along with the composts of clay and sand.

Mr Roscoe, in his extensive improvements on Chat Moss in Lancashire, used marl instead of gravel or sand. After the land had been burned and ploughed, the marl was laid on at the rate of 200 cubic yards to the acre. From the influence of the atmosphere, the marl soon crumbled down, and was spread over the land with as much exactness as possible. The moss and marl were then mixed together, either with the plough or scarifier, and a crop taken with or without manure, according to the nature of the plant sown. Mr Roscoe is of opinion that lime or marl are equally useful as an application to moss; and although he prefers the latter, he recommends the former as easier of carriage, when these substances are at a distance from the bog. He says, 'Both lime and marl are generally to be found within a reasonable distance, and the preference given to either of them will much depend upon the facility of obtaining it. The quantity of lime necessary for the purpose is so small in proportion to that of marl, that where the distance is great, and the carriage high, it is more advisable to make use of it; but where marl is upon the spot, or can be obtained at a reasonable expense, it appears to be preferable.' Sir Humphry Davy, on the other hand, holds that lime is the most useful dressing for moss. It neutralises the acids, dissolves the vegetable fibre, and converts the moss into friable mould. Lime, he says, slaked with salt water, has been found to be universally beneficial. Mr Aiton, in his Treatise on Moss, observes—' If lime or other calcareous substances are laid on the sward, though the land be neither laboured nor any seed sown, such are the effects of hot lime, that the moss plants will instantly disappear, and a rich and beautiful sward of clover, daisies, and the richest poa or meadow-grasses, will rise spontaneously.' The best application seems to be sand or gravel in the first instance, which will destroy the growth of the moss; and after this lime, to dissolve the vegetable matter.

The expense of draining and preparing moss land depends on many local circumstances. The usual cost is from £12 to £15 per acre; but much has been done at £7 or £8 per acre. The expense in either case is for the most part repaid in a very few years; and then good land, which may be let for £2 or £3 an acre per annum, may be said to have been absolutely conquered from the wilderness, and added to the available productive soil of the country.

DRAINING.

Draining is the operation of drawing off the water from over-wet lands, by open or covered channels, and thereby reducing the soil to that degree of dryness which renders it available for productive tillage. In some countries the ground is naturally so dry, and the climate possesses so little moisture, that instead of drainage, the land may require to be irrigated profusely with water at certain seasons of the year. The lands, generally speaking, of the British islands, are of a very different character. There are few parts of the country where drainage, from superabundant moisture, is not requisite; and therefore the operation of draining, in its most approved modes, should be thoroughly comprehended by every practical agriculturist.

The necessity for draining arises either from the water rising to the surface from springs beneath, or from the subsoil being of a retentive quality, by which water falling upon the surface, or absorbed in the upper stratum, cannot escape. According as either of these causes predominate, or are associated with each other, so must the process of drainage be regulated and conducted. All soils—those of a very sandy or gravelly nature in some situations excepted—are more or less liable to over-wetness, either from their own nature or the nature of the subsoil on which they rest. Clay, whether on the surface or beneath, is, from its adhesive nature, very retentive of moisture. A mixture of clay, sand, and sometimes iron, is also found very impervious; and even loams, although they absorb water freely, generally retain too much. Rich black loams usually lie on a clay subsoil, of different colours and textures, according to which the land will be in various degrees wet. The wetness in these loams is not so apparent as on other soils, but it is in every case as injurious, and as great a necessity exists for its removal. Land subject to springs is usually very varied in its surface, and may require a number of drains or conduits before water is effectually removed.

Many moist lands, though undrained, will produce crops of grain, and the crops will be the heavier the drier and finer the season; but taking these lands on a common average of seasons, it will be found that they often greatly fail in yielding even moderate crops, and that, at the very best, their crops are inferior in bulk and weight to those of grounds which have been subjected to a process of thorough drainage, and the kind of tillage consequent upon such an improvement. The outward mark of all undrained arable land is, that little or no grain grows in the furrows. The crop is seen to run along the centre of the ridges, dwarfing gradually off to the sides, where it disappears, thus leaving a large portion of every field with no crop at all. Wherever land is observed in this condition—and apparently the greater part of that in England is so—there is a want of drainage. The practice of making narrow heaped-up ridges, and deep furrows at their sides, is a proof of the land being badly drained. With a right method of drainage beneath, no portion of the surface is lost for cropping; the crop is at liberty to grow all over the field, and the furrow is little else than a slight indentation to mark off the divisions for the reapers in harvest.

Drains are of several kinds, according to the nature and situation of the land. Some drains are conduits built with stone, others are conduits filled entirely with loose stones, between which the water percolates and escapes, and others are constructed with tiles of a particular form. Of whatever description, main and tributary drains are required. We shall describe a main and a service drain in the language of one of the most experienced writers on the subject, Mr Smith of Deanston:—' The main drain should be directed along the bottom of the chief hollow or valley of the grounds, where the whole or greater portion of the drains can be led into it. If any lesser hollows occur in the field, they must also have their proportional mains or leaders. The bottom of the main drain should be at least three feet, and, if possible, three and a half or four feet under the surface where it passes along; and it should have throughout as uniform a fall or descent as the nature of the ground will admit.

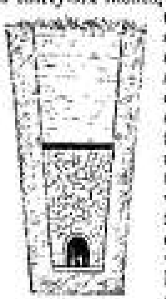
It should be flagged in the bottom, or where flagstones are expensive, built as an inverted arch, to prevent the possibility of washing away under the side building. The dimensions necessary will depend on the fall or declivity, and the area of land from which it has to receive water. With a fall in no place less than one foot in 100 yards, a drain ten inches wide and eighteen inches deep will void the rain water from 100 acres. It is of great importance to make the open area of such drains narrow and high, as smaller bottoms and covers will suit, and be less liable to give way; and the current of water being more confined, mud and sand will be less apt to settle in the bottom. (See Construction of SEWERS, No. 30.) Let the sides be smoothly and securely built with flat stones, either with or without mortar; and let strong flat covers be placed over, or where such are not to be found, rough simple arches may be built with thin stones and mortar, for the bottom and cover, packing the haunches of the arch well up to the sides of the cut. Where lesser hollows occur crossing the fields, it is necessary to cut submains along their bottoms, about three or three and a half feet deep, and having openings of suitable dimensions formed by inverted stone couples, or with drain tiles; or where a very large flow of water has to be provided for, with an inverted tile, and a covering tile placed above the bottom one, or with larger tiles made for the purpose.

There should be a cross submain at the bottom of every field or stretch of drains to receive the water from all the parallel drains; and such drain should always be cut six inches deeper than the drains running into it, that the water may have a free drop, which will prevent the lodgment of mud or sand at their junctions or mouths. Open cuts or ditches, either as mains or submains, should never, except from necessity, be adopted, being apt to get filled with mud and grass, by which water is thrown back into the drains, which often chokes them; besides, the loss of land, annoyance in ploughing, constant expense of cleaning, the propagation of weeds, danger to young cattle, and the like, are serious objections.

Having thus provided a main drain, with submains flowing into it, matters are prepared for setting off and executing the parallel frequent drains in the body of the field. The drains can be executed at any season, when the weather will permit; but the spring and summer are most suitable for the work. It is best to execute the drains when the field is in grass, as it can then be done in all weathers in a more cleanly and more expeditious manner.

In laying off the drains, the first object for consideration is the nature of the subsoil. If it consist of a stiff strong till, or a dead sandy clay, then the distance from drain to drain should not exceed from ten to fifteen feet; if a lighter and more porous subsoil, a distance of from eighteen to twenty-four feet will be close enough; and in very open subsoils, forty feet distance may be sufficient. When the ridges of the field have been formerly much raised, it suits very well to run a drain up every furrow, which saves some depth of cutting. The furrow being thereafter made over the drains, the hollow is filled up, and the general surface ultimately becomes level. When the field is again ridged, the drains may be kept in the crowns or middle of the ridges; but if it is intended to work the field, so as to alternate the crowns and furrows, then the ridges should be of a breadth equal to *double* the distance from drain to drain; and by setting off the furrows in the middle betwixt two drains, the crowns will be in a similar position; so that when the furrows take the place of the crowns, they will still be in the middle betwixt two drains, which will prevent the risk of surface water getting access to the drain from the water furrows by any direct opening.'

Small tributary drains, made with broken stones, and covered with turf, to prevent the earth from filling them up (called *rumble drains* in Scotland), are in most places falling into disuse, and are superseded by drains made with tiles. Tile-drains are peculiarly available over the greater part of England, where there is a scarcity of stone; and both there and elsewhere they will soon constitute the only kind of field-drainage in use. The tiles for these drains are made at most brick-fields, and are simple in construction. There is a flat for the bottom, and a semicircular tile to place upon it, with the concavity undermost. In hard-bottomed land, the sole is sometimes disused. The tiles measure from twelve to fourteen inches in length; and being placed neatly in a row, close to each other, a channel of four inches wide and six inches deep is formed; the water is admitted by the seams or interstices, so as readily to flow away. A little straw, stubble, or loose furze, is placed immediately over the upper tile, by which the chance of stoppage by the intrusion of earth is removed. The depth at which the tile-drain is laid is twenty-four or thirty-six inches, as above, which, being covered with



ten or twelve inches of gravel or stones, allows a sufficient depth of soil above for the operations of subsoil-ploughing. When the depth of the drain is three feet, and the soil a retentive clay, it is frequently filled up for about a foot with stones above the tile, and turf laid above the stones, the rest being made up with surface earth. The annexed figure represents a section of a tile-drain of the proper construction. It will be observed that the bent tile laid on a flat sole is advantageously placed for carrying off all the water that may trickle through the earth and stones above, and cannot be easily choked up with soil.

In cutting drains, three kinds of spades will be required—a common working spade, one a little narrower, and the third the breadth of the bottom of the drain. The cuttings should be done smoothly and neatly, preserving a descent throughout; and the tiles should not be laid till the cuttings have been carefully inspected. The terminations of the tile-drains may be led into subterranean mains, or into the shelving banks of open rivulets or sunk ditches; but in the latter case their mouths will probably require to be protected from the intrusion of vermin, or from external injury. In planning the lines of drains, the straightest side of the field should be selected, the first being laid off as parallel as possible, and the others formed at the distances thought necessary. In some places, from the extreme levelness of the land, or from obstructions in the subsoil, it will be found difficult to carry off moisture by drainage in the regular manner, and the leading of converging drains to a pit in a low part of the field will be the only course open for adoption.

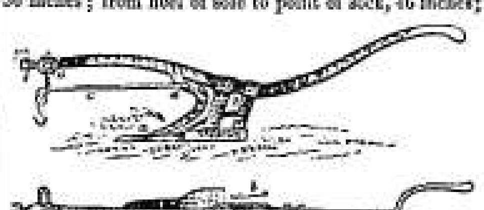
The drainage of sheep pastures is often not less necessary than land for tillage: it improves the grass, and, by drying the surface, renders the ground more salubrious—dry pasturage being indispensable for sheep. The mode of draining adopted for hilly sheep-walks is very simple: on the sides of hills, open drains a foot in depth, and from eighteen inches to two feet broad at the top, are cut, with a gentle slope towards a rivulet, into which they are to discharge themselves. They are made to slope in different directions, and thus form so many furrows, which draw off the trickling moisture of land springs, and superabundant rains.

SUBSOIL-PLOUGHING.

It has been seen, in treating of moss lands, that soils chiefly composed of inert vegetable matter, or peat, may be greatly improved by supplying a due proportion of sand or gravelly material, carted from a distance, or raised from the subsoil. The same thing may be said of all lands which have been deteriorated by repeated cropping. A time comes when the silica and other earthy bases are found to have been abstracted in the crops, and fresh materials must be added.

The process of earthy restoration may be accomplished by scattering new materials upon the fields; and this might be easily accomplished in many parts of the country, so far as silica or fine sand is concerned; but the readiest and cheapest process in most situations will consist in trenching the subsoil, and gradually assimilating it to the mould above. The subsoil, or that portion of the under stratum which lies out of reach of the ordinary plough, may already be so good as to be available for bringing towards the surface, and in such cases it admits of easy and profitable management; but in most instances in our country the subsoil is hard and stony, and will require to be trenched, and lie for a time in its underground position, before it is ready for admixture with the upper or culturable mould.

The most efficient instrument for trenching the subsoil on a large scale is the subsoil-plough, invented by Mr Smith of Deanston, whose account of it we here transcribe:—' In the design, two essential points were kept in view:—1. The construction of an instrument that would effectually open up the subsoil without throwing any of it to the surface, or mixing it with the active or surface soil; 2. To have an implement of the easiest possible draught for the horses, while it was of sufficient strength and weight to penetrate the firmest ground, and resist the shocks on the largest stones. The extreme length of the plough is about 15 feet. From the socket at the point of the beam to the first stile or upright, 6 feet; from thence to the back of second stile, 19 inches; from thence to the outer end of holding handles, 7 feet; from the sole to the bottom of beam at stiles, 19 inches; length of head or sole-bar, 30 inches; from heel of sole to point of sock, 46 inches;



broadest part of sock, 8 inches. The coulter is curved, and in order to prevent its point being driven from its place by stones, it is inserted to the depth of an inch in a socket (*a*). The lateral dimensions of the sole-piece are 2 inches square. This is covered on the bottom and land side with a cast-iron sole-piece, to prevent wear. The sock goes on the head in the usual way, and from its feather rises the spur-piece (*b*), for the purpose of breaking the subsoil furrow. When the subsoil consists of very firm clay, or other hard and compact earth, the feather and spur-piece may be dispensed with, and a plain wedge or spear-pointed sock, such as those of the old Scotch plough, may be used. The draft-bar (*c*), of 1¼ inch round iron, is attached to the beam at the strong eye (*d*), and passing through an eye in the upright needle (*e*), is adjustable to any height or lateral direction, being movable in the socket (*f*), at the point of the beam, and can be made fast at any point by a pinching-screw wrought by the lever (*g*). By the proper setting of the draught-rod, the direction of the power of the horses is so regulated as to render the guiding of the plough easy at any depth or width of furrow. The beam is about 5 inches deep in the middle, and 1¾ inch in thickness—towards the draught end it tapers to 3 inches deep, and 1 inch thick—at the holding end, where the handles branch off, it is 2 inches by 1. The whole weighs 440 lbs. imperial. This appears an enormous weight, and most people are alarmed at the strength and weight of the implement; but after repeated trials with lighter ploughs, those of the dimensions and weight now described have been found to be at once the most efficient, the most easy of draught, and the easiest for the ploughman to manage.'

When a field is to be trenched, a common plough, drawn by two horses, goes before, throwing out a large open furrow of the active soil. The subsoil-plough follows in the wake of the common plough, stirs up thoroughly and breaks the bottom, and the next furrow of active soil is thrown over it. This large subsoil-plough is a kind of *horse-pick*, breaking up without raising the under stratum to the surface. The atmospheric air being by this means freely admitted to the subsoil, the most sterile and obdurate till becomes gradually meliorated, and the common plough may ever after be wrought to a depth of from ten to twelve inches without obstruction. For this heavy ploughing most likely three horses yoked abreast will be required. The charge for subsoil-ploughing may be estimated at twenty-four to twenty shillings per statute acre, being one-fifth of what a similar depth with the spade would cost, and upon the whole, be as effectually done. The expense of subsoil-ploughing is no doubt considerable, but its advantages are incalculable. 'All who have ever studied or experienced the most common gardening, must be aware of the important advantages of deep working; and when it can be attained in the broad field of farming at so small a cost, they may easily believe that the whole will be more than doubly repaid in every succeeding crop, and abundantly even in pasture. When land has been thoroughly drained, deeply wrought, and well manured, the most unpromising sterile soil becomes a deep rich loam, rivalling in fertility the best natural land of the country, and from being fitted for raising only scanty crops of common oats, will bear good crops of from thirty-two to forty-eight bushels of wheat, thirty to forty bushels of beans, forty to sixty-six bushels of barley, and from forty-eight to seventy bushels of early oats per statute acre, besides potatoes, turnips, mangel-wurzel, and carrots, as green crops, and which all good agriculturists know are the abundant producers of the best manure.'

It would be easy to produce further evidence of the value of subsoil-ploughing for all the purposes to which we have adverted; but such testimony, we should think, can hardly be required. We conclude with the following valuable observations by the Marquis of Tweeddale:—'The system I have adopted for the treatment of the lands of my own farm, where the soil and subsoil are of the weakest, is as follows:—A great proportion of the land is valued at five or ten shillings per acre. After it is drained in grass, the land is trench-ploughed, making the furrow from fourteen to sixteen inches, the soil being turned into the bottom of the furrow. The ploughing is done by two ploughs, each having a pair of horses. As the work is harder upon the horses that turn up the till or clayey subsoil, they every hour change with the plough that turns over the sod. The till remains exposed to the frost during the winter; in the spring the land is cross-ploughed, the sod is found quite rotten, and mixes with the till. Oats are sown, and the crop is found considerably better than before the land was drained. After the crop is cut, the land is ridged up with a winter furrow, turnips being sown in spring. In ridging up the land for turnips, there is little or no appearance of till. The best crop of turnips to be found in the same district of the country is not superior to that grown after this management of the land. The land, after the turnips are eaten off by sheep, is ploughed for barley; there is an excellent crop, and the grass seeds are always well planted during the two years of grass that follow the barley, the fields having the earliest grass crop in the district. The largest number of sheep are fed on them, and are the fattest animals. The grass that formerly grew on these fields was of the worst quality, and sheep would scarcely eat it. No extra manure or lime has been applied to these fields, except on a part of one of them, which remained six years without growing anything an animal would eat, consequently it was left without stock. In the third year since it was in that state, it is grown as good a crop of turnips as can be seen in the country; and no stranger who saw the land in fallow would believe it to have been what the people of the country knew it to be previous to its improvement. It is evident that the only extra work in following out this system is trench-ploughing once; this, however, is done with the ordinary plough used for working the land, and the horses are never oppressed. It will be satisfactory to state that I have an equal dread with other farmers to bring till, before the land is drained, to the surface: it is only after that operation is effectually executed that I consider the till, when properly pulverised, forms a new soil the most valuable and easy to work of any I know.'

LIMING—TOP-DRESSING.

Lime is the most important mineral substance which is usually applied to land. It is found in the form of rocky material, in which condition it is in combination with carbonic acid gas. On being burnt, this gas is expelled, and it assumes the form of a whitish brittle mass called *quick-lime*, easily reducible to a powder by the application of water. On being exposed to the atmosphere in its soft powdery condition, it has a strong tendency to imbibe moisture from the air, and soon becomes as heavy as it was previous to burning. It also recombines with carbonic acid from the air.

The use of this artificially-prepared earth in agriculture is well known; but certain peculiarities in its action have never been satisfactorily ascertained. It possesses the power of decomposing animal and vegetable matter, and enters as an element into the fabric of plants; in certain cases it only alters the constitution of the soil, and in some instances its application would be positively injurious. Speaking of this remarkable fossil, Sir Humphry Davy observes—'When lime, whether freshly burned or slaked, is mixed with any moist fibrous vegetable matter, there is a strong action between the lime and the vegetable matter, and they form a kind of compost together, of which a part is usually soluble in water. By this kind of operation, lime renders matter which was before comparatively inert, nutritive; and as charcoal and oxygen abound in all vegetable matters, it becomes at the same time converted into a carbonate of lime. Mild lime, powdered limestone, marls, or chalks, have no action of this kind upon vegetable matter; by their action they prevent the too rapid decomposition of substances already dissolved, but they have no tendency to form soluble matters. It is obvious, from these circumstances, that the operation of quick-lime, and marl or chalk, depends upon principles altogether different. Quick-lime, on being applied to land, tends to bring any hard vegetable matter that it contains into a state of more rapid decomposition and solution, so as to render it a proper food for plants. Chalk and marl, or carbonate of lime, will only improve the texture of the soil, or its relation to absorption; it acts merely as one of its earthy ingredients. Quick-lime, when it becomes mild, operates in the same manner as chalk; but in the act of becoming mild, it prepares soluble out of insoluble matter. The solution of the question, whether quick-lime ought to be applied to a soil, depends upon the quantity of inert vegetable matters that it contains. The solution of the question, whether marl, mild lime, or powdered limestone, ought to be applied, depends upon the quantity of calcareous matter already in the soil. All soils are improved by mild lime, and ultimately by quick-lime, which do not effervesce with acids, and sands more than clays.'

Let us now proceed to the practical application of this valuable stimulant, commencing with its use in the reclaiming of waste lands. If moorish or waste soil is much infested with the tenacious roots of rushes, heaths, and other weeds which resist the mechanical action of the harrow, and yield slowly to putrefaction, the best mode is to till the ground, and allow it to lie in this state for twelve or eighteen months, or even two years, before applying the lime. It is then generally applied in autumn, and tilled in as soon as possible; but if not immediately tilled in, the soil with the lime on it should be harrowed, so that its decomposing effects may act as powerfully as possible upon the vegetable matter. After these operations, the land is sown two successive years with oats, without any fallowing; and along with the second crop of oats, some persons sow it out in grass seeds for pasture. Others, after the first or second crop of oats, give the land a summer fallow for one season, or a green crop with manure. On the following season another crop of oats is taken, along with which grass seeds are sown, and in this state it is committed to pasture. In some cases, after tillage, the soil is allowed to lie for one, two, or more years, according to its nature, after which it is reduced to a complete state of pulverisation by a well-wrought naked summer fallow. On the spring following it is limed, and the lime is well harrowed in along with grass seeds alone, and in the following season the land is committed to pasture. This, however, is a very expensive mode, and cannot be recommended to tenants whose lease is of a moderate length. It is decidedly the most enriching mode of laying down waste land with lime only for pasturage, as the energy which the lime communicates to the soil is not intermediately exhausted by grain crops.

It will now be observed that lime is a most important engine of improvement for waste lands; for it decomposes and brings into active use the inert vegetable matter, and also serves as an elementary earth for the growth of plants. For peat lands, after being drained, and generally all rough lands reclaimed from a state of nature, lime is invaluable, and equally so for either tillage or pasture. In connection with turnip husbandry, it has been the grand reclaimer in many parts of Scotland, and will effect similar ends in any district of country not possessing a sharp and active soil; in such places it is not required, and its application may do harm. Laid on merely as a top-dressing—that is, thinly powdered over the land—lime is found to have very extraordinary effects; producing a beautiful close sward of white clover, daisies, and nutritious meadow grasses, where formerly nothing but heath or the coarsest herbage prevailed.

From the result of experiments in many different situations, it seems satisfactorily proved that the proprietors of waste lands within reach of lime have themselves to blame for the grounds continuing in sterility. Their complete melioration, however, is not to be expected at once; but upon proper arrangements being entered into between the landlords and the tenants, a great proportion of the high pastoral grounds, now lying in a state of waste, might by these means be progressively improved.

It seems to be a general wish of farmers to use lime rather in tillage than by top-dressing, which is much to be regretted, as the lime, when used in tillage, conjoined with over-cropping, eventually exhausts the soil; whereas, by applying it in top-dressing, it will prove highly beneficial. Therefore, in a climate rising six hundred feet above the level of the sea, top-dressing is the most effectual way in which lime can be applied for improving barren pasture-grounds. The land is never in this way exhausted by any species of cropping; it is put in a state of being benefited by the dung of the animals grazing upon it; and by due attention being paid to keeping the land free from wetness, by draining, it will be progressively fertilised. In the application of lime, it is a rule which should invariably be attended to, always to give abundance, and in a newly-slaked condition, in order that it may have its full effect. If slaked a considerable length of time before it is applied, it does not act so powerfully either in reducing the natural herbage or neutralising the acids, as when applied in a hot powdery state. There are very thin moorish soils, however, where lime by itself will not improve the herbage, these requiring a nourishing before a stimulating manure; and on such lands a dressing of good earth will be found to have the same effects as lime has on a strong soil. Top-dressing with clay or sand may also be performed with advantage in mossy moorish tracts where lime cannot easily be obtained. These earthy materials have a wonderful effect in improving the pasturage; they entirely destroy the growth of moss plants; and if applied to the depth of an inch or so, will generate a sweet herbage, rendering the ground capable of being benefited by the droppings of the animals it supports.

IRRIGATION.

While some lands can be reclaimed only by draining, others, which are naturally dry, may be rendered equally serviceable by artificial water. *Irrigation*, as this process is termed, is of great antiquity, especially in tropical countries, and seems to have been practised from the earliest periods of their history. In Egypt, the periodic overflowings of the Nile rendered the sandy desert a land of plenty; and in ancient Persia, Ceylon, and the East generally, the superintendence of the dams and water-courses was one of the most important offices in the state. In Lombardy, the best irrigated country in Europe, it has converted a land of stagnant marshes into meadows of exuberant fertility; and in the arid region of Peru it would be impossible to reap a single average harvest without such an application. In our own country, irrigation has as yet been attempted upon a comparatively limited scale; but where experiments have been judiciously made, they have always been attended with success. Though generally applied to dry grounds, it may happen that lands naturally marshy are as much the better for irrigation as dry deserts; but in all such cases the lands must in the first place be drained. This leads to an explanation of the principle of irrigation.

When water lies in or upon the land, it stagnates, and produces a marsh, which is alike insalubrious and unproductive. The extensive Pontine marshes in the neighbourhood of Rome present a remarkable example of both these conditions. In order that water may not be injurious, it must be kept flowing, always running amongst and from the blades of herbage. Regarding the theory of irrigation, Sir Humphry Davy says, 'Water is absolutely essential to vegetation; and when land has been covered with water in the winter, or in the beginning of spring, the moisture, which has penetrated deep into the soil, and even the subsoil, becomes a sort of nourishment to the roots of plants in the summer, and prevents those bad effects which often happen in lands in their natural state, from a long continuance of dry weather. When the water used in irrigation has flowed over a calcareous country, it is generally found impregnated with carbonate of lime, and in this state it tends in many instances to ameliorate the soil. Common river water, also, generally contains a certain portion of organisable matter, which is much greater after rains than at other times, and which exists in the largest quantity when the stream rises in a cultivated country. Even in cases where the water used for flooding is pure, and free from animal and vegetable substances, it acts by causing the more equable diffusion of nutritive matter existing in the land; and in very cold seasons, it preserves the tender roots and leaves of the grass from being injured by frost. In general, those waters which breed the best fish are the best fitted for watering meadows; but most of the benefits of irrigation may be derived from any kind of water. It is, however, a general principle, that waters containing ferruginous impregnations, though possessed of fertilising effects when applied to a calcareous soil, are injurious to soils that do not effervesce with acids; and that calcareous waters, which are known by the earthy deposit they afford when boiled, are of most use on siliceous soils, or other soils containing no remarkable quantity of carbonate of lime.' Whatever be the actual properties communicated by the water, it is certain that the general effect of meadow irrigation is greatly to increase the quantity of natural herbage, and render it more sweet and nourishing for cattle.

In order to irrigate a field, there must be a difference of levels, the water being made to run in a main channel along the highest side, and thence sending small rills all over the lower parts of the ground. The principle of adjustment is by sluices. When the slope is considerable, the water requires to be sent diagonally across the field, and being catched in mains at intervals, is again distributed, if need be, in new directions. This is called catchwork irrigation, and on favourable situations may be executed so low sometimes as ten shillings an acre. The following observations on the subject occur in Stephens's Practical Irrigator and Drainer:—'In the formation of an irrigated meadow, there are two rules of the greatest weight: one is, that no part of the works be made on a dead level; and the other, that every drop of water be kept in constant motion; but to give exact directions for the formation, is beyond the ingenuity of man; for no two pieces of land are precisely alike, which renders it impossible for the irrigator to follow the same plan in one field that he has done in another. Each meadow, therefore, requires a different design, the construction to be varied according to the nature of the ground and the quality and quantity of water. Inclined planes are absolutely necessary for the purpose of irrigation; and the benefit of irrigation depends so much upon the good management and patient perseverance of those who have the superintendence of it, that I do not wonder it has so often proved unsuccessful. However simple the construction of a water meadow may appear to be on a superficial view, those who enter minutely into the detail will find it much more difficult than is commonly imagined. It is not an easy task to give an irregular surface the equal slope requisite for the overflowing of water. It is very necessary for the irrigator to have just ideas of levels; a knowledge of superficial forms will not be sufficient. Few people unacquainted with the art of irrigation, and the regularity of form which the adjustment of water requires, have any idea of the expense of modelling the surface of a field. Where land is very uneven, it is sometimes advisable to break it up with the plough, and take a crop of oats before the formation; by which means the land can be properly cleaned and pulverised before levelling it into form with the levelling plough and spade the following year—an operation which may be executed at half the expense of doing the whole with the spade and wheelbarrow. But there is one advantage by doing the whole work with spade and barrow, especially where the turf is strong, which is, that the water can be applied as soon as the beds are formed; but by breaking up, and taking a crop of oats, it will require two or three years after the grass seeds are sown before the water can be used, which some proprietors think too long to wait, therefore will rather be at an additional expense to have the turf lifted and laid down again; by so doing, the whole operations may be performed in one season. The grass seeds generally used for laying down land for water meadow are, vernal grass, crested dogstail, soft meadow grass, rough-stalked meadow grass, foxtail, fiorin grass (*Agrostis stolonifera*), which last is one of the prevailing grasses in all good meadows; and the best way of planting it is to cut the whole into short pieces, the same way as cutting straw into chaff, and sow it with other seeds. It is not always that these grasses give a good crop the first year; therefore, to obviate this evil, some perennial rye-grass seed should be sown along with the others, to produce a crop of hay before the watering commence.'

It must be understood that the irrigation of any meadow is not to be incessant. There are times when the water must be altogether turned off, and the ground left to dry; it is at these times that the herbage is to be cut and removed. In large meadows, it is customary to turn off the water from different parts at different times, by which a constant succession of crops is obtained. Speaking on this part of the management, the same authority observes:—'One of the greatest defects in the management of irrigated meadows in this country is the not paying proper attention to freeing the ground from subterraneous and stagnant water; for experience shows that, wherever there is too much moisture beneath the surface, or if the water lodges too long upon it, the crop will always be coarse and scanty. Another great error generally committed is, allowing the water to run too long at a time, without properly drying the ground. I know some instances in this neighbourhood where the ground is not attempted to be dried from the time the water is put on the meadows, in the autumn, till eight or ten days before the cutting of the hay; the consequence is, that the grass is of the coarsest quality, and the ground has become so very boggy, that the whole crop of grass is obliged to be carried by people to some other place to be made into hay. Another inconvenience arises from bad management, which, I am sorry to say, is too prevalent in this country—that is, permitting the grass to stand too long before cutting; the consequence is, coarse hay, badly made, and in many instances half rotten before being put into the stack; and, moreover, owing to the lateness of the season, the aftermath is entirely lost; so that the proprietor has not received half the value from his meadow which he might have received, if the hay had been made at the proper season.

The first operation of the irrigator is to adjust the water in the conductor, or if the meadow is in more parts than one, the water in each conductor must be first regulated; then he commences anew by regulating the stops in the first feeder; but should there not be sufficient water in the feeder, a little more must be let in, by making the aperture wider or deeper, till the water flows regularly over the sides from one end to the other; from the first he proceeds to the second feeder, and so on, until the water in all the feeders is adjusted. Let the beds of a water-meadow be ever so well formed, yet by some places sinking more than others, or by the ice raising the surface of the ground, although the water along the banks of the feeders have been ever so nicely adjusted, it often happens that there may be some places between the feeders and drains with too little water, when it will be advisable for the manager to make a third round, redressing inequalities of the surface, so as to give every spot an inch deep of water. Every part of the works being regulated, the water should be allowed to run through the whole of October, November, December, and January, from fifteen to twenty days at a time, without intermission. At the expiration of these periods, the ground should be made completely dry for five or six days, to give it air; for there are few species of grasses, which form the most nutritious part of the herbage of water meadows, that will long exist under an entire immersion of water. Moreover, if the frost should be severe, and the water begin to freeze, the watering must be discontinued, otherwise the whole surface will become one sheet of ice; and wherever the ice takes hold of the ground, it will undoubtedly draw it into heaps, which is very injurious to the plants. The object of this early preparation of the meadows is to take advantage of the autumnal floods, which bring along with them a variety of putrescent matter, which is found very enriching to land.' At the most convenient period of the year, the various channels will require to be cleaned out, and the sluices and works repaired.

It is not, however, dry pasture lands and meadows alone that may be improved by irrigation; even bogs and morasses may be totally altered in their constitution by the same process. After drainage, the vegetable soil of these morasses is loose and pulverulent, and wants consistency and the necessary admixture of other earths to render it fertile. If, therefore, such a drained moss lies in the vicinity of a river, whose waters can be allowed to overflow it at pleasure, the rich silt of these waters will not only give a temporary fertility, but in time add a new superstratum of the most productive soil. It is by this double process of adding new compounds, and facilitating the decay of the humus already existing, that moss-irrigation becomes so advantageous where there are facilities for its execution.

PROTECTION OF RIVER BANKS—WARPING.

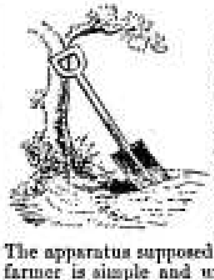
Much valuable land on the banks of rivers and rivulets is often laid waste by the encroachments of floods. A few words on this important subject seem to be necessary:—It may be laid down as a principle in natural science, that water is irresistible, and therefore it must not be resisted—it must be humoured. All windings in streams are caused by resistance. The water, in rushing onward, dashes against a projecting stone or hard part on one of its banks; this sends it in an opposite direction, and it strikes against whatever obstacle is presented. This process of interruption soon causes a mouldering of the banks in opposite directions, so that at length the water runs in a zig-zag or serpentine course. All this might have been avoided by allowing the water a perfectly free course.

The damage done to lands by flooding has led to numerous experiments for keeping the water in its channel, but seldom with any degree of success; because the attempts have been to hem in the current by sheer force. In all cases in which it is desirable to keep out tides or high floods from lands, the only secure method consists in giving the banks such a slope, that they will present no resistance whatever, but allow the water to rise and subside with equal ease and tranquillity. As a general truth, the greater the slope, the better; and it should never be less than a foot and a half for every foot in the height. Employ no stones or stakes, or anything else, for the current to catch upon; but cover the slopes with smooth turf, at a season which will allow of its growth before the floods set in. If any patches get broken, let them be annually mended. To keep out high floods, the banks must be made correspondingly high. Artificial embankments, in a flat country, should assume the form of a long mound, sloping gradually on both sides.

Notwithstanding the obvious utility of this simple and unexpensive mode of protecting river banks, instances of damage are constantly occurring from projects of an opposite kind. Mr Stephens mentions the following as one of many within his knowledge:—'An embankment was thrown round the small island Mugdrum, in the river Tay, to protect the land from being overflowed by the tide; but it was made so steep, that the first spring tides levelled the greater part of it to the ground. A second attempt was made, with the additional expense of a stone wall facing the water, which shared the same fate with the former bank. Since these failures, a third embankment has been erected with nothing but the natural soil of the land, and the whole covered with thin turf. The length of the present slope next the sea is five times the perpendicular height of the bank, and the inner slope three times; the water meeting no resistance, rolls down the long slope without doing any injury.' To prevent high tides and freshets from entering the cross drains and ditches, and thus flooding the reclaimed land, it is often found necessary to fit all water-courses passing through the embankments with sluices and self-acting valves; and where the new land is exceedingly flat and low, even steam-power is sometimes indispensable to carry off the stagnant waters. In every case, these expensive adjuncts must be regulated either by the immediate or prospective value of the newly-acquired ground. We refer to Mr Stephens's useful treatise (Blackwood, Edinburgh) for further information on this subject, as well as on irrigation and draining.

In connection with the protection of river banks, we may say a few words on the method of gaining land from rivers and tidal estuaries. This may be done if the river appears to straggle over an unnecessarily wide space, and brings down quantities of mud so as to produce impediments to navigation. The process usually followed with most advantage is that of *warping*, which consists in running out at intervals short rows of stakes, matted with twigs, calculated to catch the confluent particles of mud, but to allow the water to pass through. A sediment is thus gradually formed between the rows; in time, it rises above the water, and ultimately forms a green productive surface. When the water is affected by the tides, a row of loose stones laid between high and low water mark will similarly catch mud and sand, and while forming new land, will, by narrowing the channel, give greater impetus to the stream, and help to deepen its bed. When done on a great scale, the bed of the river is scooped by mechanism, and the rubbish brought up may afterwards assist in elevating the newly-formed banks. In point of justice to all parties, any of these processes of river-bank improvement should be done on both sides of the river at the same time; for if effected only on one side, the water may be driven to the opposite shore, to the serious damage of the land in that quarter.

SPADE HUSBANDRY.



The reclaiming and culture of small pieces of land by means of the spade and other instruments of manual labour, is usually spoken of under the name of spade husbandry; but is also sometimes called cottage-farming, or field-gardening—the operations of the culturist bearing an intimate resemblance to those applied in ordinary kinds of gardening. The apparatus supposed to be employed by the cottage farmer is simple and unexpensive. It consists of two or three spades of different sizes, a pickaxe, three-pronged digging-fork, hoes, rake, light harrow which he can draw, scythe, reaping-hooks, hay-forks, flail, wheelbarrow, &c. according to means. It is of great importance for the cottage farmer to be able to sharpen or mend his tools, and for this purpose he should have a grinding-stone and small forge, also some carpenters' tools. No horse or paid servant is kept. All the work is done by the manual labour of the farmer and his family. The only live stock is a cow or cows, pigs, and poultry. The homestead consists of a cottage with several apartments—a cow-house, pigsty, and barn. The size of the farm is supposed to vary from four to six or eight acres, and to be laid out in six or eight distinct field-plots, properly fenced.

Trenching.

The basis of cottage-farming is deep trenching with the spade; but before regular trenching can commence, the land, if in a rough state, must be cleared and drained. We have already shown how these preliminary operations are performed on a large scale, and they may very easily be modified for manual labour. Suppose the patch of land is part of a moss, dig open drains round it to draw off the water; scarify the surface with the spade, and burn the heaps of turf; scatter the ashes on the land along with any sandy material or lime which can be procured, and then delve all from one end to the other. This process will cause a large portion of the mossy fibre to decay, and the exposure to the atmosphere and draining will be found to meliorate the soil. In twelve months, the face of the land will be more like *earth* and less like peat than it was at the time of delving.

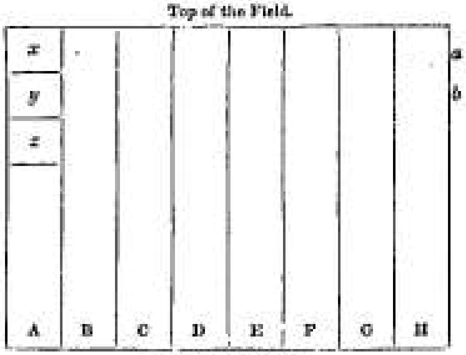
If the land be choked with stones or roots, all these incumbrances should be removed to the depth to which you design your trenching should go; and the sooner you get rid of them the better. The whole ground should be free of everything which can present the slightest impediment to the spade. Where sub-draining is required, the stones may be employed to lay in the drains. With respect to the first crops taken from the delved field, it will depend on the natural fertility of the ground and other circumstances. If the land be comparatively dry and fertile—as, for instance, the forest land of North America—a good meliorating and opening crop is potatoes; but in the case of poorer soils, manuring will be required, and the first crop may be grass. If the land can be conveniently partitioned into separate fields, a different crop may be taken from each, thus commencing a regular rotation. In proportion as the upper layer of earth is meliorated and exhausted, it will be necessary to go the deeper down. On large farms, certain fields are occasionally left fallow—that is, doing nothing, unless it be gathering what strength can be procured from the atmosphere. (See p. 488.) In cottage-farming, this practice must be unknown. Instead of trying to recruit the land by giving it a rest, you must recruit it by turning up the layer of mould immediately below that which has been affording nourishment to your crops. This stratum, which we shall call layer No. 2, extends from nine to eighteen inches below the surface, supposing you to have been employing a nine or ten-inch spade. It is, generally speaking, neither soil nor subsoil, but partakes of the qualities of both; and after two or three years' cropping, will be found to have imbibed a share of the manure delved in for the crops. The art, then, consists of raising up this layer No. 2, and turning down No. 1 in its stead. By doing so, perhaps manuring may be omitted for a year, and at anyrate a light manuring will suffice.

In some districts the depth of available soil may not be so much as eighteen inches, the layer beneath being rock or chalk, in which case the stirring of the soil cannot be carried deeper, unless at an immense cost of labour; but in the greater number of instances, the soil rests on a till of a hardish clayey substance, usually called subsoil; and this, which we may call layer No. 3, must be stirred and gradually brought up in aid of the upper soils. As mentioned under the head *Subsoil-Ploughing*, the proper method of nourishment consists of first stirring or breaking up the hard subsoil. Get down to it, and go over it with a pickaxe. Next year it may be incorporated with layer No. 2, and in two or three years the whole three layers may be indiscriminately mingled or made to change places. Such is the principle of trenching, by which three layers of soil are alternately, or at proper intervals, compelled to do duty; and thus a farm of six acres, by being, as it were, three storey deep, is practically as extensive as one of eighteen acres, but one storey deep. When we add, that while the plough leaves lumps of earth unbroken, and comparatively useless to the crop, the spade dashes and pulverises the whole soil, bringing all into effective play on the roots, the value of spade over plough husbandry will be at once apparent. Another important advantage of deep-trenching with the spade, is the turning down and destroying the larvæ of insects and seeds of weeds which may be about the surface; and it will be found that the first crops of trenched ground are always remarkably free of these nuisances.

The process of trenching to effect these important advantages is no doubt very toilsome; this, indeed, is a fact not to be concealed; but without almost constant labour, and labour in which a pleasure is taken, cottage-farming will generally come to nought; and he who is disinclined to undergo the trouble, should not commence the undertaking. To render the work as easy as possible, it should be strictly methodic, and bit by bit, and always the more the ground is tilled, the less difficult will the trenching be.

Trenching, either for gardening or farming, is usually performed as follows:—Mark off the field in strips of two feet in width, as in the annexed diagram. Commence at *x* and *y* at top of the field, and take from each

Top of the Field.



Bottom of the Field.

the top layer, which wheel across to *a* and *b*, beyond the top of the strip H. Then dig out the lower layer or subsoil from *x*, and wheel it away to a separate heap near where you have laid the top earth. The patch *x* being now empty, fill it two-thirds, first with layer No. 2, and next with layer No. 3 of *y*, and cover it with layer No. 1, or top earth of *z*. Thus go on wheeling and shifting till you come to the bottom of A. You now turn and trench upwards the strip B in the same manner; trench down C and up D, and so on till you have in every patch laid a layer No. 2 undermost, and a layer No. 3 above it. The overplus, wheeled aside, will fill up the strip H. You may vary the process in many different ways; and if you think proper, place layer No. 2 uppermost, and layer No. 1 in the centre; but all this must be left to your own ingenuity, and your ideas of what will be best on the occasion. As a further means of melioration, some trenchers stir the bottom of each strip when it is exposed with a pickaxe, which is a good plan; for the more the subsoil is loosened and prepared for being brought into activity, the more fertile will the fields be.

General Management.

Whether the land of a cottage-farmer be part of a reclaimed bog or waste, or a section of fertile soil, or whether it be his own property, or rented, he must necessarily exert unremitting industry not only in digging and trenching his small fields, but in all the ordinary routine of manuring, cropping, and in attending to the other affairs of his establishment. To procure manure in sufficient abundance, he must keep one or two cows and a pig, and into a pit adjoining the cowhouse all the solid refuse, including all that may be collected from the dwelling-house, must be removed. The urine from the cow-house should be collected in another pit, or in a barrel sunk in the ground, protected from the air. This will be found a most valuable liquid for throwing over the land, to excite a young growing crop. While on the subject of manures, it cannot be out of place to mention that most surprising results have been effected in agriculture and market-gardening by the use of night soil. In some foreign countries, where this is well understood, the night soil is carefully saved, and to destroy its offensive effluvia, is mixed with gypsum or earth; for a few shovelsful of earth thrown over it at once removes all offensiveness in this respect, besides being otherwise useful. So little thought and trouble have hitherto been taken in Britain to preserve this material for manure, that for the use of enterprising agriculturists, quantities are still imported from France in a dried and prepared condition.

There are other means of increasing the quantity of manure. From every piece of ground a quantity of rubbish may be collected—as withered leaves, stalks, clippings of branches, roots, &c. Improvident persons burn much of this refuse, but we strongly advise the cottager or gardener never to burn anything, except it be stumps of trees or pieces of branches as fuel. Collect all the inferior stuff into a heap, to which scrape or carry all the mire that can be gathered from the pathways, and the whole will make a compost dunghill; a pailful of cow urine thrown occasionally over the heap will be a valuable addition, and so likewise will be a shovelful of night soil. A little lime will hasten the rotting of any compost. If properly managed, in twelve months all will be rotted, and then begin taking from one end for manure. To the other extremity you may keep adding new matter that is collected. The treatment of the ordinary dung-pits is to be on the same plan. Do not remove the manure till it has lain a sufficient length of time to decompose, but keep taking from one that is ready while another is collecting.

If a rivulet can be made to run upon a meadow, as previously described under the head *Irrigation*, the cottager will add prodigiously to his stock of grain, fodder, and hay. From a single acre, well irrigated, as much as 200 stones of sweet nourishing hay may be gathered every year, besides a quantity of green stuff. The proper saving of this artificial meadow hay requires considerable tact; if anyway spoiled, the cattle will probably not touch it.

In the scheme of working a cottage farm, it should be an object to make the very most of every day out of doors, when the season and weather permit, and to occupy the dead of winter and days of bad weather at work in the barn or house. There is always some implement or gearing to make or mend; and where the cottager has willows and straw at command, field-baskets, beehives, and the like, might often be made either for his own use or for sale. The Swiss small farmers do much by working at some handicraft employment, particularly weaving and making toys, during those seasons when prevented from labouring out of doors; and in many instances they keep one member of the family at the loom. In short, none must be idle; the grown-up children, when not at school, being made useful as far as their capacities will admit of.

It is calculated that an active spadesman would find little difficulty in bringing half an acre annually into an improved state; for as eighty rods make the half acre, and there being 313 working days in the year, to accomplish this it would require little more than a quarter of a rod to be trenched daily, whereas a moderate day's work, even where the soil is stony and difficult to trench, would considerably exceed a rod. But where there is a boy or two to assist, an acre per year might with perfect ease be brought into an improved condition.

Whether it would be preferable to devote a cottage farm to a mixture of green and grain crops, as in ordinary husbandry, or make it chiefly a dairy farm, in which the raising of green crops for fodder is the principal if not the only object, must depend on local circumstances. If near a city where fresh dairy produce could be profitably disposed of, dairy-farming might be most suitable, although the large rents usually exacted near populous towns would prove an obstacle. Several experiments have been made in order to ascertain the quantity of produce in roots, artificial grasses, &c. that an acre of ground, under this sort of culture, could be made to yield; and the result has been, that even less than eighty rods, or half an acre, will produce food sufficient to maintain a cow. This calculation is founded upon the well-known fact, that 100 pounds weight of green food, a considerable portion of it roots, is a sufficient daily allowance for an ordinary cow. But cows kept upon such produce must not be allowed to pasture on those portions of the ground that are devoted to grass crops, such as clover, lucern, tares, &c.; but for the better health of the animals, they should have an open space to move about in adjoining the shed or out-building, where they find shelter from the storm and cold; for in soiling cattle during the hottest part of summer, an open shed, with a rack for their food, is to be preferred to shutting them up in close stables. Mr Allen, in his 'Colonies at Home,' very properly remarks—'Whenever it is possible to make a rod of ground produce 500 pounds of the artificial grasses, in the several cuttings during the season, I greatly prefer it to anything else, for cows thrive best upon grass and hay.' He afterwards observes, in reference to this sort of food—'As it sometimes suffers much in dry seasons, we must not depend entirely upon it; but I have proved that it is possible to keep a cow all the year round upon the produce of half an acre of land, if it be carefully cultivated.' He then proceeds to give a list of the produce he raised, which consists of lucern, cabbage, tares, mangel-wurzel, potatoes, turnips, parsnips, and carrots; and as a portion of hay is indispensable along with some of the root-crops during the winter season, he did not attempt to grow it, but sold a portion of his potatoes, and laid out the sum he received for them in hay. We need only add, that whatever number of cows be kept, they must be fed entirely within doors, and only suffered to go out in any small enclosure for the sake of air and exercise.

Plan of a Three-Acre Farm.

With the view of keeping up in the country a certain number of peasant families who should be able to assist farmers at particular seasons, the late Sir John Sinclair planned a system of cottage farms of three acres each; these were individually to be cultivated entirely by manual labour, and by the cottager and his family. From the account of the method of managing these cottage farms, which he has given in the second volume of the 'Farmers' Magazine,' we select the following particulars:—

'*Course of Crops.*—The three acres proposed to be cultivated should be divided into four portions, each consisting of three roods, under the subjoined system of management:—

	Roods.
Under potatoes, two roods; under turnips, one, -	3
Under winter tares, two roods; spring tares, one, -	3
Under barley, wheat, or oats, - - - - -	3
Under clover, with a mixture of rye-grass, -	3
Total, - -	12

Other articles besides these might be mentioned; but it seems to me of peculiar importance to restrict the attention of the cottager to as few objects of cultivation as possible. It is proposed that the produce of the two roods of potatoes shall go to the maintenance of the cottager and his family, and that the rood of turnips should be given to the cow in winter and during the spring, in addition to its other fare.

The second portion, sown with tares (the two roods of potatoes of the former year to be successively sown with winter tares, and the turnip rood with spring tares), might partly be cut green, for feeding the cow in summer and autumn; but if the season will permit, the whole ought to be made into hay for the winter and spring food, and three roods of clover cut green for summer food.

The third portion may be sown either with barley, wheat, or oats, according to the soil or climate, and the general custom of the country. The straw of any of these crops would be of essential service for littering the cow, but would be still more useful if cut into chaff for feeding it.

The fourth portion, appropriated to clover and rye-grass, to be cut green, which, with the assistance of the orchard, will produce, on three roods of land, as much food as will maintain a cow and her calf for five months—namely, from the end of May or beginning of June, when it may be first cut, to the 1st of November—besides some assistance to the pigs. It is supposed that an acre of clover and rye-grass, cut green, will produce 20,000 pounds weight of food for cattle. Three roods, therefore, ought to yield 15,000 pounds weight. A large cow requires 110 pounds weight of green food per day; a middling cow, such as a cottager is likely to purchase, not above 90 pounds; consequently, in five months, allowing 1320 pounds weight for the calf and the pigs, there will remain 13,680 pounds for the cow. Were there, however, even a small deficiency, it would be more than compensated by the rood of land proposed to be kept in perpetual pasture as an orchard.

Mode in which the Family may be Maintained.—It is calculated that three roods and eight perches of potatoes will maintain a family of six persons for about nine months in the year, but according to the preceding plan, it is proposed to have but two roods under that article; for however valuable potatoes are justly accounted, yet some change of food would be acceptable; and the cottager will be enabled, from the produce of the cow, and by the income derived from his own labour, and from that of his family, to purchase other wholesome articles of provision.

Manner in which the Stock may be kept.—It appears, from the preceding system of cropping, that ten roods of land, or two acres and a half, are appropriated to the raising of food for the cow in summer and winter, besides the pasture of the orchard; and unless the season should be extremely unfavourable, the produce will be found not only adequate to that purpose, but also to maintain the calf for some time, till it can be sold to advantage. It is indeed extremely material, under the proposed system, to make as much profit of the calves as possible, as the money thus raised will be a resource, enabling the cottager to replace his cow when a new one must be purchased.

For the winter provision of the cow, which is the most material, because the summer food can be more easily procured, there is the produce—1. Of about three roods of tares made into hay; 2. Of three roods of straw, deducting what may be necessary for litter; and if dry earth be put into the cow's hovel, and removed from time to time to the dunghill, little or no litter will be necessary; 3. Of one rood of turnips.

The whole will be sufficient for seven months in the year; namely, from the 1st November to the 1st June; and during the remaining five months, the pasture of the orchard, some of the winter tares, and the produce of three roods of clover and rye-grass, will not only suffice, but will furnish a surplus for the calf, if it is kept for any length of time, and some clover for the pigs. The inferior barley, potatoes, &c. will of course be given to the pigs and poultry.

Value of the Produce.—The land thus managed will certainly produce, by means of the extra industry of the family, and at a small expense, a most important addition to the income which the cottager may derive from his ordinary labour. For instance—

	Per Annum.		
1. The orchard, after the trees become fruitful, will probably yield, - -	£1	10	0
2. Three roods of turnips and potatoes, -	4	0	0
3. Eighteen bushels of barley at 4s., -	3	12	0
4. The cow and calf, - - - -	7	0	0
5. Hogs, - - - - - -	3	0	0
6. Poultry and eggs, - - - - -	2	0	0
Total, - - - -	£21	2	0

Where wheat can be raised instead of barley, the profit would be still more considerable. Opinions will differ much regarding the value put on each article; but that is of little consequence, as the total cannot be accounted too high.

Time required for Cultivating the Land.—The quantity of land intended to be cultivated will not materially interfere with the usual labour of the cottager. It will only require to be dug once, and is then fit to be cropped. It is proposed that only nine roods shall be annually cultivated (the remaining three roods being under clover and rye-grass), and nine roods may be dug in the space of about 558 hours, or at the rate of sixty-two hours per rood. This may be done at by-hours (more especially when the family of the cottager shall be somewhat advanced, and consequently more able to furnish assistance); but supposing that the digging, manuring, harvesting, &c. will require twenty entire days per annum, in addition to the by-hours, and allowing sixty days for Sundays and holidays, there will remain 285 days for the ordinary hand-labour of the cottager, which, at 1s. 6d. per day, would amount to £21, 7s. 6d.; the earnings of the wife and children may, at an average, be worth at least £4 per annum more. This is certainly a low calculation, considering how much may be got during the hay and corn harvests. But even at that moderate estimate the total income of the family will be as follows:—

1. Produce of the farm, - -	£21	2	0
2. Labour of the cottager, - -	21	7	6
3. Earnings of the family, - -	4	0	0
Total, - - -	£46	9	6

Rent and Balance of Income.—The rents of cottages and of land vary so much in different parts of the kingdom, that it is difficult to ascertain an average. But if the cottage shall be stated at £3 per annum, the land at 25s. per acre, and the orchard at 16s., the whole will not exceed £7, 13s. The cottager will also be liable to the payment of some taxes, say to the amount of £1, 5s. more. Hence the total deductions would be about £9, leaving a balance in favour of the cottager of £37, 9s. 6d. Considering the cheap rate at which he is furnished with a quantity of potatoes, equal to several months' consumption, and with milk for his children, surely with that balance he can find no difficulty not only in maintaining himself and family in a style of comfort, but also in placing out his children properly, and laying up a small annual surplus, that will render any parish assistance, either in sickness or old age, unnecessary.

Advantages.—The land possessed by the cottager would be completely cultivated, and rendered as productive as possible. The dung produced by the cow, pigs, &c. would be amply sufficient for the three roods under turnips and potatoes, which would afterwards produce—1. Tares; 2. Barley; and 3. Clover; with a mixture of rye-grass in regular succession, without any additional manure. The barley should yield at least eighteen bushels, besides three bushels for seed; and if wheat is cultivated, in the same proportion. The milk, deducting what may be necessary for the calf and for the cottager's family, might be sold in its original state, if there shall be a market for it; or converted into butter, for the purpose of supplying the neighbouring towns or villages. Such cottagers also might certainly send to market both eggs and poultry.

It is hardly possible to suggest a measure more likely to promote the benefit of a numerous and valuable body of people. The system of keeping cows by cottagers, which has been found so advantageous in the grazing districts, may thus be extended over the whole kingdom; and indeed, if the above plan is found to answer, in place of four or five acres employed in feeding a single cow, it would be much better, even in the grazing counties, to restrict the land to a smaller quantity, under a tillage mode of management.

It is of infinite consequence to establish the practicability of this system, as the means of removing a most unfortunate obstacle to the improvement of the country. It is well known to be the only popular objection to the enclosure of our wastes and commons, that, while unenclosed, a number of cottagers are enabled to keep cows by the means of their common rights, and that their cows disappear when the commons are enclosed. But if so small a portion of land as 3¼ acres, when improved and properly cultivated, can enable a cottager to keep a cow to more advantage than with a right of common, which can hardly be doubted, as he is enabled to provide winter as well as summer food, there is an end to that obstacle to improvement. Indeed, if sufficient attention be paid to the principles above detailed, the situation of the cottager, instead of being deteriorated, would be materially bettered by the enclosure; and his rising family would be early accustomed to habits of industry and order, instead of idleness and vice.

I shall conclude with asking if any one can figure to himself a more delightful spectacle than to see an industrious cottager, his busy wife, and healthy family, living in a comfortable house, rented by himself, cultivating his little territory with his own hands, and enjoying the profits arising from his own labour and industry! Or whether it is possible for a generous landholder to employ his property with more satisfaction, or in a manner more likely to promote not only his own but the public interest, than by endeavouring to increase the number of such cottagers, and encouraging by every means in his power the self-sustaining exertions of so meritorious and so important a class of the community.'

To the article comprehending the above account there is added an appendix, containing a letter from Sir Henry Vavasour, describing the field-gardening on his estate. We extract from it the following passages: —' I have for some years encouraged my cottagers in Yorkshire in this mode of managing their small garths or gardens, which are in general from one to three acres. I have now an opportunity of stating the husbandry of a poor industrious cottager's garth, whose land I visited almost every day during the last harvest. His stock was two cows and two pigs; one of his cows had a summer's gait for twenty weeks with his landlord. The land was partly ploughed and partly dug with the spade, cultivated (the ploughing excepted) by the man, his wife, and a girl of about twelve years of age, in their *spare* hours from their daily *hired* work, seldom a whole day off, except in harvest: made the rent in butter, besides a little used in the family. The man relates that he thinks he clears, one year with another, from the three acres, about £30. The daily wages his family earns nearly keep them. It is very evident that this man clears, from his three acres, more than a farmer can possibly lay by from more than eighty acres of land in the common husbandry of the country—paying for horses, servants, &c.; and it must be obvious to every one how great the advantages must be to society in cultivating land in this manner. It would have taken more than half the quantity of his three acres in pasture for one cow at grass during half the year; whereas (excepting the summer's gait for one of his cows, as mentioned before) his stock of two cows and two pigs is kept and carried on the whole year. The family lives well, and a handsome sum has been yearly saved, to place out two sons, and supply them with clothes, washing, &c.'

Spade Husbandry in Belgium.

As a picture of rural affairs under a well-conducted system of spade husbandry, we present the following from the report of Mr George Nicholls respecting Belgium, laid some years ago before parliament:—

'The extensive manufactures which at no very remote period flourished in Belgium, appear to have congregated a numerous population of artisans in and around the great towns. As the scene of manufacturing industry changed, this population was deprived of its means of handicraft employment, and was compelled to resort to the cultivation of the soil for subsistence. This seems to have been the chief, though possibly not the sole, origin of the system of the small farms which still prevails, and which are cultivated by the holder and his family, generally without other assistance. The farms in Belgium very rarely exceed 100 acres; the number containing fifty acres is not great; those of thirty and twenty acres are more numerous; but the number of holdings of from five to ten and twenty acres is very considerable, especially those of smaller extent; and to these I chiefly confined my inquiries.

The small farms of from five to ten acres, which abound in many parts of Belgium, closely resemble the small holdings in Ireland; but the small Irish cultivator exists in a state of miserable privation of the common comforts and conveniences of a civilised life, while the Belgian peasant-farmer enjoys a large portion of those comforts. The houses of the small cultivators in Belgium are generally substantially built, and in good repair: they have commonly a sleeping-room in the attic, and closets for beds connected with the lower apartment, which is convenient in size; a small cellarage for the dairy, and store for the grain, as well as an oven, and an outhouse for the potatoes, with a roomy cattle-stall, piggery, and poultry-loft. The house generally contains decent furniture; the bedding sufficient in quantity; and although the scrupulous cleanliness of the Dutch may not be everywhere observable, an air of comfort and propriety pervades the whole establishment. In the cow-house the cattle are supplied with straw for bedding; the dung and moisture are carefully collected in the tank; the ditches had been scoured to collect materials for manure; the dry leaves, potato-tops, &c. had been collected in a moist ditch to undergo the process of fermentation, and heaps of compost were in course of preparation. The premises were kept in neat and compact order, and a scrupulous attention to a most rigid economy was everywhere apparent. The family were decently clad, none of them were ragged or slovenly, even when their dress consisted of the coarsest material. The men universally wear the blouse, and wooden shoes are in common use by both sexes. The diet consists, to a large extent, of rye bread and milk; the dinner being usually composed of a mess of potatoes and onions, with the occasional addition of some pounded ham or slices of bacon. The quantity of brown wheaten bread consumed did not appear to be considerable. I need not point out the striking contrast of the mode of living here described with the state of the same class of persons in Ireland; and it appears important to investigate the causes of this difference.

In the greater part of the flat country of Belgium the soil is light and sandy, and easily worked; but its productive powers are certainly inferior to the general soil of Ireland, and the climate does not appear to be superior. To the soil and climate, therefore, the Belgian does not owe his superiority in comfort and position over the Irish cultivator. The difference is rather to be found in the system of cultivation pursued by the small farmers of Belgium, and in the habits of economy and forethought of the people. The cultivation of the small farms in Belgium differs from the Irish—1*st*, In the quantity of stall-fed stock which is kept, and by which a supply of manure is regularly secured; 2*d*, In the strict attention paid to the collecting of manure, which is most skilfully managed; 3*d*, By the adoption of a system of rotation of five, six, or seven successive crops, even on the smallest farms, which is in striking contrast with the plan of cropping and fallowing the land prevalent in Ireland.

In the farms of six acres, we found no plough, horse, or cart; the only agricultural implement, besides the spade, fork, and wheelbarrow, which we observed, was a light wooden harrow, which might be dragged by the hand. The farmer had no assistance besides that of his wife and children, excepting sometimes in harvest, when we found he occasionally obtained the assistance of a neighbour, or hired a labourer at a franc per day. The whole of the land is dug with the spade, and trenched very deep; but as the soil is light, the labour of digging is not great. The stock on the small farms which we examined, consisted of a couple of cows, a calf or two, one or two pigs, sometimes a goat or two, and some poultry. The cows are altogether stall-fed on straw, turnips, clover, rye, vetches, carrots, potatoes, and a kind of soup made by boiling up potatoes, peas, beans, bran, cut hay, &c. into one mess, and which, being given warm, is said to be very wholesome, and to promote the secretion of milk. In some districts the grains of the breweries and distilleries are used for the cattle; and the failure of the Belgian distilleries has been reckoned a calamity to the agriculture of the country, on account of the loss of the supply of manure which was produced by the cattle fed in the stalls of these establishments.

The success of the Belgian farmer depends mainly upon the number of cattle which he can maintain by the produce of his land, the general lightness of the soil rendering the constant application of manure absolutely necessary to the production of a crop. The attention of the cultivator is always, therefore, especially directed to obtain a supply of manure. Some small farmers, with this view, agree with a sheep-dealer to find stall-room and straw for his sheep, to attend to them, and to furnish fodder at the market price, on condition of retaining the dung. The small farmer collects in his stable, in a fosse lined with bricks, the dung and moisture of his cattle. He buys sufficient lime to mingle with the scourings of his ditches, and with the decayed leaves, potato-tops, &c. which he is careful to collect, in order to enrich his compost, which is dug over two or three times in the course of the winter. No portion of the farm is allowed to lie fallow, but it is divided into six or seven small plots, on each of which a system of rotation is adopted; and thus, with the aid of manure, the powers of the soil are maintained unexhausted, in a state of constant activity. The order of succession in the crops is various; but we observed on the six-acre farms which we visited, plots appropriated to potatoes, wheat, barley, clover (which had been sown with the preceding year's barley), flax, carrots, turnips or parsnips, vetches, and rye, for immediate use as green food for cattle. The flax grown is heckled and spun by the farmer's wife, chiefly during the winter; and we were told that three weeks' labour at the loom towards the spring enabled them to weave into cloth all the thread thus prepared. The weavers are generally a distinct class from the small farmers, though the labourers chiefly supported by the loom commonly occupied about an acre of land, sometimes more, their labour upon the land alternating with their work at the loom. In some districts, we were informed, every gradation in the extent of occupancy, from a quarter or half an acre to the six-acre farm, is to be found; and in such cases more work of course is done on the loom by the smaller occupiers.

The labour of the field, the management of the cattle, the preparation of manure, the regulating the rotation of crops, and the necessity of carrying a certain portion of the produce to market, call for the constant exercise of industry, skill, and foresight, among the Belgian peasant-farmers; and to these qualities they add a rigid economy, habitual sobriety, and a contented spirit, which finds its chief gratification beneath the domestic roof, from which the father of the family rarely wanders in search of excitement abroad. It was most gratifying to observe the comfort displayed in the whole economy of the households of these small cultivators, and the respectability in which they lived. As far as I could learn, there was no tendency to the subdivision of the small holdings. I heard of none under five acres held by the class of peasant-farmers; and six, seven, or eight acres is the most common size. The provident habits of these small farmers enables them to maintain a high standard of comfort, and is necessarily opposed to such subdivision. Their marriages are not contracted so early as in Ireland, and the consequent struggle for subsistence among their offspring does not exist. The proprietors of the soil retain the free and unrestricted disposal of their property, whether divided into smaller or larger holdings. The common rent of land is about twenty shillings an acre, and the usual rate of wages for a day labourer is a franc (or 10d.) a day.

A small occupier, whose farm we examined near Ghent, paid 225 francs per annum for about two *bonniers*, or six acres, of land, with a comfortable house, stabling, and other offices attached, all very good of their kind; this makes the rent (reckoning the franc at 10d.) equal to £9, 7s. 6d. sterling per annum; and if we allow £3, 7s. 6d. for the rent of the house, stabling, and other offices, there will be £6, or £1 per acre for the land, which accords with the information we obtained at Antwerp, Brussels, and other places, as to the rent of land in the flat country, the soil of which is generally of the same quality throughout. This farmer had a wife and five children, and appeared to live in much comfort. He owed little or nothing, he said; but he had no capital beyond that employed on his farm. We questioned him respecting his resources in case of sickness. He replied, that if he were ill, and if his illness were severe and of long duration, it would press heavily upon him, because it would interrupt the whole farm-work; and in order to provide for his family, and to pay the doctor, he feared he should be obliged to sell part of his stock. If his wife and family were long ill, and he retained his strength, the doctor would give him credit, and he should be able to pay him by degrees in the course of a year or two. The thought of applying for assistance in any quarter appeared never to have entered his mind. We suggested that the Bureau de Bienfaisance, or charitable individuals, might afford him aid in such a difficulty; but, with evident marks of surprise at the suggestion, he replied cheerfully that he must take care of himself. If a sick club or benefit society were established among these people, so as to enable them by mutual assurance to provide for the casualty of sickness, the chief source of suffering to their families would be obviated, and there would be little left to wish for or amend in their social condition.'

Comparative Value of Spade Husbandry.

It is, we believe, an indisputable fact, that a garden produces heavier crops, space for space, than a field under ordinary culture with the plough. 'In regard to difference of produce'—we quote the Code of Agriculture—'an experiment was tried in the neighbourhood of Hamilton, expressly to ascertain that point. A field was taken, which had been cropped with beans the preceding year, and the previous year with oats. Two ridges were dug, and two ploughed alternately, and the whole was sown on the same day. A part both of the ploughed and dug was drilled with the garden-hoe. The whole was reaped the same day, and being thrashed out, the result was, that the dug land sown broadcast, was to the ploughed sown broadcast as fifty-five bushels to forty-two; while the dug and drilled was as twenty and a quarter bushels to twelve and a quarter upon the ploughed and drilled. The additional grain produced was not the only beneficial result gained by digging; for in this instance there was also a great deal of straw, and the land was much more free of weeds, and more easily cultivated in the following year.'

Some soils, however, are unsuitable for spade husbandry; as, for instance, heavy wet lands liable to inundation; stony, gravelly, or shallow soils, more especially if incumbent on chalk. Manual labour is also inapplicable where the climate is precarious, and it is necessary to be expeditious in tilling the land, and in sowing and harrowing for a crop. On these accounts spade husbandry cannot be universally resorted to with advantage either to the culturist or the community. With respect to its economy, where it is available, there are two questions.

First, Whether the cottage farmer, with his six acres, can raise as much produce, and at as cheap a rate, as the capitalist can from any given six acres on his farm? If he cannot raise so much at so cheap a price, and cannot pay the same proportion of rent, cottage-farming is decidedly injurious to the community; but if he can compete on all these points, there can be no solid objection against the practice. From the foregoing evidence of Sir John Sinclair, and from what is known respecting spade husbandry in Belgium and some other continental states, it is placed beyond a doubt that more produce is raised for human subsistence—space, soil, and climate being equal—by small farmers using only manual labour, than by large farmers with horses and ploughs; and it is certain that the produce is always more accessible to the public than that of large farmers, who, by means of their capital, which is very frequently not their own, but borrowed from banks, can hold themselves indifferent respecting sales, till, by a fortunate contingency, the prices rise, and become highly remunerative.

Second, How far is spade husbandry available in the shape of paid labour to the capitalist farmer? We are unable to answer this question from our own experience, and therefore refer to a paper written by a competent authority on the subject. This is an essay by Mr Archibald Scott of Southfield, near Haddington, who obtained a prize of £100, which the Rev. C. Gardiner, a clergyman of the Church of England, had proposed to grant for the best plan of giving employment to the poor:—

'I am quite convinced,' proceeds Mr Scott, 'there is but one way of employing the surplus population of England and Ireland, and that is by a judicious introduction of spade husbandry.

To show that I am not a mere theorist, but a practical man, I may mention that I rent a farm from the Earl of Wemyss in East Lothian, consisting of 530 Scotch acres; that I have cultivated land to a considerable extent with the spade for the last three years, and that the result has exceeded my most sanguine expectations. In 1831, I determined to ascertain the difference of the expense and produce between trenching land with the spade and summer fallowing with the plough in the usual way; I therefore trenched thirteen acres of my summer fallow-break in the months of June and July; I found the soil about fourteen inches deep, and I turned it completely over, thereby putting up a clean and fresh soil in the room of the foul and exhausted mould, which I was careful to put at the bottom of the trench: this operation I found cost about £1, 10s. per Scotch acre, paying my labourers with 1s. 6d. per day. The rest of the field, which consisted of nine acres, I wrought with the plough in the usual way, giving it six furrows, with the suitable harrowing. I manured the field in August; the trenched got eight cart-loads per acre, the ploughed land sixteen; the field was sown in the middle of September. The whole turned out a bulky crop as to straw, particularly the trenched portion, which was very much lodged. On threshing them out, I found them to stand as under:—

By trenched wheat per acre, 52 bushels at 6s. 9d.,		£17 11 0
To two years' rent at £2, 10s. per acre,	£5 0 0	
Expense of trenching, - - -	4 10 0	
Seed, three bushels at 6s. 9d., - - -	1 0 3	
Eight cart-loads of manure at 4s., -	1 12 0	
Expense of cutting, threshing, and marketing, - - - - - - -	1 10 0	
Profit, - - -	3 18 9	
		£17 11 0

By ploughed wheat per acre, 42 bushels at 6s. 9d.,		£14 3 6
To two years' rent at £2, 10s. per acre,	£5 0 0	
Six furrows and harrowing at 10s., -	3 0 0	
Seed, three bushels at 6s. 9d., - - -	1 0 3	
Sixteen cart-loads of manure at 4s., - -	3 4 0	
Expense of cutting, threshing, and marketing, - - - - - - -	1 10 0	
Profit, - - -	0 9 3	
		£14 3 6
