I now saw, that though it might be difficult to trench over my fallow-break during the summer months, it was by no means making the most of the system, as the operation was not only more expensive, owing to the land being hard and dry during the summer, but that it was a useless waste of time to take a whole year to perform an operation that could be as well done in a few weeks, provided labourers could be had; and as in all agricultural operations losing time is losing money, as the rent must be paid whether the land is carrying a crop or not, so that in taking one year to fallow the land, and another to grow the crop, two years' rent must be charged against the crop, or at least there must be a rent charged against the rotation of crops for the year the land was fallow. As I felt satisfied that, by trenching with the spade, the land would derive all the advantages of a summer fallowing, and avoid all the disadvantages attending it, I determined on trenching thirty-four acres of my fallow-break immediately on the crop being removed from the ground, and had it sown with wheat by the middle of November 1832. I may here remark, that I did not apply any manure, as I thought the former crop was injured by being too bulky. As it is now threshed out and disposed of, the crop per acre stands as follows:—

By average of 34 bushels per acre at 7s.,		£15 8 0
To rent of land per acre, - -	£2 10 0	
Expense of trenching, - - -	4 0 0	
Seed, - - - - -	1 1 0	
Cutting, threshing, and marketing, -	1 10 0	
Profit, - - -	6 7 0	
		£15 8 0

The advantages of trenching over summer fallow are, in my opinion, very decided, as it is not only cheaper, but, as far as I can yet judge, much more effectual. I am so satisfied of this, not only from the experiments above noticed, but from the apparent condition of the land after it has carried the crop, that I have this autumn cultivated about a hundred acres with the spade, and the crops at present are very promising. When I first commenced, I was laughed at by my neighbours; but now, when they see me persevering in what they considered a very chimerical project, they are suspending their judgment, and several of them have made considerable experiments this year. I should think there are at least 250 acres under crop cultivated in this way this season in East Lothian; in 1831, the year I commenced, there was not a single acre. I have therefore the satisfaction of knowing that I have been the means of causing £1000 to be spent this year amongst the labouring classes in my immediate neighbourhood; and I feel confident, that should the season turn out favourable for the wheat crop, and fair prices obtained, their employers will be handsomely remunerated for their outlay. I do not say that this system will succeed in every description of soil, as it must necessarily be of some depth to admit of the operation; but there are few districts where such soil will not be found in sufficient abundance to give ample employment to the surplus population of the neighbourhood.

Now this is going on in a county where agricultural labourers *are better employed* than almost any other in Great Britain. The system was not introduced, nor is it persevered in, for the purpose of giving employment to the poor, but entirely for the benefit of the employer. The East Lothian Agricultural Society are now offering premiums for the most satisfactory reports on the subject. I last year received a medal from the Highland Society of Scotland for introducing the system; and what I value still more, I received a piece of plate from the labourers I employed, as a token of their gratitude. The system, I admit, is only in its infancy, but I have this year put it completely to the test; and should it succeed as well as it has done hitherto, it must take root and spread over the kingdom; and the landed interest in those districts of England where the poor-laws are so oppressive, and still more the Irish proprietors, will do well to investigate the system, and have it introduced with the least possible delay, that what is now a burden on their estates may become a source of wealth, and what is now a curse may become a blessing.

This system, if it succeed to my expectation, possesses all the requisites you require: it furnishes employment for the surplus population by substituting manual labour for that of horses—and certainly, if there is a lack of food for both, it is desirable that the one should give place to the other; it will make bread plenty, as the naked summer fallows of Great Britain will be covered with grain instead of lying waste for a season; it will render corn laws unnecessary, as we will be then independent of foreign supplies; farmers will be enriched who are enterprising and industrious, and they only deserve to be so; it will raise rents, by increasing the capabilities of the soil, enabling the farmer to cultivate wheat to double the present extent; it will raise up a home-market for our manufactures, as the paupers, who are at present starving, or living a burden on the parish, will find employment, and thereby be enabled to procure the necessaries and comforts of life; it will check the poor-laws, as there will then be none but the aged and the helpless dependent on parochial aid.'

We might add other testimonies in favour of spade husbandry, all less or more conclusive of its advantages in certain situations and under certain circumstances; but we forbear, leaving consideration of the subject to those who may be personally interested in its adoption. This, however, we may state generally—that on light loams which have been long under croppage, it will be highly advantageous to have the exhausted substratum occasionally turned up, and this cannot be done more effectually than by a spading of fourteen or sixteen inches; that on wet, turfy soils, it is frequently the only system of tillage which can be adopted to shear down the turf, and thoroughly to bury the herbage; that in the case of lands infested with small boulders, nothing save spade-trenching can be applied; and that in the neighbourhood of towns, where manual labour is abundant, it will be found most effectual for the rearing of all species of green cropping, or root-crops. It is true that in remote districts it can never be extensively followed, and its adoption is also rendered less necessary by the invention of the subsoil and trench ploughs; but for those having abundance of hands and capital at their command, and who have soils such as we have above described, or who wish to subsoil thoroughly, spade husbandry has advantages to recommend it over any other known mode of tillage. Without at all entering at length upon the merits of the Allotment System, it is clear that in the present state of agriculture the plough must continue to be the main implement of tillage; and we only, but strongly, recommend the spade where the requisite amount of labour can be easily procured, and where the soils require a thorough upturning and incorporation. The question of cost should scarcely enter into consideration, for a well-executed spade-tillage must be regarded more in the light of a permanent improvement than a temporary expedient. On this point our views are fully corroborated by the following observations of the Rev. Mr Hickey (Martin Doyle)—one of our ablest agricultural authorities:—' However gratifying to the benevolence of an individual farmer it may be to employ a vast number of men to dig his land in preference to the usual course of plough and horse-labour, he must consider that there is a limit beyond which he cannot multiply his labourers without occasional inconvenience and perplexity to himself, and without *unceasing superintendence*. Should any of the numerous causes which may occasion a change of occupiers on a given farm, or a change of *system* occur, what is to become of the numerous families collected by an individual who has largely introduced the practice of manual labour, and confined his operations to that system alone? What is to become of an excessive population of agricultural labourers, if their services be no longer required by the successor of the spade-husbandry farmer? If any one replies, "Oh, let the system be generally introduced, and there can be no danger of their want of employment somewhere," the answer is plain. If you substitute the spade for the plough to such an extent, you raise the price of labourers beyond what you can afford to pay, and you diminish the chances of success in your general farm operations, by giving up too much time to one department of labour. Time is money to a farmer; let him lose a week in a critical season, and the delay may be highly injurious to him in many respects. Promptitude and despatch are essential to his completion of farm labours at the proper times: without the aid which improved machinery affords him, it would be utterly impossible for him to get through his work in due course. Let him abandon the more rapidly-working plough, and take the tedious spade, and he will soon heartily regret his exchange. After what we have premised on this subject, it is almost superfluous to repeat, that if these latter remarks possess any accuracy at all, they are merely true in their application to *large* farmers, and not intended by any means to affect the subject as it is connected with the cotter or small farmer, who has rarely any capital but his labour, and "needs no other if he be suffered to use it freely and fairly." What is the limit, then, to the capital of his labour? What sized farm should he have that will make it the most productive? Why, the exact amount to which he can apply all his capital. Has he a family, he may then have more capital of labour to bestow by their assistance; consequently a larger allotment will be needed to employ all the capital of more extended labour. Is he single, then less will suffice.'

The only point that remains to be settled is one connected with political economy. It is alleged by the leading political economists of England that cottage-farming, while calculated to promote the growth of a population of paupers, is only distracting manual labour from its proper field of employment. If it could be shown that every able-bodied man could make five shillings a day by working as a weaver, at a factory, or any other branch of labour, the assertion would in part be correct; but such is not the case. There are countries in which remunerative employment cannot be permanently had, and in such situations—to which society in England seems advancing—the choice is in a great measure between spade husbandry and starvation, not between spade husbandry and well-paid employment. Besides, the political economist entirely overlooks the fact, that the cottage farmer derives immense advantages from the labour of his wife and children, not one of whom, most likely, would be able to earn a penny at any kind of labour in towns. It is by calling up these engines to assist him that he can outdo the large farmer with all his capital and machinery—a fact distinctly proved, at least as respects the keeping of cows and selling their produce; no joint-stock company of cowkeepers being able to compete with the miscellaneous and unmarketable labour of a humble dairyman and his family. As to the allegation that cottage-farming would cause a deterioration in society, it is also founded on narrow views. In some parts of the canton of Vaud, and elsewhere in Switzerland, where the farms are all small, and mostly wrought by their proprietors, there is no pauperism worthy of the name, no overplus population; and who would compare the orderliness of manners, the sobriety and thriftiness of the people, and the small amount of crime in that country, with the vice, intemperance, and poverty, for which England and Scotland, with all their large and splendid farms, are now becoming unhappily distinguished? It might be difficult to prove that large farms have been, in any material degree, the cause of the social evils now exciting so much attention; but it is clear that they have not prevented those evils. Without going so far as to say that cottage-farming would furnish a universal remedy, we think that, independently of its use in increasing the productive surface of the country, it would at least afford some relief, and add to that section of the population which is still in a healthful moral condition.

THE KITCHEN GARDEN.

THERE are various kinds of gardens—the Italian gardens, with their splendid terraces, vases, and statues; the old French gardens of Le Notre, of which we have a specimen at Versailles, with their long straight walks, clipt hedges, formal parterres, and fountains; English gardens, with their elegant blending of natural with artificial beauty; and so on. But it is to none of these princely kinds of gardens that we intend, in the present series, to direct attention. We propose to treat of the three departments which belong to the greater number of gardens of the middle and humbler classes; those, in short, which, designed on a moderate scale, are intended to afford the three staples of garden culture—*vegetables* for the kitchen, *flowers* to charm the eye, and the more easily attainable kinds of *fruit*. These various articles are for the greater part the production of one garden, a section or scattered part being set aside for each; but for the sake of clearness, we shall confine ourselves in the present sheet chiefly to the economy and products of the kitchen garden.

LAYING OUT OF GARDENS.

A garden of the ordinary mixed description usually extends from the eighth of an acre to a whole acre; but the more common size in country places is about half an acre. Whatever be the dimensions, the garden ought to be enclosed with a wall from ten to twelve feet high, and, if possible, be surrounded by a strip of cultured land, which should be fenced with a hedge and shrubbery, so as to remove the appearance of stiffness from the walled enclosure, and serve for other useful purposes. Besides a wicket or small door for ordinary entrance and exit, there should be a gate that will admit a cart, to take away produce or bring in manure. A much more important circumstance than size or an external appearance is exposure. In a flat country, the garden must of course be level; but if there be a choice as to situation, select by all means a spot which lies with an easy slope—an angle, for instance, of fifteen degrees—towards the sun at his meridian. In the British islands this will be facing the south. The next best exposure is towards the south-west, and after that the west. Avoid a northern or eastern exposure. An exposure towards the morning and mid-day sun, even though at a very small inclination, is as good as being many degrees farther south; hoar-frost on the grass and plants will be melted within an hour after sunrise; whereas if the garden lie in the smallest degree away from the sun, the hoar-frost will remain unchanged perhaps the whole day. Allow no house, wall, or trees, to interrupt the fair action of the morning sun on your garden; for the sun is the main agent in bringing vegetation to perfection, and if you be deprived of it, your operations will be blighted and retarded in every possible way. So important are the sun's rays, that, if your garden be small, rather have no wall on the south and west sides, but only a low fence, than submit to their exclusion. Some gardens are so disposed that they receive the sun in abundance in summer, but only partially the rest of the year. These gardens are imperfect. The garden should be visited all over by the sun daily, except perhaps in the heart of winter, when his rays have comparatively little effect. The exposure should also allow a free admission and currency of air; for this reason a garden is best away from dense old woods, and is most advantageously placed in an open sloping lawn, overlooked by, or near, the house of the proprietor.

The shape of a garden is of little consequence. It may be square, oblong, semicircular, or irregular, according to taste or local circumstances. In the greater number of instances, an oblong, as represented in the following figure, will be found most convenient. It is surrounded by a wall, in which is an entrance marked *e*. Within the wall is a border of several feet wide, and dotted round with flowers or flowering shrubs. Next is a gravel walk; and within is another border containing fruit bushes, or perhaps fruit-trees on espaliers, and in the centre is the body of the garden laid out in three plots, marked *a*, *b*, and *c*. Between these plots and around them are paths (represented by dotted lines) of twelve or fourteen inches in width, not for or-

dinary walking, but for admission to the various plots or sections into which the ground may be divided. These paths are only flattened by the foot or by the spade, and are to be delved up annually in the course of digging. At the opposite side of the garden from the door there may be supposed to be an arbour or summer-house, overhung with climbing plants and honeysuckle, and fitted up according to taste.

The regular walks in all moderately-sized gardens should not be wider than three feet; anything wider is a mere loss of ground. Much care is required to keep walks in order, for they are very liable to show crops of weeds and grass. The best remedy is to bottom the walks well with broken cinders or slag from furnaces; this effectually prevents worms coming up, and also stops the growth of weeds. Over a smooth bed of cinders put a layer of small gravel that will bind, or, failing this, a layer of brayed yellow ashes from a furnace, if they can be procured. Smooth all with the rake, and flatten with a roller. Such walks should be scuffled with the Dutch hoe, raked, and rolled down at least once a year. Many small flowering plants, such as daisies, Virginian stock, and thrift, are used for edgings to walks; but if not constantly attended to, they straggle over the borders. The most effectual and also the prettiest edging is dwarf box. It is easily planted in an even row, grows readily and regularly, requires little trouble in trimming—for it should not be always close shaved—and, summer and winter, is ever fresh and green.

No precise directions can be given respecting garden tools and apparatus; the following are the articles required in moderately-sized gardens of a mixed kind:—Spades of three sizes, a trowel for lifting flowers, Dutch and common hoes, a broad iron rake, a rake with short teeth for the walks, a small rake for flower borders, a strong claspknife for pruning, a pair of strong pruning shears, an axe, a hand-saw, a hammer and nails, a wheelbarrow, a wooden scuttle for carrying a little earth or manure, a roller, a pair of large compasses, a dibble and line, a watering-pot, and a ladder. Flower pots of different sizes, conical earthenware blanching pots, bell-hand glasses, and glazed frames of different sizes. These frames are among the most serviceable parts of a garden apparatus, and may be had either in one piece or with a movable top, as in the following figure. A neat small kind, framed in zinc, useful for protecting early seedlings or flowers, may be had in London for 1s. 6d. each. Other utensils employed by gardeners, such as forcing-pumps to wash wall trees, fumigating bellows, &c. need not be particularised. A person possessing only a small garden will shortly discover by experience what are the articles required in his operations. For gardens in which cucumbers and melons are to be grown, glazed frames and brick-built pits will be necessary. It is a great advantage for every garden to have a command of good fresh water for the purpose of irrigation, and also a small pond in which aquatic plants can be grown. If water is procured from a pump-well, it should be allowed to stand in the open air in a trough for at least a day before being poured on the plants. By this means it not only absorbs carbonic acid gas from, but gradually acquires the temperature of, the atmosphere.

A garden is in all cases laid out according to the taste or fancy of the proprietor; but there are certain general rules which all follow. The wall is reserved for fruit-trees. As fruit-trees require much air and sun, the borders must not be clogged up with bushes, peas, or any other tall vegetables. The borders should contain only small articles which are delved up yearly, because the soil at the roots of the trees requires occasional renewal and loosening, and these operations cannot be done if the ground is encumbered with permanent plants. If a row of gooseberry or other small fruit bushes be placed on the borders, they should be near the outside, and not less than ten feet apart. Let it be observed also that flowering plants should occupy the border most exposed to the sun, while those naturally loving the shade should be placed on the south and west borders, from which the sun's rays are generally less or more excluded.

The body of the garden within the walks is laid out in larger or smaller plots, according to taste. These plots are generally oblong, and are subdivided into sections, rows, or beds for the different kinds of kitchen vegetables. In the corner of one plot are the cucumber and melon pits, partially secluded by bushes. In different corners are plots, and round the edgings are the flower parterres, disposed to meet the eye, and to be easily accessible from the walks. In some gardens much of the ground is overshadowed by fruit-trees. This is seriously detrimental to the growth of the plants beneath, exhausts the soil, and prevents the proper flowering and fructification of every vegetable within reach. Permit no tree to overshadow your ground; the only allowable places for trees are the walls and narrow espaliers running up one side of the central plots. When a garden possesses the addition of an outside strip, enclosed by a hedge, the exterior sides of the walls may be lined with fruit-trees, and the ground laid out for potatoes and other common classes of vegetables; it will also afford the most proper site for compost dung-heaps, forcing-pits, and the like.

SOILS—COMPOSTS—TRENCHING.

The soil of a garden should be deep, rich, and easily penetrable. Whatever it may have been originally, the soil admits of vast improvement, and no trouble can be considered too great to bring it into a good condition. If shallow, trench it according to the plan mentioned in the previous sheet on Spade Husbandry, so as to loosen the subsoil, and gradually bring it into operation above. In many instances the soil is too stiff or clayey. Such a soil may not be unfit for plough husbandry, but it is out of place in a garden. The method of loosening and meliorating a clayey soil is to give it a large volume of sand and vegetable manure, which may be delved in at the winter digging, and at the spring digging the new and old materials will be well mixed. In general, far too little attention is paid to adding sand as a restorative; such is absolutely necessary in all soils but those of a very sandy nature, because every crop actually carries away a certain proportion of the silica lodged in the soil. If the soil be already too sandy, it may be assisted by clay, silt from ditches, vegetable earth, &c. Whatever be the nature of the soil, it should be thoroughly pulverised. Lumps thrown up by digging at the commencement of winter are meliorated by the frost, and have imbibed nutritious gases from the atmosphere. In spring, all should be well delved, cutting and breaking every spadeful as it is turned down, and leaving no hard part impervious to the tender roots of the vegetables. A garden should not contain a single stone the size of a boy's marble. Every particle of soil should be capable of doing duty in feeding the plants. It will save much future trouble in lifting stones by the hand, if every spadeful of mould were at first put through a sieve. Persons owning small gardens ought to pay particular attention to this. A working man having only a small patch for his amusement at leisure hours and on holidays, could not do anything more serviceable than trench his ground bit by bit, and riddle it carefully as he proceeds.

No garden can be conducted with the least advantage without giving it a regular manuring. If you hunger a garden, it will hunger you in return. In connection with every rightly-managed garden, there must either be a compost heap, in which dung is preparing for use, or there must be some means of readily purchasing old manure when it is required. The manures employed are the same as in agriculture (see p. 490); but being required for a more delicate purpose, they must in general be well rotted, and ready to unite with the soil. A compost dung-heap is prepared by putting alternate layers of stable dung, or night-soil, &c. with earth, peat moss, decayed leaves, and general refuse of vegetation, turning the whole occasionally till the mass appears to be sufficiently decomposed for use. A small quantity of this stuff will often be required to place at the roots of plants.

The practice of professional gardeners as respects composts may be learned from the following brief notice in the 'Encyclopædia of Gardening':—'Composts for particular plants may be reduced to light sandy loam from old pastures; strong loam, approaching nearly to brick earth, from the same source; peat earth from the surface of heaths or commons; bog earth from bogs or morasses; vegetable earth from decayed leaves, stalks, cow-dung, &c.; sand, either sea-sand, drift-sand, or powdered stone, so as to be free as possible from iron; lime rubbish; and lastly, common garden earth. There are no known plants that will not grow or thrive in one or other of these earths, alone, or mixed with some other earth, or with rotten dung, or leaves. Nurserymen, whose practice may be considered a safe criterion to judge from, have seldom more than three sorts of earth: loam, approaching to the qualities of brick earth; peat or bog earth from heaths or morasses; and the common soil of their nursery. With these, and the addition of a little sand for striking plants, some sifted lime-rubbish for succulents, and some well-rotted cow-dung for bulbs and some sort of trees, they contrive to grow thousands of different species in as great perfection (taking the difference between plants in pots and plants in the free soil and air) as in their native countries; and many, as the pine, vine, camellia, rose, &c. in a superior manner.' The same author afterwards observes: 'Peat earth, or heath earth, being generally procured in the state of turfs full of the roots and tops of heath, requires two or three years to rot; but after it has lain one year, it may be sifted, and what passes through a small sieve will be found fit for use. Some nurserymen use both these loams and peats as soon as procured, and find them answer perfectly for most plants; but for delicate flowers, and especially bulbs, and all florists' flowers, and for all composts into the composition of which manures enter, not less than one year ought to be allowed for decomposition, and what is technically called sweetening. French gardeners allow for orange-tree composts from three to six years.'

Near large towns, where there is a constant demand for kitchen vegetables, market gardens are established for producing the required articles in variety and abundance. The finest market gardens in the world are near London, where the soil is deep, and any quantity of manure, in the form of night-soil, from the metropolis, is easily obtainable. The plan on which these gardens are conducted might serve as a model for all kitchen gardeners in this country. It is thus briefly described in the article *Gardening* in the 'Penny Cyclopædia':—'The gardeners' year properly begins in autumn, when the land is dug, or rather trenched, and well manured. Various vegetables, which will be required in winter, are now sown, and especially those which are to produce plants to be set out in spring: spinach, onions, radishes, and winter salads are sown, and when the weather is severe, are protected by a slight covering of straw or mats. In February, the cauliflowers, which have been raised in frames or under hand-glasses, are planted out. The cabbage plants are pricked out. The radishes, onions, and salads go to market as soon as they are of sufficient size, and sugar-loaf cabbages succeed them. As the cauliflowers are taken off, they are succeeded by endive and celery, and the same is the case with the cabbages. Thus there is a constant succession of vegetables, without one moment's respite to the ground, which, in consequence of continual stirring and manuring, maintains its productive power. Deep trenching in some degree prevents that peculiar deterioration of the soil which would be the consequence of the frequent repetition of similar plants. This effect is most perceptible when the plants perfect their seed, which is seldom or never allowed to take place in market gardens; but great attention is paid to the species of plants which succeed each other on the same spot. The principle which experience and theory unite in establishing, is that of avoiding the too frequent recurrence of plants which belong to the same natural families. The greater variety cultivated in gardens, in comparison with the common produce on a farm, enables this principle to be fully acted upon. Those gardeners who overlook this, and repeatedly sow or plant the same kind of vegetables in the same spots, are soon aware of their error by the diminution of the produce, both in quantity and quality, and by various diseases which attack the plants, however abundant may be the food supplied to them, or however careful the tillage.

The principle on which the gardens are cultivated is that of forcing vegetation by means of an abundant supply of dung, constant tillage, and occasional watering. The whole surface is converted into a species of hotbed; and crop succeeds crop with a rapidity which is truly astonishing. Those vegetables which arrive at a marketable state in the least time are always the most profitable, and those also for which there is a constant demand at all times of the year. With an abundant supply of manure, the market gardeners have no fear of exhausting the soil; and dissimilar vegetables may grow together on the same ground.

The value of the produce in one year from an acre of garden ground in the most favourable situation, as stated by Mr Middleton, from the account which he received from a market gardener, is almost incredible. It is as follows:—Radishes, £10; cauliflower, £60; cabbages, £30; celery (first crop), £50; (second crop), £40; endive, £30: making a total of £220 for the gross produce of an acre in twelve months. The expenses of cultivation are no doubt great. In inferior situations, the produce is much less, but the expenses are also somewhat less. When it is considered that there are nearly 2000 acres thus cultivated, the gross amount of produce must be very great.'

The domestic gardener will now perceive, that independently of a good soil, he must give his ground plenty of rich manure, and by so doing he need scarcely ever have any part of the surface unoccupied. To attain and keep up fertility is the grand principle of his operations: the delving may be awkward, the lines of beds uneven, the raking may not be neat, but all is of no importance in comparison with keeping the ground in good heart. Although the most available manure be that from the common dung-pit, the kitchen gardener should thoroughly acquaint himself with the peculiar properties of the specific manures—guano, bone dust, phosphate of lime, nitrate of soda, ammoniacal water, and the like—which are now in extensive use and reputation. Many of these act specifically on certain kinds of plants, supplying to their constitution some principle of growth not to be found in the soil, and but sparingly, or not at all, in the ordinary dung-heap. All this he should learn either by direct experiment or from the experience of others. He should likewise maintain a regular connective rotation, leaving no cropping to caprice at the time, or to a system of unintelligent routine.

GENERAL OPERATIONS.

Digging or delving with the spade is the principal means of garden culture. The spade usually employed is ten inches deep in the blade or spit; but as delving is not direct downwards, but sloped, the depth to which the spade goes in digging is seldom more than nine and often not more than eight inches. In commencing to dig a piece of ground, take out a spadeful all along one side, and carry it to the opposite side where you are to leave off. Now begin at one end of the trench just opened; thrust the spade with the foot into the ground, taking about five inches in breadth, lift it up, and turn it over into the open trench, the top undermost, and the fresh earth above. Do the same with the second spadeful, and so on with all the others to the end of the line. Take care to dig always a uniform depth and breadth, so as to keep the line even, and the trench or open furrow one width. If there be any weeds or loose refuse on the surface, put them in the trench, and cover them in—avoiding to bury weeds which have ripened, the seeds of which are sure to be a cause of future annoyance. All such refuse ought to be well rotted in the dung-pit, or, what is better, reduced to ashes, and then spread over the soil. Break or pulverise the mould as you proceed, and keep the fresh surface level. When you have delved row after row to the last, the earth laid aside will fill up the concluding trench. Ordinary digging is performed best in dry weather; but digging to throw up lumps for winter melioration should, if possible, be performed when the soil is somewhat moist. In this kind of digging do not touch the lumps with the spade after throwing them up; for the more rugged and uneven the surface, the more thorough is the exposure to the influence of the frost.

Raking is usually performed after delving. Hold the handle of the rake at an angle of forty-five degrees, and draw it lightly over the surface of the newly-dug ground. The object is not to draw earth along, but to smooth or comb down the irregular surface, and to bring away any loose refuse or stones. Like digging, it should be performed in dry weather.

Marking with the Line.—When there is any difficulty in delving in a straight line by the eye, mark off the ground with a cord, drawn from a reel stuck in the earth at one end to a dibble or pin at the other. This reel cord will be indispensable in marking off the edges of parterres, plots, &c. In such cases, having fixed the line, go along it with the spade, taking out a very small quantity of earth immediately beneath the cord. Then do the same with the opposite side and ends of the plot, and so its dimensions will be fairly marked. The gardener measures and marks off all his figures in the ground with his line and spade. With the line he can draw a circle round a central pin, or make an oval from a union of two circles, or form semicircles, spirals, triangular spaces, or polygons. When he wishes to make a small path between rectangular plots, he sets his line accordingly, and walking along it, with a foot on each side, he tramples down the earth from one end to the other, and then he can smooth it and beat it down with his spade.

Hoeing.—With a common hoe, the earth is cut and drawn towards the operator. The object of hoeing is to draw the earth up the stalks of plants growing in a row, or to destroy weeds. In hoeing weeds, cut off the weed beneath the surface, and do not cover the stalk. If convenient, rake away all the loose stalks, and place them on the dung-heap. Weeds, such as dandelion and groundsel, which become winged when ripe, should be hoed and removed before seeding. As many such weeds which infest gardens are blown into them from adjacent roadsides, it would not be misspent time to clear the neighbourhood periodically.

Animal Annoyances.—All gardens are less or more exposed to the destructive inroads of wild animals. Hares and rabbits gnaw the bark off the stems or lower branches of trees, and also the buds in season. To prevent the encroachments of these quadrupeds, the garden ought to be properly fenced; but if they get in notwithstanding, the trees may be saved by smearing the lower parts with a mixture of cow-dung, soot, and water, reduced to the consistency of thin paint; a smearing of tar will also answer the purpose. Moles, rats, and mice may be caught by trapping; moles also may be got rid of by placing slices of garlic, or onion, in a green state, within their holes, as they have a great antipathy to the odour of these vegetables.

Birds are sometimes an annoyance, particularly when new-sown peas or seeds may be easily scratched up. But though in some instances injurious, it is believed that on the whole their visits are beneficial; for they pick up large quantities of slugs, insects, larvæ, or caterpillars of different kinds. Wall-fruit may be preserved by nets, or by the more simple method of fixing horizontal lines of black worsted in front of the trees; the repeated ineffectual attempts to alight on these lines is said to scare the animals, and cause them to desist. Lines of threads, in which feathers are fastened, are employed in many cases to protect beds of seeds from birds; this preventive can be easily tried.

Insects are the grand pest of gardeners; their appearance is so mysterious, and their devastations so varied, that all schemes to extirpate them are often ineffectual. They are most destructive in their first condition of larvæ or caterpillars. In this state they should be removed by the hand from kitchen vegetables. To destroy the smaller kinds of larvæ, fumigation of tobacco smoke, by means of a fumigating bellows, may be employed with advantage; and the plants may be cleansed with a syringe and water. For the cleansing of fruit-trees from insects, we refer to our article on FRUIT GARDENING, No. 35.

Slugs are another chief annoyance, especially in low-lying situations. A little salt destroys them; but, as in the case of caterpillars, the best plan is to clear them out at their first appearance by the hand. Worms in the ground are not considered injurious; in a properly-trenched garden, however, they exist only in small numbers. Salt kills them.

Sowing.—The greater number of garden vegetables are reared from seeds, which are sown at certain seasons in the ground. Some seeds, such as peas, are sown in drills, the hand deliberately dropping them in a straight shallow trench. Other seeds, such as those of onions, leeks, cress, &c. are sown broadcast, which is a thin and equable scattering over a bed prepared for the purpose. There is no necessity for any species of sowing machine in a common kitchen garden. Most seeds, peas included, require to be pressed down by treading or gentle rolling, and then covered up by the hoe or rake. All seeds should, if possible, be sown and covered up in dry weather.

Planting.—Many vegetables require to be removed while young from the bed in which they were grown from seeds, and planted out in rows. A straight row is made with the line, which is gently treaded on each side. Commence now at one end of the trodden line, and in the central or untrod part pierce the earth with the dibble. Into the hole so made insert the root of the plant, and pierce the earth at its side, so as to press the mould round the root, leaving no vacant space below. The common error in planting is injuring the tap-root and rootlets by careless pulling the young plant from the nursery, by rudely using the dibble, or by pressing the earth too firmly round the collar, and neglecting to do so with the roots. If a plant is carefully transplanted in damp weather, it should never show any symptoms of the change.

Watering.—In dry seasons, artificial irrigation is of great use for giving due liquid aliment to plants, and is indispensable to those newly transplanted, in order to consolidate the roots. Watering, for whatever purpose, is most advantageously performed in the morning or evening. If done during the time the sun is shining, take care not to water the leaves of any plant, for the heat will raise the temperature of the liquid, and the leaves will be scalded. If the day be cloudy and cool, watering the tops of plants can do no harm. The watering, in any case, should resemble as nearly as possible a soft shower, and be performed with a rose watering-pot. The greater number of flowers are injured by watering, if the water touches their petals.

KITCHEN VEGETABLES.

The vegetables usually grown in kitchen gardens belong to various natural classes, which, for convenience, we shall arrange in the following groups:—1. The cabbage kind of vegetables; 2. The pea and bean kind; 3. The root kinds, or those grown only for the sake of their roots and tubers; 4. The onion and leek kinds; 5. The salad kind; 6. The various kinds of sweet herbs; and 7. Miscellaneous kinds, including several of a delicate nature. This grouping, it will be understood, has no reference to botanical arrangement, and has only been adopted in preference to the confusion of common alphabetic lists. For the technical classification of the plants here treated, the reader is referred to the sheets on SYSTEMATIC BOTANY.

The Cabbage Tribe.

This includes some of the most hardy, easiest cultivated, and useful of kitchen vegetables. The following are those which we would recommend to be cultivated: broccoli, Brussels sprouts, common cabbage, red cabbage, cauliflower, savoy cabbage, and Scotch kale.

Broccoli is one of the best kinds of greens, and is valuable for coming at a season when not liable to be affected by caterpillars. There are various kinds of broccoli, but all may be arranged under two heads—those for spring use, and those for use from September to Christmas; the latter are termed 'Cape' or autumn broccolies. The most approved varieties for spring use are Bowles's new sulphur, Moody's dwarf, Grange's cauliflower, and Portsmouth cream or buff colour.

One ounce of seed of broccoli is calculated to sow a bed four feet wide by ten long, broadcast on a prepared bed; but if sown in drills, rather less seed will be sufficient. Each kind should have a place allotted to itself. The soil should be a fresh sandy loam, not manured, and the season for sowing will be comprised between April and July. The Cape plants are finally set out in beds made rather rich with manure, at any time when they have leaves six or eight inches long; two feet distances, plant from plant, will be sufficient. Each plant is to be firmly secured in the soil; and if the weather be dry, every hole should be filled with water. This species will come in season in August, and continue to produce a supply throughout the autumn; in mild seasons, some heads may be cut even so late as the turn of the year.

The spring hardy varieties are treated by most persons in the same way as the Cape—that is, the plants, when they are six or eight inches high, are transplanted as they become ready, between the first week of July and that of September, into beds of richly-manured loam, and set two feet apart, the largest sorts, as the

Portsmouth, at thirty inches, and they are kept perfectly free from weeds. If the seasons be favourable, a successional supply of broccoli is thus obtained from the first week of March to the end of May. It is also customary to lay down plants in September, with the heads turned from the sun, applying earth on the south side over the stems, to protect them from snow and frost. We prefer to plant in six-inch-deep trenches, properly manured, removing the plants to them when not less than a foot high, filling each hole with water, and repeating the watering for two or more successive evenings. This treatment, even in the driest seasons, will secure the plants; and as the winter approaches, by drawing the earth from the ridges on each side, and thus filling up the trenches, the stems will be protected, and the ground levelled and rendered light. We have practised this method during seven or eight winters, and have lost no opportunity to recommend it to others. Broccoli plants do better in trenches than any other members of the Cabbage family.

To save seed, it is only necessary to watch the progress of some very fine plant left late in the spring, to cut out all the weakly and crowding parts of the heads when expanded, and to secure the seed before it be quite ripe, or rather before the seed-vessels shed the seed. But as all these plants pass, by crossing or hybridising, into other varieties, it is generally not desirable to attempt seed-growing.

Brussels sprouts produce tall stems, three or four feet high, which support a head somewhat resembling an open savoy, of little value. This being cut off, the lateral buds down the stem protrude a succession of little green heads, like small savoys, delicate in flavour, very much admired, and yet but seldom seen, inasmuch as the true vegetable is not easily obtained. Our best authority is still that of Professor Van Mons of Brussels. The following is transcribed from the last edition of the 'Domestic Gardener's Manual,' wherein the Brussels practice is noticed, and a few experimental remarks appended:—'The plants are raised from seed sown in March or April, of which an ounce may be requisite for a seed-bed of four feet by ten. Van Mons says, "The seed is sown in spring under a frame, to bring the plants forward; they are then transplanted into an open border with a good aspect. By thus beginning early, and sowing successively till late in the season, we contrive to supply ourselves in Belgium with this delicious vegetable fully ten months in the year; that is, from the end of July to the end of May. The plants need not be placed at more than eighteen inches each way, as the head does not spread wide, and the side leaves drop off." In England, the Brussels sprout is so hardy, that it will stand twenty degrees of frost; and its head about Christmas is a tender and delicate species of greens. Being then cut, the plant will remain nearly torpid till the advancing sun causes it to start into new vegetation; then the spaces between the rows should have a little leaf-soil or good manure lightly forked in; and the young heads, all of which were quiescent, but visible in the winter, will speedily advance from the axils of the leaves, and yield a supply for many weeks, if they be properly pulled or cut off in succession.'

We cannot add much to the above, but may observe that, if any one can procure true seed, it will be advisable to try to ripen some, and to abandon seed-growing of every other kind of the cabbage during that season, for fear of crossing it; also to try Van Mons' repeated sowings, for in truth a more delicate family vegetable cannot be cultivated.

Cabbage.—The cultivated varieties of the common or white-hearting cabbage are very numerous; and as all can intermingle, so no one who aims at raising seed can be confident of what he shall produce. The best varieties in ordinary use are—1. Small and large York; 2. London, variety of York; 3. Sugar-loaf; 4. Knight's Downton; 5. Battersea; 6. Vanack. The cabbage is a biennial plant; it runs a two years' course, bears seed, and dies. Therefore to obtain hearted cabbages throughout the year, two or more sowings must be made; one in the spring, the other in summer. Spring-sowing can be effected at once, or it may be divided into two or three operations; because, from the third week of March to the first week of May, the seed can be successfully sown for the supply of summer and winter. Yet by attentive management, one sowing may be made to produce all that a family can require: we restrict our directions to that simple operation.

Prepare a bed of good sound loam in an open exposure, and let it be very slightly manured, for cabbage seedlings benefit much by strong contrasts, and ought not to be made to run up while tender. Dig the ground for four rows, nine inches asunder, and from fifteen to twenty feet long. Break the earth finely, and leave it to settle for three or four days; then place boards to tread on, while a first drill, one inch deep, is struck by the line; make the bottom of this and every other drill even, and a little solid, either by pressing a long pole into it, or by patting it with the back of a wooden-headed rake. Sow the seeds rather thickly, because it is better to thin out an abundance of plants than to lose the greater part of a thin crop by insects. When sown, cover the drill with fine earth, proceed to make and sow other drills, till the bed be finished, and then either tread the surface over with the feet placed nearly close together, or pat the surface with the spade, and then finish it off smooth with the back of a rake. Always avoid to tread ground into holes, and therefore recede from the work backward; prefer to use the feet in light sandy soil, but rarely with stiff and binding ground. In a very dry season, seeds will not easily vegetate; therefore in such cases strike the drills, and water effectually along them for three successive evenings, covering the plot with mats throughout the day. In the third evening make the drills even, sow, cover with earth, sprinkle again, and lay on the mats by day, till the plants be visible, then dust them once with the finest road sand while the dew is on, and in the evening with air-slacked lime. These precautions need not be repeated. We never saw a set of cabbage, turnip, or celery plants so dusted with road sand that was much infested with the turnip beetle; and as to slugs, lime, or lime with coal-soot, will effectually prevent their ravages, or destroy the vermin.

When the plants begin to produce their true leaves, thin them out, first to an inch asunder, and again to two inches; they will thus gain strength rapidly; and when they have three or four good leaves four inches long, they will be fit to go out, some into nursery beds, and others to the plots where they are to remain. Those set in the former, six inches asunder, will acquire stocky roots, and be prepared for successional beds. The size of the plants will indicate the season during any of the summer months. Those planted permanently will require the ground to be made rich with manure, and the transition from poor to rich earth will make them grow rapidly. The smaller Yorks, &c. should stand twelve or fifteen inches apart, the large varieties twenty to thirty inches. Set each plant as deep as the base of the lower leaves, and observe the directions given for the treatment of broccoli. These seed and nursery beds will supply the table from May to November, and in fine seasons even later.

Cabbage coleworts—a favourite vegetable in London, known by the name of *spring greens*—are raised by sowing the seed of the hardier middle-sized cabbages from the end of June to the middle of July, to be transplanted in August and September in rows twelve or fifteen inches asunder, the plants nine inches from one another; they form pretty little heads—not properly cabbages—at a period when the old stock is exhausted, and the spring cabbage is not come in.

The main summer crops are raised from seeds sown between the 25th of July and the 10th of August: the last week in the former month comprises the most favourable period. The directions previously given will apply in every respect to the treatment of the plants; we need only remark that it is advisable to plant the young cabbages first in nursery beds of simple loam, wherein they will be more secure during the frosts than they would be in rich beds; but being transferred to the latter at the end of February, or early in March, they will make rapid progress, and according to the season, produce hearted cabbages in April, May, and June. All the departments must be kept clean, and free from litter or weeds. Seeds can easily be raised, but the result is always doubtful.

Red cabbage is only used for pickling; it is raised by a two years' course—that is, by sowing in August, and transplanting, as directed above; but this variety requires a little more space. The heads form in the ensuing summer, and are in fine condition in October. If sown in spring, little-hearted cabbages can be obtained, which may supply a loss, or serve as a substitute for the others.

Cauliflower, which is grown only for its rich white head, requires in the open air a warm and moist climate, or it must be grown under glass. In Holland, it grows to great perfection, and like many of our garden vegetables, is most likely imported from that country. One of the chief difficulties attending its open-air culture is its destruction by caterpillars, and therefore great care is in many respects necessary to bring crops of it forward. Under glass, the plants are rendered very expensive.

Spring-sowing, for a first crop, may be made in March, over a temperate hotbed. The seedlings are to be pricked out when the leaves are an inch broad; and from this nursery bed they are moved to the garden bed in May, to stand more than two feet asunder, the ground being made extremely rich. The plants, after they begin to grow, are occasionally watered with the liquid manure collected from the drainage of dunghills. A second spring-sowing is made in the open border in May, to obtain plants from September to November, by a similar mode of treatment. The last sowing occurs in the middle of August. The plants, when about four or five weeks old, are to be thinned out to two or three inches apart, the best to go into nursery beds of rich earth, three or four inches asunder. Here they must grow till November, when the strongest are to be set out in rows, to be preserved under bell or hand-glasses. Dig a bed of rich ground in an open situation, and make it still richer with manure; set three or four plants together, five inches apart, in patches, each patch a yard asunder; give water, and cover close with a hand-glass till the plants begin to grow. When fairly taken with the soil, tilt the glasses on the sunny side with a brick; and thus continue to give air on mild days during the winter, and on some occasions take the glasses quite off, but replace them and cover close every night.

In the spring thin the plants to two under each glass, making good any deficiencies with some of the best plants thus taken up, and plant the surplus in a warm spot of ground two feet apart. Keep the glasses on the other plants, raising them more and more, occasionally exposing them to mild rains till about the beginning of May (unless in the event of intense frost, such as we have experienced within a few years), when the glasses may be finally removed. Cauliflowers will thus be produced in succession from the end of May throughout June.

Other plants should, in November, be placed in frames four inches apart, in a bed of rich dry loam, over a very slight hotbed: give water, close the lights, and be guided as respects the admission of air by the directions for the hand-glass division. The lights should be covered with mats and boards during severe frosty nights. In February, March, and April, the plants are removed in succession to beds richly prepared; and the cauliflowers will come into perfection during July and August. It is customary to form the earth immediately around the stems into the shape of basins, to contain water or the liquid manure: it is a useful practice, and this, with hoeings between the rows, will comprise the general treatment.

The savoy is very hardy, and the most useful of winter cabbages. Its culture is very easy, and admits of four sowings. There are two approved varieties—the *hardy small green* and the large *yellow*; the former is generally preferred. Begin to sow in February, sow a second time in March; a third, and this is for the main crop, in April, about the middle of each month. Let the situation be open, the soil a good natural loam, if possible, and laid out in a bed three or four feet wide, digged, and made fine. Scatter the seeds evenly, and rake them. Repeat, for the fourth time, in August. The plants of this last sowing will attain a large size by the following August and September, if planted out in April. As the plants of all the sowings, after thinning, become four or five inches high, they are transplanted between crops standing widely apart, as in the single-row system of asparagus, or as succession on potato land. Moist weather should be chosen, and the savoys should stand two feet apart. Keep the ground clean, stir it occasionally, and draw a little toward the stems on each side, always, however, leaving a sort of furrow three or four inches wide, to receive the rain, and convey it to the roots. Seed can be sown in the second year, but may be rendered spurious.

Scotch kale and *German kale* are the hardiest among our winter greens. They are raised by sowing the seeds either in beds or single drills late in February or early in March; to be first thinned out to three inches apart, and finally transplanted to beds or rows, wherein the plants are to stand thirty inches asunder. The plants may go out in succession from June to the middle of July. The heads are cut first, and subsequently side-shoots arise, which produce excellent winter greens, till early cabbages come in. The plant runs to flower and seed during the succeeding summer.

Instead of growing kale, cabbage, or any other of these plants from seed, it will save much trouble to the cultivator of a small garden to purchase young plants by the hundred from a nursery of such vegetables.

The Pea and Bean Tribe.

Of the pea there are various sorts, but it is only those of a fine kind which are cultivated in gardens, and called *garden-peas*, that we require to notice. When fresh, they are a bright green, and when dry for seed, most are a buff yellow. Peas are a summer delicacy, and the chief art is to produce them in the open air, by the middle of May, and to keep up a succession of crops till other vegetables supersede them. Skilful gardeners do not consider it a difficult process to effect an early crop, as the plant is very hardy, and sustains violent transitions without much danger. Peas, therefore, may be accelerated in frames and vineries during February, and being transplanted into rows fronting a south and east wall, will continue to advance progressively though the weather be cold. They can also be sown (provided there be no frost) in the open ground at any time. The chief varieties for the earliest and latest crop are the *early Warwick*, *bishop's dwarf*, *Charlton*, *frame*, and some others peculiar to localities. The varieties for the main summer crops are the *blue Prussian*, the *imperial*, *Knight's*, *dwarf* and *tall*, *marrowfats*, and the *scymitar-podded*.

The soil in which this vegetable most luxuriates is a free, light, but rich loam, abounding with vegetable matter, but not manured with recent dung. The situation for crops from June to August should be exposed and open. The times of sowing are very various. Some obtain an excellent yield from seed sown early in November in long drills; and if the winter be open, success is nearly certain. At whatever season persons commence, a better general rule cannot be adopted than to sow for a successional crop as soon as the peas of the preceding sowing are fairly above the surface. The plants, when three inches high, should have earth drawn against their stems on both sides, after which the soil may be superficially opened by passing the hoe lightly through it, and thin branchy sticks, of a height suitable to the habit of the variety, ought to be thrust into the ground, converging a little, so as to meet at top, and interlace each other. Shallow soils over chalk are soon over-cropped by peas, and refuse to bring a healthy plant; and in all kinds of ground the frequent repetition of pea-sowing is to be deprecated. The land must also be purified by a rotation of cabbage and potatoes.

Stakes for peas are indispensable in keeping them from trailing on the ground; and therefore every person who wishes to grow this vegetable in his garden should take care to preserve the stakes from one season to another, as long as they are serviceable. Any kind of branchy twigs, such as those of the beech and the larch, will answer the purpose; and the better if they are open and spreading, and stript of their foliage. When all the pods are taken, remove the haulm or pea-stalks to the compost dung-heap.

Dwarf-beans are planted in rows, and the seeds are generally sown at different periods between the 1st of May and the middle of July. The situation should be open, not crowded by other vegetable crops, or under trees — the soil a free-working loam, moderately manured. The drills should not be nearer to each other than thirty inches, and not more than two inches deep. In these the beans are to be dropped at regular distances, not exceeding three or four inches. Make the ground firm at bottom, but let the covering earth be light, and only slightly raked, not trodden or made hard. The one leading principle of successful growth is to bring the plants up as soon as possible, and this is effected by selecting warm weather, and opening the drill early in the day, that its base and the loose soil about it may be rendered hot by exposure to the hottest sun for two or three hours. A cold, wet, cloddy condition of the land causes decay.

The kidney-bean comprises two species of plants, which, though of one family, are of very different habits. Both, however, are natives of the East, and are very impatient of cold; hence the necessity of deferring the sowings till the weather be nearly settled in the spring, and the ground warmed to the depth of several inches. The two species are, first, the dwarf with its numerous varieties, all bearing the title of *French beans*; and second, the climber,* commonly termed *scarlet beans*, or runners, although there are varieties with white and variegated blossoms: one of the latter, *the painted lady*, is very prolific. There are few of the many varieties of the dwarf which can surpass the buff or dun-coloured bean—it is free of growth, and fertile, either when forced in pots, or planted in the open ground. The black speckled dwarf is also an excellent bearer; the white-seeded is the true *haricot* of the French; in Kent it is called *caracansera*.

Runner-beans are planted with similar precautions, or if sown early in pots and boxes, will transplant very well. When the plants attain the height of three or four inches, they should have a little earth drawn about the stem, and be staked; that is, somewhat tall branchy sticks should be placed on each side, converging towards each other at the top; these props ought to be eight feet high; and when the plants reach their summits, they should be nipped off and kept stopped, to cause them to produce fruit-bearing laterals. 'Gather beans, and have beans;' that is, never leave any pods to ripen; if redundant, let them be given away, or go to the pig-stye, for a maturing pod arrests the fertility of the plant by tasking all its powers. Keep all the crops clean, and the surface of the ground about them rather open. The roots of the members belonging to this section are accounted narcotic and poisonous.

The garden-bean is known to every one, and it has been in use from time immemorial, as appears by the allusion made to it by ancient classical authors. Though a native of the East, it is, in all its cultivated varieties, very hardy; these varieties are numerous: some of the more approved are, the early *mazagan* for the first crops, which may be sown from October to February; *early long-pod*, an excellent fertile bean for general use, not highly flavoured; *broad Windsor*, the best of all beans for flavour, but not a prolific bearer, a hybrid between the two last, combining the fertility of the one with much of the high flavour of the other.

Beans prefer a sound and rather firm loam, retentive of moisture. They suffer much in a very dry season and soil, particularly if attacked by the black blight (*aphis*), which covers the tops, preys upon the fluids of the plant, and often almost entirely destroys whole fields in a very short time. *Topping*, when the insects are first seen, appears to be the only remedy. The seeds should always be sown in rows, and one pint is considered enough for eighty feet. The beans ought to be sown in one long row, three inches deep and four inches apart, returning the soil and treading along the course of the row; after which the rake should be employed to level the surface. Beans transplant extremely well, and therefore may be sown thickly in autumn, covering the plants with hoops and mats, or with a garden frame and lights.

When the plants rise in the rows, or begin to grow after being transplanted, loosen the earth by pushing the Dutch hoe along the surface, and draw three inches of it to each side of the stems; or rather shovel up two or three inches of the earth, and lay it flat a foot wide on each side of the row of beans, shelving rather towards the stems than from them, for then the rains would find their way directly to the roots. The seasons of sowing are autumn for the mazagan, January and February for long-pods, and from March to June for the Windsor. Sow succession crops one after the other, according to the demand, as soon as the plants of the preceding sowing shall be quite above ground. To cross the variety, sow Windsor and long-pods alternately in the row, and save the beans, introducing in future sowings an occasional Windsor bean, till the desired rich flavour be attained.

As the beans ripen and turn black, draw them up, and place them to dry in an airy situation, guarding the pods from mice, which are rather partial to the bean, and thus, as we have found, deprive the gardener of a choice variety, which he had been at considerable pains to procure.

Esculent or Root Vegetables.

The vegetables grown for the sake of their roots are of two kinds:—1. Those in which the roots are round or lumpy, including the Jerusalem artichoke, the potato, and the turnip; and 2. Those which are tap or taper-rooted, including the carrot, the beet-root, the radish, and the horse-radish. Strictly speaking, the tubers of potatoes, &c. are not *roots* (see VEGETABLE PHYSIOLOGY), but merely concentrated stems of the vegetable below ground, the real roots being small fibres which shoot out from the tubers, and bring nourishment to the whole. All require depth of soil to penetrate, and also looseness and breadth of mould to allow of expansion.

The Jerusalem artichoke is a root which may be said to combine, in point of flavour, the turnip with the potato. Its name is an absurdity, for the plant has no resemblance to an artichoke; and the word *Jerusalem* is a corruption of the Italian name *Girasol*. The plant is a native of Brazil, and botanically belongs to the same family as the sunflower, but it rarely produces flowers in the British islands. The tubers, which alone are eaten, are produced abundantly under the surface, close to the base of the main stem. The plant is set like the potato, by either whole roots or cuts with one or more eyes to each. The pieces or cuts should be prepared at the time of planting, and set by depositing in shallow trenches two feet apart, and one foot asunder in the row; and being covered with earth, nothing more will be required but to keep the ground clean by the hoe. The season for planting is in the first dry weather of March; and half a peck of tubers, according to Abercrombie, will plant a row 120 feet long. A good mellow loam is the proper soil, and the spot for planting should be apart from the vegetable garden, otherwise this prolific plant may intrude, and become a complete nuisance. Being set in March, the plant is perfected about October or November; the crop is ready for use when the stems are quite dry. Dig only when wanted, if that be convenient; but if there be a danger of frost, as will most likely be the case, lift the crop, and store away for winter use in moist sand or any kind of light soil through which the frost cannot penetrate.

The potato, like the Jerusalem artichoke and some other plants, is a naturalised exotic in English gardens from the wilds of America, and has been greatly improved by culture within the last hundred years. There are now many varieties, individually distinguished by colour and flavour; and as some are better than others, it is very important that proper sorts should alone be cultivated. There are two distinct kinds—*early* and *late*. Early potatoes are a premature and transient kind; they soon come to perfection, and cannot be stored for future use. On this account no cottager should have anything to do with early potatoes, which are never grown but as a luxury; and after all, they are in general poor waxy stuff. The true potato is the late kind, which will store for winter and spring use. Of this there are hundreds of sorts, every district apparently having one which is best adapted to its soil and climate. The sorts to be preferred are those possessing the quality of mealiness, and which will not degenerate or fail in cropping. The kinds we recommend, as far as they may be found suitable as to climate, &c. are kidney-shaped, or long and flattish; red roughs, a round reddish-coloured potato; and those white kinds which are smooth-skinned. Of early potatoes, the ash-leaved kidney is among the best for open-garden culture.

The potato may be cultivated either from seed procured from the apple on the stalk, or from the tuber itself. If from the seed, the first crops of tubers are only a little larger than peas, and several seasons are required to bring the plant to an edible size. The common method of cultivation is by pieces or cuts, each having at least one well-defined eye; cuts with two eyes are generally preferred. These are set in trenches, the ground being in good heart with previous manuring, or good old manure placed along with the sets. The season for planting is late in April. Dig and plant sets, fresh cut as the work proceeds, placing the sets from nine to twelve inches apart, and the rows being about twenty inches asunder. Heap six inches of soil loosely over the sets, and when the shoots have risen sufficiently above ground, keep earthing them up with a hoe. When the stalks begin to decay in October, the crop is ready for lifting. (For further information on potato culture, see AGRICULTURE.)

Of the turnip there are many varieties, but three only are grown in gardens: these are the *early Dutch*, which is white; the *yellow Dutch*; and the *Swede*, also a yellow kind. The white is the most delicate while young, but the yellow Swede is preferable as a keeping or late turnip. The yellow Dutch has also an excellent flavour. Turnips are cultivated from seed in drills one foot apart, and thinned when they come into leaf, to afford room for their expansion. For the two Dutch varieties, the best soil is sandy, enriched with bone-dust, guano, or good old stable-dung. One ounce of seed will go over a great space—Abercrombie says as much as 200 square feet of surface. Small sowings should be made in succession from March till July, and then the main crop for winter should be sown. Swedes, as directed under AGRICULTURE, should be sown in April and May. Deeply hoe the ridges after thinning, and keep the surface clear of weeds.

Of the carrot, the favourite varieties are the *early horn*, the *Altringham*, the *long orange* or *Sandwich*, and the *long red Surrey*. All require a deep light soil. The early horn is sown in February for the spring crop, and in July for a late crop; the other kinds are sown in March, April, and May. All are sown broadcast in beds, and on a calm day, if possible, as the seeds are very light: they should also be rubbed between the hands, and mixed with some dry sand or wood-ashes, to separate them, and so facilitate an equable sowing. The seed may be saved by planting a few of the best carrots to stand the winter; seed will not retain its growing principle above a year, and therefore requires to be purchased with caution. Carrots may be stored like potatoes in winter; and it adds materially to their preservation in a sound and sweet condition to riddle over the layers a few barrowfuls of dry mould or sand.

The parsnip is a taper-rooted vegetable resembling the carrot in shape, and in England is a favourite vegetable with salt fish and salted meats. It is also used in the preparation of soup, of a species of marmalade, and in the manufacture of a wine which is said to approach nearest the malmsey of Madeira and the Canaries than any other. It is also an excellent agricultural as well as horticultural vegetable, and is extensively grown for cattle on the continent. It requires a rich deep soil, trenched and manured as if for a crop of carrots. The seed is sown in drills a foot asunder. The period of sowing is comprised between the last week of February and the first week of May. On thinning out, let the remaining plants be nine inches apart in the row. Parsnips are not liable, like carrots, to be injured by severe weather; but if taken up before Christmas, and properly protected, they will continue good till May in the following spring.

Of the radish there are two distinct kinds, which comprise all the numerous varieties now so generally cultivated. According to Lindley's catalogue, these are—The *taper-rooted spring radish*, of which the varieties are—1. The long white; 2. Purple or salad radish; 3. Salmon or rose-coloured; 4. Scarlet; 5. White Russian radish.—The *round turnip-rooted spring radish*.—6. Crimson turnip-rooted; 7. Yearly white; 8. Purple turnip; 9. White turnip; 10. Yellow turnip.—*Winter radish*.—11. Black Spanish; 12. Brown oblong; 13. Large purple; 14. Round brown; 15. White Spanish, a large bulb, which in good soil grows to the size of a small stubble turnip.

Numbers 2 and 3 are the best of the spindle-rooted radishes; numbers 6 and 7 of the early turnip-rooted. The winter black radishes are rarely seen in gardens; but the large white (15) is very mild, if the soil and season be favourable, and its texture is tender.

Sown in February and March, the spring radishes come into use in April and May; if required earlier, they must be protected by frames or mats. The market gardeners obtain them early by gentle forcing, covering the beds every severe night. The sowings of all the early varieties may be repeated monthly till August. The winter radishes are sown in July and August, and come into use from September till the spring. A rich and light soil suits the radish, with occasional copious supplies of water; and rapidity of growth is required, otherwise the roots will not be tender, nor will the flavour be mild.

Horse-radish is a vegetable which in certain soils is of extremely difficult culture, in others of uncontrollably luxuriant growth: it is a most pernicious weed where it intrudes, because of the multitude of vital germs with which its root-stock abounds, and by which it is rendered a sort of vegetative polypus, every inch of it being capable of developing a growing bud.

Such being the difficulty of artificial propagation, it may be questioned whether much trouble is not expended uselessly to effect that which nature produces by the most simple means. However, horse-radish can be procured by trenching two feet deep a plot of free loam, removing all stones as the work proceeds. One trench being well cleared, a layer of manure two inches thick should be laid at the bottom (for none must be mixed with the soil), and upon that three inches of the fine loam. Some fine straight roots being in readiness, they are to be cut into two-inch lengths, and piece after piece pressed into the soil eight inches asunder, in a row, to the whole length of the trench, and exactly in the middle. The soil is then to be dug out another two feet space, turning it into the open trench, clearing away the stones and other rough substances. Thus alternately trenching and planting, a bed will be formed of any extent that may be required. The work should be performed either in October and November, or in February; and the driest weather of the season should be selected.

Abercrombie, one of the best practical writers on gardening, made the following judicious remarks, which will, if duly considered, throw light upon those habits of the plant which have led to the deep method of culture just described:—'The root,' he says, 'being durable, forms itself into a thick knotty stool at a certain depth, sending up several erect, straight root-shoots, in length proportionate to the depth of the stool or main root, which, if planted fifteen or eighteen inches below the surface, the shoots or sticks of horse-radish will rise to that length. They will rise in May, increasing all summer till October, when in rich ground they will be sometimes large enough to dig up for use, being an inch thick; if not, they must have another year's growth, taking them up clean to the bottom by cutting them off close to the old stool, which remaining, sends up a fresh supply annually.' These habits indicate two important facts. First, that the crown or stool must enjoy all the benefit of the manure, to enable it to send up a straight stem, and to nourish that stem by its own power; therefore no manure must be placed in the upper soil, since it might excite lateral growth. Second, it points out the method of taking up the roots, which should always be that of trenching, beginning at one end of the bed and clearing away the soil to the full depth of the original trench. Thus a row can be taken without disturbing the crowns, by cutting off the upright shoots close to the head of each stool or stock; and what is surplus of each digging can be preserved in sand till more be required.

Beet-root or *red beet* is one of the most valuable of the spindle-rooted vegetables; it has heretofore been wasted by most persons, who, overlooking the really useful purposes to which a root so salubrious can be applied, have considered it as little more than a garnish to salads. Beet-roots should be boiled or baked till they become perfectly tender, when they may be eaten warm as a dinner vegetable. When cold, they should be cut into slices, and covered with vinegar. The plant is a biennial—that is, it grows and perfects its roots in one season; in the following spring it sends up its flower-stalk, ripens its seeds, and dies. Seed, therefore, can thus be procured; but it is better to purchase or exchange than to grow it. Of the two varieties of red beet, the smaller deep-purple variety is greatly preferable to the larger, which approaches to, and is little better than, mangel-wurzel. We select two varieties. 1. The short-rooted deep-purple beet, for its root. 2. The *beta cycla*, or silver beet, the leaves of which only are used in lieu of spinach.

To grow the red beet well, the ground ought to be light and pulverisable, otherwise the spindle-root will be diverted if it meet with obstacles, and become forked and distorted. Trench the plot to the depth of eighteen inches, removing large stones, roots, and hard clods of earth; lay a stratum of manure at the bottom of the trench, in order to attract the root downward; then return the fine earth. Let the work be completed before frost set in, and mark out the beds according to the number of rows required. At the middle or latter end of March the seeds are to be sown. These are contained in a curious seed-vessel of rude shape, and cannot conveniently be separated from it. In sowing, stretch the line, and draw an even drill about an inch or an inch and a half deep, and drop the seed-vessels at even distances, two or three inches asunder; for although these spaces are much too small for final growth, it is in all cases wise to be liberal of seed, because insects and other enemies destroy many plants, and thus a season may be lost. Cover with light fine earth, and either tread or beat the covering earth with the spade till it lie firm on the seeds. If the plants rise equally, thin them gradually, till they stand from nine to twelve inches apart every way, or even eighteen inches for the large rooted variety. Beet will transplant, but the operation dwarfs the plants; and at best it is attended with some risk. Keep the rows or beds entirely free from weeds by hand-weeding or flat-hoeing. Some roots will be ready in September, and thence throughout winter. In using them, or prior to storing up during winter, cut off the straggling leaves, being careful not to wound the roots; they keep well in dry and well-washed sand, but become tainted if wet straw or decomposable vegetable substances are present.

To collect seed, either reserve two or three of the best roots in the spot where they grow, or transplant them in autumn to a convenient situation. The flower-stems will be produced in the following spring, and should be secured by stakes till the seeds ripen. Then cut them in stalks, and dry them on a cloth under an airy shed; separate the seed-vessels, and preserve them in paper bags in a dry and cool situation; the seeds will retain vegetative power for several years.

Remark applicable to Beet, Carrot, and Parsnip.—In stiff clayey or cloddy land these spindle-root vegetables succeed very indifferently, carrot especially; therefore, to avoid repetition, it is thought right to observe that at the time of sowing the land having been previously trenched, and left exposed to frost in ridges), the soil is to be levelled, and holes made along the course of a garden line with a strong pointed crowbar about four inches asunder and twelve inches deep. Fill them with very light sandy earth sifted, and make a little cavity in the centres, into which drop four or five seeds; cover them with the same light earth, and beat the surface level with the flat of the spade; the roots so treated will tap downward, and be preserved as in a sort of sheath by the binding earth around them. Thus carrots, which always fail in certain soils, as we have often observed, may be produced of handsome figure and good quality, and beet-root may be grown without a fork in it—a circumstance of considerable importance with a root which is so liable to be injured by the loss of its saccharine juice whenever it is wounded by the knife.

The Onion Tribe.

This savoury class of kitchen vegetables comprises the onion, leek, garlic, and shallot, the two former being by far the most important. All are natives of Eastern countries; but they grow to great perfection, as respects pungency of flavour, in the British islands:—

The Onion.—For a crop of onions, the soil should be rich, light, and deep, and well exposed to the sun. Before sowing, work and enrich the bed to the depth of eighteen inches, and then beat it flat and firm with a spade. Sow the seeds at any time in March, thus—scratch drills by the line just so deep as to be clearly discernible, and sprinkle the seeds along them about three or four in an inch. Sift fine sandy earth over the seeds, and pat the surface even. As the onions advance, thin them out according to the variety, allowing alternately an intervening space fully equal to the breadth of the onion between bulb and bulb. In September twist the necks, take up the crop when the leaves become yellow, and expose the onions to sun and air under a shed till they be externally quite dry. Many sow onions broadcast in beds, in which case they likewise require thinning.

A summer supply of onions, at a time when the previous stock is exhausted, and the growing autumn crop has not come into season, must be desirable, and it is easily obtained. Prepare the ground early in February; select a number of those small bulbs that are always found in every bed of the larger kinds, which are not above an inch broad. The bed being ready about the end of the first week, mark out squares on the surface by means of cross-strings, but do not move the ground. At each intersection of the lines, press in an onion, the root downward, to one-third of its depth, so that the bulb remain firm and erect. Thus, when completed, the bed will exhibit the onions in squares five or six inches asunder. The onion forms its bulb in the first year of its growth, and the flower and seed in the second year. These small onions will therefore naturally attempt to produce a flower head, which, as soon as it is fairly visible, is to be pinched off. Another attempt will be made, and that also must be frustrated. The natural course of the vital-fructifying sap being thus interrupted, will be diverted to the bulb, and gradually, almost imperceptibly, two, three, or four onions of medium size will be produced and grow freely. These are to be taken, as soon as they are ripe (which, if the summer be fine and sunny, with occasional showers, will be in July), and dried in the open air as before directed.

The leek is another of the garlic family, and if properly treated in a favourable soil and situation, grows to a very large size. It is a plant which is much improved by proper transplantation, but yet can be grown very well in its seed-bed: the London leek is the best. Sow the seeds in a shallow drill at the close of February or early in March, and cover them with half an inch of fine soil; as the plants grow, keep the surface clear of weeds by hand-picking and passing the Dutch hoe lightly on each side of the leeks. Presuming that they are thinned out at first to stand three inches asunder, half of the plants will remain, and the other half will be removed to another situation. Thus the plants in the seed-bed will stand six inches asunder, and will be greatly assisted if the ground be opened on each side of them at the distance of nine inches, and manured spit deep. A crop of fine middle-sized leeks will thus be obtained in the succeeding autumn.

To transplant leeks, prepare a bed at the end of June, to contain either two or four rows, nine inches asunder, and manure the soil richly to the depth of a foot or fifteen inches. Let the bed settle during a week or more, and in July make holes along the intended lines six inches deep and as far apart. Collect a number of the strongest leeks, trim off the straggling roots, and all the suckers or offsets. Drop a small handful of powdery manure or reduced year-old cow-dung into each hole, place in it a leek, and holding it by one hand, fill the hole with water. The object is to fix the leek as in a case, to which it can adapt itself, and will fully occupy, becoming, under propitious circumstances, a plant of large size and of most excellent quality.

Garlic, one of the most pungent species of *allium*, is increased by dividing the bulbs into cloves or small bulbs, and planting them in good sandy loam at any period between the middle of February and the end of April. Draw drills two inches deep and ten inches apart, then press the root-end of each clove firmly into the earth till it stand erect; let the distance between each be six inches, and fill up the drills with fine sand. Keep the ground free from weeds, and when the leaves turn yellow—which usually happens about the end of July or the beginning of August—take up the bulbs with a trowel or handfork, and keep them in a dry room. *Rocambole*, a mild species of garlic, may be cultivated in the same manner.

The shallot is a native of Palestine; its culture is precisely the same as that of garlic, therefore both may be grown to great advantage by adopting the plan suggested by the late Mr Knight, described in the 'Transactions of the London Horticultural Society,' vol. ii. Let a rich soil be placed beneath the roots, and raise the mould on each side to support them till they become firmly rooted. This is then removed by a hoe, and by pouring water from the rose of a watering-pot, till the bulb stand wholly out of the ground. Thus they become mere surface bulbs, supported entirely by the fibrous roots, which pass deeply beneath into the rich soil. The growth of these plants, Mr Knight adds, so closely resembled that of the onion, as not readily to be distinguished from it till the irregularity of form became conspicuous. 'The form of the bulbs, however, remained permanently different from all I had ever seen of the same species, being much more broad and less long; and the crop was so much better in quality, as well as more abundant, that I can confidently recommend the mode of culture to every gardener.' Shallots have a strong but not unpleasant odour, and are therefore generally preferred to the onion for various purposes of cookery, and for making high-flavoured soups and gravies.

Chives, one of the smallest of the garlic tribe, is a hardy and useful vegetable, far superior to young immature onions. The plant grows in tufts somewhat like small rushes in appearance, but of a colour resembling the yellow green of young onions or scallions; it never bulbs. A crop is readily increased by dividing the roots in April or early in May.

Salads.

Salads are those watery plants whose long fresh leaves are eaten at table raw, or only dressed with zests and condiments without the preparation of cooking. The principal vegetable of this kind is

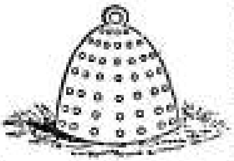
The lettuce, of which there are several varieties, but all may be classed under two heads—the upright or cos lettuce, and the open or cabbage lettuce. Of the upright, the green and white cos, and of the open, the inner cabbage and grand admirable, are the best. In spring culture, sow every month in very shallow drills of fresh-digged ground, in good heart, made extremely rich with rotten manure. Strike the drills a foot asunder, and as the plants rise, thin them to stand in regular order, first to two inches, then, for table use as small salad, to six inches, and for the larger sorts, finally to one foot. Never transplant during spring and summer, as the plants, by removal, sustain a check which urges them to fly up to seed. Spring and summer lettuces are sown from February to July. In September, two small sowings should be made of the hardy sorts, to come in use during late winter and spring; but it would be safer to make use of a large three-light frame. Some lettuces heart freely; those which do not should be assisted by passing a string of bast round them from the middle upwards. This bandage must not remain many days, otherwise the plant will run to seed, and become bitter.

In autumn culture, sow in August, in drills pretty close together, for the express purpose of transplantation in September or October; they will not then run up. When the plants are three inches high, thin out half of them, and transplant some into warm quarters, and others under a frame; protect by coverings of hoop and mats those in the open ground; and if they bear the winter, thin the plants early in the spring to six inches apart. The plants in the frame will rarely fail if the earth be free from slugs.

To save seed, transplant some of the finest lettuces when about half grown; they will produce a flower-stalk, and when the down of the seeds becomes visible, cut off the upper portion of the stalk, and dry it in a warm and airy room: thus save all the seed as it ripens in succession, for it is very valuable.

Endive is a salad of a pleasant bitter taste, and some authorities say it has been imported from China. There are three principal sorts in ordinary cultivation—the *green-curled*, *white-curled*, and *Batavian*, with undivided flat leaves. The seeds are sown at different periods between the beginning of June and the second week of August, as required for the autumnal, winter, and spring crops. When the plants are three or four inches high, they may be removed to beds of moderately-enriched loam, to stand a foot apart. But transplantation is not essential, for very fine plants are produced in the seed-beds. When they are nearly full grown, they must be prepared for the table by blanching, as otherwise they would be too bitter for use.

Blanching may be effected by several methods: the most simple is that of passing a string of soft bast matting round the centre of each plant, so as to exclude the light from the heart; but as hard frost is very injurious, some plants ought to be removed to a bed of dryish earth or sand under an airy shed; or a garden frame, partially covered, might be placed over a certain number of those already tied up. A good kind of pot for blanching is one of French invention, made of earthenware, and perforated with holes, as represented in the adjoining figure. Many persons blanch



by only throwing straw loosely over the plants, but this makes a litter not very pleasing in a garden. The curled endives would blanch in a short time without tying within a darkened frame or pot, and be thus less liable to decay; for it is known that the plants suffer from being tied. The Batavian endive, however, requires a bandage at all times, otherwise its harsh green leaves will be useless, and the central heart, which alone is edible, will never be rendered tender and white. Some persons blanch in a simple way by laying a tile over the open heart of the vegetable.

Corn-salad, or *lamb's lettuce*, a native of Britain—formerly used much more than it now is, and cultivated in gardens as an agreeable but rather insipid salad. A quarter of an ounce of seed was estimated by Abercrombie as sufficient to sow a bed four feet by five broadcast. The first sowing is effected in August, the second in September, for winter use. Thin out the plants when an inch high, to stand at three times that distance asunder. For summer salading sow once a month, beginning in March. Cut the plants for use as soon as they are large enough; this the taste will determine; but they should be taken very young, otherwise they become rank.

Garden cress.—In alluding to the culture of this common salad, we will include *mustard*, because they naturally are companions, and are always mentioned together, though they are of two very different families. In cultivating mustard and cress, it is essential only to remark, that the latter should be sown three or four days in advance of the former, because cress is more tardy than mustard. Both are very accommodating herbs, inasmuch as they will grow upon wetted flannel in a saucer placed in any apartment, as well as on the floor of a green-house. On shipboard, under cover, they can thus be obtained throughout the winter; and in the garden from March to November, by successional sowings made once every fortnight. Sow either broadcast over the surface of a fresh-digged bed, raking, and patting in the seeds by the flat of the spade, or in shallow drills half an inch deep, covering the seeds with a little fine soil. Sow thickly, and if the young plants rise, as they are apt to do, with a covering or cake of earth over them, remove it by means of a light heath-whisk. Salad should be taken before the true rough leaves be fully developed.

Water-cress, a valuable antiscorbutic, and wholesome as a fresh alterative to the inhabitants of cities, is grown to most advantage by the edge of running streams. If a small rivulet can be introduced into the garden, nothing can be more easy than to plant the roots in spring, and when they have once seeded, there will be speedily a mass of water-cress, which it requires only trouble to pull. The moisture is required principally in summer. The soils best calculated to bring the plants forward are loams inclining to gravel. The London markets are now supplied with immense quantities of 'fine spring water-cresses,' from the moist lands of Essex and neighbouring counties.

Celery is a native of Britain, found in ditches and marshes near the sea. The odour of the wild plant is very rank and disagreeable, and its juice is acrid and dangerous. By cultivation, this dangerous weed has been brought to the condition of that highly-esteemed vegetable which is called sweet celery. Of this there are three varieties:—1. The common upright hollow white celery; 2. The purple-stalked; 3. The giant white and red. Of the last (for which Manchester is particularly celebrated) there is a new sub-variety, extremely tender and delicate in flavour, the plants growing in favourable soils, and under skilful management, to an enormous size, but in ordinary cases not larger than the common white, yet always possessing a superiority in texture and flavour. Half an ounce of seed is deemed sufficient to sow a bed 4½ feet wide, and ten feet long, comprising, therefore, forty-five square feet of surface; and it may be sown in a frame, with gentle heat, at the end of February, for the first crop, and thence to the end of May, on a warm sheltered border for succession. All the seedling plants should be pricked out into intermediate beds of soft rich earth (the first sowings over a gentle hotbed), to bring strong transplants in June and July.

The roots of celery become bushy, and its leaf-stalk firm and stout; it likes moisture, and the soil to be rich with decomposed vegetable matter. Self-sown seed, that which falls from a seedling plant, if it light on rich earth, as that of a newly-dressed asparagus bed, in October, will bring noble plants in the spring, fit to go at once into trenches. Such plants may be thus shortly described: they are about six or eight inches long, with numerous stout leaves, and a massive collection of short fibrous roots. If these be produced by autumn-sown seed, nothing more is required; but the spring-sowings will always furnish weak and lax plants, that, when grown three inches high, must be removed to a nursery bed over manure to strengthen and become stocky. Few kitchen gardeners can obtain these plants till June, unless grown constantly under glass.

To trench for celery, prepare the trenches by previously manuring the whole plot in the method recommended for asparagus; and after the ground has settled, dig a trench or two for the first plants a moderate spade's depth, depositing the earth on a ridge to the right and left of the trench. Clear the bottom, lay on it three inches of leafy manure, and re-dig the ground, to incorporate it with the manure. Then select a number of the strongest and most regular plants, trim off loose straggling fibres, and all the side suckers, but do not touch a true leaf: set the plants four or five inches, and the large sorts six inches asunder, and fill the holes with water; shade during sunshine for three days, and give water every evening, unless there be copious showers. The size of the young plants will indicate the season for transplanting.

As to future attention, water the plants frequently in the evenings till they begin to grow; and when they become three inches higher, stretch a line along each edge of the trench, and cut down by the spade as much soil as will suffice to earth the stems to that height; break it fine, and grasping each plant firmly in the left hand, insinuate the soft soil around it; then place a little finely-reduced manure along the channel of the trench on each side, remote from the stems; this will nourish the fibres, without coming into contact with the leaves; water poured once or twice along the course of this manure will promote its action. Repeat the earthings as often as the plants advance three inches, and manure the extreme edges where the spade has made a groove, till at length the trenches become level with the surface of the ground. Then dig out soil, and add it, sloping ridgewise, till the plants are 'landed' up fifteen, eighteen, or more inches above the surface level. Celery may be preserved from frost by boards placed as a pent-house over the leaves.

Celeriac, or turnip-rooted celery, is raised and nursed the same as celery; but in planting out, the ground is dug and enriched, not trenched, and the plants are set by the dibble or garden trowel along the course of shallow drills drawn by the hoe, six inches apart, watering them freely. As the growth advances, bring earth to the plants, by which the knobby roots will be bleached, and made delicate and tender. When these are the size of small turnips, they are fit for the table. Celeriac is never eaten raw; it is boiled, and served up with melted butter. The seeds of both the species ripen freely in the summer of the second year, and many fine plants are obtained from self-sown seeds; which may serve as excellent substitutes should the spring-sowings fail.

Sweet Herbs.

These we shall class under two heads—namely, those that are fragrant, and esteemed for that quality alone, and those which are used for culinary purposes.

Rosemary and lavender are hardy undershrubs, natives of the south of Europe. They yield powerful essential oils when distilled with water, that of lavender being employed, as are also the dried flowers, in the preparation of the spirit usually, but erroneously, called *lavender water*. Bees are extremely partial to the flowers of rosemary. Both these plants are propagated with great facility by slips of the young side shoots, trimmed of the strip of ragged bark, and merely dibbled into the soil. They will grow almost anywhere, and in any aspect; but the flowers possess the highest degree of fragrance when the plants grow in a dry, sandy, or gravelly earth. Spring or September is most favourable to the propagation by slips.

Thyme and *lemon thyme* are used in seasonings; the latter is one of the most fragrant herbs of the garden; both are raised from seeds sown early in spring, or by opening the earth around the stems, spreading the reclining shoots like layers upon it, and strewing some fresh sandy mould over them. Roots are soon formed, and thus a supply of young plants is obtained. It appears essential to renew thyme, and to place it (lemon thyme particularly) in new soil, otherwise the plant dwindles and perishes. A dry and rather poor soil seems most favourable to the growth and fragrance of thyme, which may be economically grown as a border.

Sage, red and green, is propagated in the same way as lavender. 'All that is necessary,' says Mr Roger in his 'Vegetable Cultivator,' 'in the after-culture, is keeping the plants clear from weeds in summer, cutting down the decayed flower-stalks in autumn, and slightly digging between the rows.'

Of marjoram there are three sorts—*pot marjoram*, *sweet* or *knotted marjoram*, and *winter marjoram*, all hardy or sub-hardy perennial and biennial small shrubs, natives of the south of Europe, which grow readily in a dry light soil, but require change of situation. The first and third sorts may be propagated by division, in the manner of thyme, but the sweet marjoram should be raised from seeds sown in April every year, the plants to be thinned out to the distance of six inches. The flowers are gathered usually in July.

Savory.—Winter and summer savory; the former is propagated either by slips and cuttings, by separating the lower shoots, or rooted offsets, in spring; the latter is an annual, sown in April, and becoming fit for gathering in the summer and autumn.

Mint.—Spear or garden mint, and peppermint, are not properly sweet herbs; the latter, indeed, is only used medicinally, the essential oil possessing extremely pungent qualities, which render it one of the best diffusible stimulants we possess. Spear, or garden mint, is used in the kitchen for a variety of purposes familiarly known. All the species, including *pennyroyal*, another medicinal mint, are cultivated by division of the roots in spring. Mint delights in moisture; and when growing in a soil which it affects, extends with great rapidity. Care, however, is required to give it a new situation when the plant becomes weak, and its leaves appear of a pale and yellowish hue.

To dry and preserve these herbs, select the shoots just as the flowers form and show colour, but before they expand; suspend them in an airy situation, under cover, not exposed to the sun.

Miscellaneous Vegetables.

Artichoke, though esteemed by many, yet is found in few gardens; it is a native of the south of Europe, and was brought to England nearly three hundred years ago. Two varieties of it are cultivated in the best gardens—the conical oval-headed, and the round-headed, with dark purplish heads, the scales turned in at top. The plant has fibrous, rather fleshy roots, large deeply-cut leaves, whitish with down, and it produces an upright stem, bearing at the summit an oval or roundish flower-head, not unlike a thistle. Artichokes can be raised from seed, but much more speedily by offset-suckers, which are produced freely by the parent plant. Select a spot of open ground; any soil will do, but a free light loam is to be preferred. Dig out a trench two feet wide, and of the same depth, if the good soil extend so low; if not (and this remark will apply to every future allusion to trenching), remove all the good soil, whatever its depth, to a space beyond the boundary of the farthest intended trench, and dig and turn the inferior bottom soil, incorporating with it three or four inches of good half-decayed stable manure. Then mark out another two-feet trench, and throw into the first eight or nine inches of the surface-soil of the second trench; add another similar layer of dung, and work it and the earth thoroughly together. Again, throw in the remainder of the good soil of trench 2, and add a third layer of manure, which mix also with the soil. Thus trench 1 will be completed; and by repeating the work till the earth dug out of 1 be deposited in the last intended trench, all will be manured and laboured alike; and a piece of rich ground will be prepared that may be expected to keep in heart during many years. These directions apply to all enriched trenching, and need not therefore be repeated. The work ought to be performed before frost sets in; and if the land be heavy, it will be prudent to set it up in ridges.

Suckers are generally ready at some period of April; and gardeners are willing enough to part with them. Having procured the desired number, level the ground, dig a portion of it again, and reduce the surface to the finest condition possible; then, after trimming off decayed leaves and damaged roots, plant the suckers in a row, two feet asunder. It is usual to form a complete bed of three or more ranks, the rows to be five feet apart—and we have prepared ground, as above, for such a bed—but in truth artichokes and all other permanent vegetables ought to be set in single rows ten feet apart, because the ground between the rows can be cropped with other annual vegetables, which will benefit the artichoke, not only by the rich manure applied at the first, and other successional croppings, but by abstracting from the soil whatever it may exude from their roots of an excrementitious nature, and which, of necessity, must be injurious to the individual itself, though nutritious as manure to a vegetable of a different habit and character. The garden, in all its crops, permanent or temporary, ought to be made a laboratory of corrective rotations, wherein one crop shall attract and consume that which another deposits. A dozen good artichokes will be sufficient for a moderate family; but as some suckers may fail, it will be prudent to set the plants one foot asunder, securing the roots firmly in the soil, and giving a copious watering at the time of planting; the supernumeraries can be removed when all are safe.

The subsequent culture is as follows:—Hoe occasionally to destroy weeds, and keep the surface open. A crop cannot be anticipated during the first year; and if little heads be pushed up, it will be wise to remove them as soon as seen. When the plants become torpid and yellow in autumn, a few of the outside leaves are to be scaled off by the hand; the ground should then be marked by the line on each side at eighteen inches distance from the plants; and being cut straight by driving the spade to its full depth along the line, the earth is to be dug up, broken fine, and laid on the surface of the eighteen inches left on each side of the plants, bringing it carefully against them, so as not to fall into their hearts, but yet to protect them effectually near the tops of the leaves; the operation is called *landing up*. This done, fill the trenches with stable litter, straw, dung, or fern; and in the event of hard frost, bring more litter close to the plants, and lay it over the *landing* earth, for artichokes are rather tender, and may be destroyed during severe winters. This practice is to be observed every year, with the additional precaution to cut the flower-stems close down.

Spring-dressing consists in removing suckers after levelling the earth, and digging in a little of the short manure that is left on the ground after clearing away the straw, &c. and making the soil neat. One or two of the strongest suckers may be left on the stock.

Asparagus is justly esteemed one of the choicest vegetables of the garden; and indeed it possesses every quality to recommend it—flavour for the palate, hardihood of constitution, facility of culture, and it brings profit to the grower. It is a native of the British isles, but in its wild state bears little resemblance to the plant in a state of cultivation. Perfectly hardy, so much so as to resist a frost below zero, it nevertheless benefits by protection and generous tillage. In forming new plantations, it is customary to purchase two years' old plants, because they are safely removed at that age, and will come into bearing in two years more. April is the best season for planting; but having ourselves produced beds from *seeds*, we prefer that method of propagation. Let the ground be prepared before frost sets in by deep trenching and rich manuring; but by all means adopt the practice recommended by Grayson, who produced what he styled *giant asparagus* about the year 1830. We give his own concise directions in the following quotation:—'If your ground be stiff and unpleasant to work, get some milder earth to mix with it, and a very large cart-load of rotten dung to about every ten square feet; trench it two spit deep, and loosen the bottom; let the dung and earth be well mixed together. When your land is fit for planting, draw your drills six inches deep and sixteen inches from the first row to the second; that will form a bed; and ten inches between each plant in the row. Do not raise your beds till they have been planted one year; then put on about four inches of mould out of the alleys, and cut till the 10th of May. If you keep them well manured, they will last twenty years; but *never cut later than the 4th of June*. Let them be eight feet in the clear from bed to bed, so that you may crop between, and lose no land.'

Here we find the sum of all that constitutes asparagus planting; but after all, persons must be content with such plants as the constitution of their ground will produce; for this very sort, which in the rich water-deposited grounds (alluvial) about the Thames, produced shoots an inch in diameter, would and did dwindle in the loams of ordinary gardens to less than half that size. Nevertheless, if the beds be narrow, thoroughly manured at first, remote from each other; if, also, about February of the first year after planting, a trench eighteen inches deep, and a foot wide, be formed on each side of the narrow bed, and twelve inches distant from the plants, and be half filled with the best rotten dung, incorporated with an equal quantity of the earth dug out, a most excellent asparagus will be obtained speedily, and the quality will not deteriorate. This enrichment may be occasionally renewed, but these auxiliary trenches are to be made at an increased distance each time, so as to avoid cutting and mutilating the roots, which extend very rapidly. As this vegetable will no doubt be sold by the cottager, too much pains cannot be bestowed in order to obtain an early supply of the very finest quality.

The seed of asparagus may be purchased, but it is yielded abundantly by every good bed, and should be gathered before it falls off, and kept in the berry till spring. We will presume the object to be double—first, to raise bearing beds; and second, to raise a stock of young plants for forcing. In the former case, the ground is to be in readiness for narrow beds, eight feet asunder; in the latter, wide beds, like those directed for artichokes, should be made. Towards the latter end of March rub out the seed, and place the line along the course of the bed; strike two drills with the hoe at the distances directed by Grayson, two inches deep: or in the broad beds make similar drills nine inches asunder; and in both scatter the seeds pretty thickly, say half an inch apart; cover with fine earth, and pat it to a smooth surface with the spade. Watch the coming up of the plants, and be prepared to dust them with air-slaked lime, if slugs threaten them. When they shall have fairly formed rows of young seedlings six inches high, thin out the *narrow beds* first to four inches apart, and again to nine inches. The *seed rows* for forcing, thin first to three, and afterwards to five inches, and then leave both to grow, observing to use the Dutch or thrust hoe repeatedly to keep down weeds.

In future treatment, suffer the stems to become yellow, then cut them down at two inches above the soil; clear the surface with hoe and rake, and lay on the beds eight inches of decayed leaves. This surface-manuring, which will generally take place about the end of October, will tend greatly to protect the young plants, and impart a stimulating principle to the ground; so that in early spring the plants will be strongly excited, and rise through the remaining manure in perfect safety. The trench manuring also, before alluded to, will come in aid of the top-dressing. We have cut excellent 'grass' within three full years of the sowing, and still reap profitable crops from beds twelve years old. These annual enrichments, be it observed, might be persisted in with every bed that is used for cutting; but for the beds devoted to raising plants for forcing, it will suffice to make the ground thoroughly rich at the time of trenching; because the plants, when three or four years old, will be removed to the forcing department; yet a coating of half-decayed leaves or manure, after the stalks are cleared off, will not be lost, as the stronger the plants, the more remunerative will be the produce.

When once asparagus is in full bearing, if the cuttings be judiciously made—that is, by taking only the strong shoots, always leaving one or two of medium strength to each crown, and duly applying manure—a bed may keep in high condition for twenty years. But it must not be forgotten that if every shoot be taken off a crown, to the end of a long season that root will be destroyed. To prevent the crowns from being too deeply buried, in consequence of the autumnal dressings, it is customary to fork the beds late in March, digging them carefully, or rather loosening the surface with a fork of three prongs, and raking the rough earth into the alleys; this operation also gives freedom to the plant by opening the top soil.

With respect to forcing, it is very easy with narrow distant beds to bring the plants somewhat more forward in the spring, by digging trenches eighteen inches wide, or wider, and above a foot deep, and filling them with warm stable dung, blended with a third part of forest-tree leaves, raising the dung to six inches above the surface-level. The gentle warmth communicated will stimulate vegetation, and it would be assisted by covering the beds with hoops and mats, or with boards set up ridgeways, in the event of sharp frosty nights. Successional forcing-beds are prepared as soon as the cutting of the earlier begins to decline, or even when it is at its height.

The cucumber and *melon* are somewhat delicate in growth, and require a fine climate and extremely rich soil. The cucumber is usually grown over a heap of old horse-dung, on a spot of ground open to the south, and large enough to permit a two or three-light frame to rest upon it. Dig out the soil a foot in depth, and lay it on one side, or around the trench. If this soil be a light friable loam, incorporate it, a month before it is to be used, with one-third part of leaf or vegetable earth and old decayed dung, and again dig this mixed earth two or three times. But if the soil produced from four or five year-old couch-grass roots, harrowed from a field of sound loam, can be procured, it is the best aliment for the cucumber. The soil should be ready in

April, and the work of planting begun in the first week of May, by filling the excavation with stable manure to the height of six inches above the surface-level of the unmoved earth, and placing on it the frame and lights. In a week the manure will have settled, and is then to be covered with a six-inch layer of the couch mould or other soil, and a hill of dryish earth raised a few inches higher under each light, in which eight or ten seeds of any approved variety may be sown. If preferred, the seeds may be prepared by previous sowing in pots in a slight hotbed, and the plants so raised can be transferred to the hills. But as the plan now recommended is not one of forcing, it is safer to begin on the spot by sowing seed and covering the bed with the lights, and these with mats or boards every night.

As the plants rise, observe them carefully, and pick out the central buds when the true leaves have become strong. Persons differ much in opinion at this stage concerning the practice of stopping the shoots. M'Phail, gardener to Lord Liverpool at Addiscombe, Surrey, pointed out the true theory and results of stopping, as may be perceived by the following abbreviated extract from his work on the cucumber. He first directs to stop (nip back) the young seedlings at their second joint, then—'When the plants shoot forth after a second stopping above the second joint of the laterals, produced by the first, they seldom miss to show fruit at every joint and also a tendril, and between this tendril and the showing fruit there may be clearly seen the rudiment of another shoot. This shoot is then in embryo, but if developed, it becomes a fruitful lateral. And when the leading shoot has extended itself fairly past the showing fruit, then with the finger and thumb pinch it and the tendril off just before the showing fruit, being careful that, in pinching off the tendril and the shoot, the showing fruit be not injured. This stopping of the leading shoot stops the juices of the plant, and enables the next shoot—the rudiment above-mentioned—to push vigorously, and the fruit thereby also receives benefit.' The remarks will avail equally with the melon-plant as with the cucumber; and after the few remarks which follow on forcing, nothing farther need be said of the cultivation of melons.

Whether cucumber and melon plants have been raised separately in pots, or from seeds sown in the frame, they ought to be progressing early in June, and should be stopped occasionally, till fruit begin to show itself. The soil must never be wet, but always retained in a free and rather moist condition, water being kept in the frame for the express purpose. No water ought to be poured against the stems—it should be applied to the soil around the slope of the hills only. Air ought to be admitted in all warm days, by tilting the back of the lights till three o'clock; but after that hour the frame should be kept closed. When fruit is visible, stopping, according to M'Phail's direction, should be persevered in, and its fertilising effects will soon be apparent. Cover with mats, and boards over them, at sunset. Every decayed leaf and weak shoot should be removed as soon as perceived.

In order to raise and fruit cucumbers or melons before midsummer, *forcing* must be employed. The hotbeds of the best-regulated gardens are conducted without masses of manure under the roots; heat is excited by an atmosphere of warm air; thus injury from internal rank vapour is avoided, and manure is economised. By this method cucumbers and melons can be produced during the spring and summer months with certainty and precision. In the cultivation of both these plants equability of heat is important; and nothing would be more likely to secure this, and also to ward off sudden accession of cold, than to case the frame with an inner lining of thin boards, leaving a space of an inch or two between them, to be filled with some imperfectly-conducting substance, such as powdered charcoal or dry sawdust, taking care to secure it from the ingress of water. The expense would be trifling, and the security afforded very great.

Nasturtium, or Indian cress, is a native of South America, but is not tender; it is used occasionally (that is, the green seed-vessels are) as a pickle. These, when they ripen, separate and drop on the ground, where they remain torpid till the spring. Thus the plant sows itself, and so do most of the garden ornamental varieties. It therefore requires no minute directions; and any one who once possesses a plant, can multiply it by sowing seed in any way or place which may suit his taste. It may be sown with safety from the middle of March to the middle of May.

Parsley.—Several species and varieties of parsley are in cultivation; these are the plain and curled-leaved, and the common and the broad-leaved, or Hamburg parsley. Preference ought to be given to the curled-leaved parsley. This vegetable is one of the most easily cultivated, and it will long keep the ground with little trouble. It is sown in drills (generally in March) in any spare patches of border, lies long in the ground before springing, and arrives at maturity the next season. When it has attained this state, sprigs may be taken from it when required; even during a long winter storm, if the precaution has been taken to cover a drill or two with pease-stakes or other close wattling. When it becomes rank, it may be rooted out, and fresh parsley sown.

Rhubarb is a large vegetable, grown for the sake of its firm leaf-stalks. The leaves are very broad and spreading, to catch moisture, and shelter the ground around the main stem from the exhausting heat of the sun. When once planted, it requires no trouble, but keeps growing till the plant runs up to seed. To give additional size to the stems, cut off the seed-stalk. Suckers taken from known and approved plants succeed well, but the plant can easily be raised from seed. Each plant requires considerable space. In taking away the stalks for use, do not cut them, but wrench them from the main stock, so as to take them out by the socket. The earliest sorts in repute are *Buck's scarlet*, and the *new Tobolsk*, or yellow stalked. *Radford's scarlet Goliath* is later, but remains in season till August; it surpasses for delicacy, fullness of flavour, and extreme productiveness, all its competitors. Rhubarb may be forced by very simple means. A common method is to cover it in the early part of the year with a box, to which air is admitted, and covered with a little stable manure. This blanches, as well as brings forward the stalks; but that is an advantage, as it renders the vegetable more tender and delicate in flavour. Some bring forward rhubarb in pots in darkened forcing-houses, and for this purpose plants two years old are most suitable. Watering copiously is necessary in the early stages of growth, whether in the open air or under boxes. As rhubarb forms a valuable vegetable for tarts in spring, before gooseberries are ready, it would not be misspent time or trouble for a cottager to attempt forcing by the simple means above recommended. A well-planted plot of rhubarb, according to Mr Paterson, will continue productive for seven years; but a new one should be made a year or two before removing the old, and in the meantime some light crop may be raised on the new ground, which is but thinly occupied by the young plants.

Sea-kale is a perennial vegetable, deriving its name from being found growing in a wild state on the sandy downs which border the southern coasts of England. The method of garden culture is as follows:—Beds or spaces for single rows should be trenched and prepared as for asparagus; and at any dry period of March, when the surface earth will work freely, one or more drills should be drawn by the line, two inches deep, and the seeds scattered along the drill; or the line being strained tight, five or six seeds should be inserted in rings two inches deep, made at the distance of two feet apart. The seeds are then covered with earth, and when the plants become strong, they are to be thinned of supernumeraries, leaving one or two of the strongest remaining eighteen inches or two feet asunder every way. If the plants be weak, it will be prudent to retain double the number. During the first season, nothing more will be required than to keep the bed or row free of weeds. In the following spring, if the plants stand nearer to each other than eighteen inches, the surplus number should be carefully raised, and transferred to another prepared space, planting the crowns of the roots two inches below the surface. Eighteen inches to two feet, according to the strength of the plants, may be the regular distances at which they are to remain. The first bed, if pots be placed over the crowns, will yield a moderate supply of blanched kale during April or May of the second spring.

Sea-kale may be forced at various periods, commencing with November, by inverting large pots over the plants, and covering those with warm dung, or dung and leaves, to excite and maintain a heat in the pot and soil of about fifty-five degrees. Sea-kale, like other plants subjected to heat, can be, as it were, educated and made to conform to induced habits. Thus at first it seems to remain long torpid, even though the heat be considerable; but after a second season, provided the gardener be himself regular, the plants will yield to the stimulant almost to a day, though is be comparatively mild; hence sea-kale is at command from December to March by heat, and then the succession can be maintained during April and part of May by the cold beds or rows. 'You may have excellent sea-kale,' says the author of the 'Manse Garden,' 'in April from drills ridged up with earth; in which case every pair of drills must have greater distance for the convenience of mounding, and the plants may be so much closer in the bed. Straw in contact with the plants is unsuitable to blanching, as it communicates a bad flavour; but raked leaves do well, perhaps fern, sand certainly. Where the plant grows wild, as it does by the seashore in several parts of England, it is gathered in the finest condition when whitened by the sand, which the wind piles gently over its head in the manner of a snow-wreath.' As soon as the kale is cut from one or more roots, a sharp spade should be thrust through it, so as to cut the plant level with the surface.

Spinach is an annual of which there are many varieties. The following are the principal kinds:—1. The round-leaved, smooth-seeded, which is sown chiefly for spring and summer crops; 2. The triangular-leaved, prickly-seeded, or winter spinach—it is sown in August, stands the winter, and continues in full-bearing during spring and till midsummer; 3. The New Zealand spinach, a plant very different from the true spinach, and now neglected; 4. The white beet spinach, cultivated only for the leaves. The round-leaved should be sown about the end of January, and again in February and March, for successive spring and summer crops. The triangular-leaved is to be sown at the end of July or first week of August, and the leaves come into use at the beginning of winter; the plants require thinning and hoeing. The outer leaves only are to be taken during winter and spring, the inner leaves forming in their turn an ample succession. The seed or flower-stalks will become apparent in the early part of the summer, and some of the best plants, male and female (for spinach produces both separately), should be left to perfect the seeds. Plants designed for seed should be thinned to the distance of eight or ten inches. Spinach, according to the 'Vegetable Cultivator,' succeeds in any common garden soil; but the more that soil has been previously enriched with dung the better; and for winter spinach especially it is hardly possible to manure the ground too highly. Always select an open situation, not too near low-spreading trees, &c.; as in close and shady places it is mostly drawn up weak, and soon runs to seed, without attaining perfection.

Vegetable marrow is a species of gourd (*cucurbita*) cultivated extensively of late years—the pulp of which, from its richness and flavour, has been called *marrow*. It was brought originally from Persia, and was particularly noticed by Mr Sabine, in the 'Horticultural Transactions,' vol ii., where he described the best culinary variety as bearing a 'fruit of uniform pale-yellow or light-sulphur colour; when full grown, about nine inches in length, four inches in diameter, of an elliptic shape, the surface being rendered slightly uneven by irregular longitudinal ribs, the terminations of which uniting, form a projecting apex at the end of the fruit, which is very unusual in this tribe.' There are other varieties which produce fruit that weighs twenty or thirty pounds, oblong in figure, and quite green during growth; such fruit, however, is coarse in flavour, and in no respect equal to the small cream-coloured variety.

Sow in pots of any light soil early in April, treating the plants exactly as cucumbers under glass. About the middle of May, transfer them to a bed of rich earth over a trench filled with warm stable dung. Protect the plants by a hand-glass or frame, which, if the shoots are to run on the ground, should be raised by four or more bricks, giving air freely. When danger of frost ceases, remove the light or frame.

We have seen the best plants nailed and secured to a wall, as trees usually are. They bear profusely in summer and autumn, and are not subject to be injured by damp. The seeds are sown on the spot at the end of May, and one strong plant remains, being stopped once or twice at the tips of the advancing shoots, of which six are enough for each plant. It would be wise to place a large spare light or two sloping in front till midsummer, and again early in September. Glass diminishes the direct solar power to the extent of from eight to twelve degrees, but it wards off the primary attack of frost, which is at once fatal to these vegetables. If it be desirable to save seed, preserve the fruit first formed on a plant reserved for the purpose.

Mushrooms.—We have great hesitation in saying anything of the artificial growth of this species of vegetable, both on account of the difficulty which unprofessional gardeners labour under respecting the right sorts, and the complex methods which require to be employed for bringing forward crops. The greater number of mushrooms brought to market are of natural growth on old rich pastures; and it would appear that, without providing a similar kind of soil full of decaying matter, the plants cannot be raised. The method of procedure is very peculiar. The mushrooms are not sown in the form of seeds, for they have no observable seeds, but by spawn, or portions of their substance, mingled in the prepared soil. Mr Rogers, in his work 'The Vegetable Cultivator,' to which we would refer for much useful information on kitchen gardening, describes the process of mushroom culture, which, he says, is that approved of by the Horticultural Society. We extract a few passages for the sake of general information. 'In June or July take any quantity of fresh horse droppings (the more dry and high fed the better), mixed with short litter, one-third of cow's dung, and a good portion of mould of a loamy nature; cement them well together, and mash the whole into a thin compost, and spread it on the floor of an open shed, to remain till it becomes firm enough to be formed into flat square bricks; which done, set them on an edge, and frequently turn them till half dry; then with a dibble make two or three holes in each brick, and insert in each hole a piece of good old spawn, about the size of a common walnut. The bricks should then be left till they are dry. This being completed, level the surface of a piece of ground, under cover, three feet wide, and of sufficient length to receive the bricks, on which lay a bottom of dry horse-dung, six inches thick; then form a pile, by placing the bricks in rows, one upon another, with the spawn side uppermost, till the pile is three feet high; next cover it with a small portion of warm horse-dung, sufficient in quantity to diffuse a gentle glow of heat through the whole. When the spawn has spread itself through every part of the bricks, the process is ended, and the bricks may then be laid up in a dry place for use. Mushroom spawn, made according to this direction, will preserve its vegetable power many years if well dried before it is laid up; but if moist, it will grow and exhaust itself.

The next subject to be treated of is the preparation of the dung for the bed; and for this purpose none answers so well as that of the horse, when taken fresh from the stable: the more droppings in it the better.

About Michaelmas is the general season for making mushroom beds (though this may be done all the year round). A quantity of the dung mentioned should be collected, and thrown together in a heap to ferment and acquire heat; and as this heat generally proves too violent at first, it should, previously to making the bed, be reduced to a proper temperature by frequently turning it in the course of a fortnight or three weeks; which time it will most likely require for all the parts to get into an even state of fermentation. During the above time, should it be showery weather, the heat will require some sort of temporary protection, by covering it with litter or such-like, as too much wet would soon deaden its fermenting quality. The like caution should be attended to in making the bed, and after finishing it. As soon as it is observed that the fiery heat and rank steam of the dung are gone off, a dry and sheltered spot of ground should be chosen on which to make the bed. The place being determined on, a space should be marked out five feet broad, and the length (running north and south) should be according to the quantity of mushrooms likely to be required. If for a moderate family, a bed twelve or fourteen feet long will be found (if it takes well) to produce a good supply of mushrooms for some months, provided proper attention be paid to the covering.

On the space marked for making the bed a trench should be thrown out, about six inches deep; the mould may be laid regularly at the side, and if good, it will do for earthing the bed hereafter; otherwise, if brought from a distance, that of a more loamy than a sandy nature will be best. Either in the trench, or if upon the surface, there should be laid about four inches of good dung, not too short, for forming the bottom of the bed; then lay on the prepared dung a few inches thick regularly over the surface, beating it as regularly down with the fork; continue thus, gradually drawing in the sides to the height of five feet, until it narrows to the top like the ridge of a house. In that state it may remain for ten days or a fortnight, during which time the heat should be examined towards the middle of the bed, by thrusting some small sharp sticks down in three or four places; and when found of a gentle heat (not hot), the bed may be spawned; for which purpose the spawn bricks should be broken regularly into pieces about an inch and a half or two inches square, beginning within six inches of the bottom of the bed, and in lines about eight inches apart; the same distance will also do for the pieces of spawn, which, in a dung ridge, are best put in by one hand, raising the dung up a few inches, whilst with the other the spawn can be laid in and covered at the same time. After spawning the bed, if it is found to be in that regular state of heat before-mentioned, it may be earthed. After the surface is levelled with the back of the spade, there should be laid on two inches of mould—that out of the trench, if dry and good, will do; otherwise, if to be brought, and a choice made, that of a kindly loam is to be preferred. After having been laid on, it is to be beaten closely together, and when the whole is finished, the bed must be covered about a foot thick with good oat-straw, over which should be laid mats, for the double purpose of keeping the bed dry and of securing the covering from being blown off. In the course of two or three days the bed should be examined; and if it is considered that the heat is likely to increase, the covering must be diminished for a few days, which is better than taking it entirely off. In about a month or five weeks (but frequently within the former time, if the bed is in a high state of cultivation) mushrooms will most likely make their appearance, and in the course of eight-and-forty hours afterwards they will have grown to a sufficient size for use; in which case the author recommends that, instead of cutting them off close to the ground, they be drawn out with a gentle twist—the gatherer filling up the cavity with a little fine mould, gently pressed in level with the bed.'

As mushrooms may be said to cost no more than a little trouble, manure, and space for growth, at what an inconsiderable cost might not this excellent vegetable be abundantly procured! No product of the garden has hitherto been less attended to, and few afford so high a relish, either in their substantial form or as ketchup.

HORTICULTURAL MONTHLY CALENDAR.

Having in almost every instance mentioned the seasons for sowing, planting, transplanting, and otherwise attending to the culture of vegetables in the kitchen garden, it would only be waste of room to repeat directions, as is usually done, in connection with the different months. It is hoped, therefore, that the following general references to the months will be sufficient:—

January.—Trench and delve up all open grounds, if the weather permit; and in warm exposures, sow articles that are to be brought forward early.

February.—Continue turning up the ground designed for early crops; sowing may go on a little more briskly, especially in warm and well-sheltered borders.

March.—This is a particularly busy month, being, from its open and drying character, favourable for all works of preparation. Peas, beans, asparagus, onions, carrots, &c. are sown; and various articles are transplanted from frames.

April.—A continuance of preparing, sowing, and planting; hoeing, thinning, and clearing out of weeds require also to be attended to. In very dry weather seedling beds should be carefully watered.

May.—The main crops are now to be sown, early peas earthed up and staked, and young plants transplanted. The garden is now supposed to have assumed its perfect summer garb, with all things advancing in their early and mid-stages of growth.

June.—Sow kidney-beans, runners, &c.; water growing plants, if required; hoe potatoes, cabbages, and peas; and thin out beds. Gather medicinal and sweet herbs, when in bloom, and dry in the shade for winter use.

July.—Sow broccoli for the last time; also turnips, lettuces, &c.; and prepare all the unoccupied plots of ground for autumn and winter crops.

August.—Commence now to sow for the crops of next year, such as onions, early cabbages, and parsley; also winter spinach. Earth celery; hoe and thin turnips; cut down stems of gathered artichokes, and generally clear out all stumps and stalks of used plants, for their continuance exhausts the ground to no proper purpose. Cut herbs for distillation or for winter use; and gather all bulbous crops, such as onions, as soon as they are withered in the stem.

September.—The kitchen gardener has now got his principal labours in cropping over, and his chief work is continuing to sow for winter and spring successions; he also digs potatoes that seem ready, and takes care to cut down and clear off weeds.

October.—The garden having been prepared for spring vegetables, sow what was left over last month, including celery, asparagus, also early peas and beans. The cabbages and savoys require to be earthed up as high as the leaves. Remove carrots and other roots, which store away for winter use.

November.—If temperate and open, a little sowing may be continued in sheltered borders; but frost usually sets in early in the month, and puts a stop to cropping operations.

December.—During the latter end of November, and the open period of this month, the chief operations are digging, manuring, or trenching vacant ground, and attending to the preparation of composts. In frost, the labour exerted on the plants need only be protective; and the gardener usually occupies much of this period in pruning his trees, and attending to the more delicate plants in frames and sheltered borders. In mild weather a few early peas and radishes may be sown in dry warm borders, and small salads and cucumbers in hotbeds.

THE FLOWER GARDEN.

Flowers are the ornament of vegetable existence, and have in all ages been cultivated by persons of leisure and taste, for the beauty and variety of their forms, colours, and fragrance. While generally healthful and exhilarating, from being pursued in the open air, flower-culture is justly reckoned a pure and harmless recreation, which, by leading to the tranquil contemplation of natural beauty, and diverting the mind from gross worldly occupations, has a positively moral and therefore highly beneficial tendency. It has also the advantage of being alike open to the pursuit of high and low, the peasant and the peer, the over-toiled man of business and the industrious artisan. It may be followed with equal enjoyment by both sexes, and as is well known, on every imaginable scale, from that of a single flower-pot or tiny front-plot, to the princely green-house and exquisitely varied parterre.

The natural grace, simplicity, and attractive colouring of flowers have afforded endless themes to moralists and poets; and volumes have been penned to show how many associations of feeling, simple and sublime, these beauteous subjects are calculated to excite. As our desire is to improve the feelings as well as to instruct the understanding, we hope to escape censure for pausing an instant over this agreeable view of the importance of floriculture, and would refer, for one of the most glowing eulogies on the subject, to the elegant work of Miss Sarah Stickney—the 'Poetry of Life.' According to the well-expressed sentiments of this lady, few natural objects are more poetical, or more calculated to refine the taste than flowers. 'From the majestic sunflower, towering above her sisters of the garden, and faithfully turning to welcome the god of day, to the little humble and well-known weed that is said to close its crimson eye before impending showers, there is scarcely a flower which may not from its loveliness, its perfume, its natural situation, or its classical association, be considered highly poetical.

As the welcome messenger of spring, the snowdrop claims our first regard, and countless are the lays in which the praises of this little modest flower are sung. The contrast it presents of green and white (ever the most pleasing of contrasts to the human eye), may be one reason why mankind agree in their admiration of its simple beauties; but a far more powerful reason is the delightful association by which it is connected with the idea of returning spring. Perhaps we have thought long of the melting of the snow that impeded our noonday walk. But it vanishes at last; and there, beneath its white coverlet, lies the delicate snowdrop, so pure and pale, so true an emblem of hope, and trust, and confidence, that it might teach a lesson to the desponding, and show the useless and inactive how invaluable are the stirrings of that energy that can work out its purpose in secret, and under oppression, and be ready in the fullness of time to make that purpose manifest and complete. The snowdrop teaches also another lesson: it marks out the progress of time. We cannot behold it without being reminded that another spring has come, and immediately our thoughts recur to the events which have taken place since last its fairy bells were expanded.

It is of little consequence what flower comes next under consideration. A few specimens will serve the purpose of proving that these lovely productions of nature are, in their general associations, highly poetical. The primrose is one upon which we dwell with pleasure proportioned to our taste for rural scenery, and the estimate we have previously formed of the advantages of a peaceful and secluded life. In connection with this flower, imagination pictures a thatched cottage standing on the slope of the hill, and a little woody dell, whose green banks are spangled all over with yellow stars, while a troop of rosy children are gambolling on the same bank, gathering the flowers, as we used to gather them ourselves, before the toils and struggles of mortal conflict had worn us down to what we are now, and thus presenting to the mind the combined ideas of natural enjoyment, innocence, and rural peace—the more vivid, because we can remember the time when something like this was mingled with the cup of which we drank—the more touching, because we doubt whether, if such pure drops were still there, they would not to our taste have lost their sweetness.

The violet, while it pleases by its modest, retiring beauty, possesses the additional charm of the most exquisite of all perfumes, which, inhaled with the pure and invigorating breezes of spring, always brings back in remembrance a lively conception of that delightful season. Thus in the language of poetry, "the violet-scented gale" is synonymous with those accumulated and sweetly-blended gratifications which we derive from odours, flowers, and balmy breezes; and above all, from the contemplation of renovated nature, once more bursting forth into life, and beauty, and perfection. The jasmine, also, with its dark-green leaves and little silver stars, saluting us with its delicious scent through the open casement, and impregnating the whole atmosphere of the garden with its sweetness, has been sung and celebrated by so many poets, that our associations are with their numbers rather than with any intrinsic quality in the flower itself. Indeed, whatever may have first established the rank of flowers in the poetical world, they have become to us like notes of music, passed on from lyre to lyre; and whenever a chord is thrilled with the harmony of song, these images present themselves, neither impaired in their beauty nor exhausted of their sweetness for having been the medium of poetic feeling since the world began.

It is impossible to expend a moment's thought upon the lily, without recurring to that memorable passage —"Consider the lilies of the field, how they grow. They toil not, neither do they spin; and yet I say unto you, that Solomon in all his glory was not arrayed like one of these." From the little common flower called heart's-ease, we turn to those well-known lines of Shakspeare, where the fairy king so beautifully describes the "little western flower." And the forget-me-not has a thousand associations tender and touching, but, unfortunately, like many other sweet things, rude hands have almost robbed it of its charm. Who can behold the pale narcissus, standing by the silent brook, its stately form reflected in the glassy mirror, without losing himself in that most fanciful of all poetical conceptions, in which the graceful youth is described as gazing upon his own beauty, until he becomes lost in admiration, and finally enamoured of himself; while hopeless Echo sighs herself away into a sound, for the love which, having centered in such an object, was neither to be bought by her caresses nor won by her despair! Through gardens, fields, forests, and even over rugged mountains, we might wander on in this fanciful quest after remote ideas of pleasurable sensation connected with present beauty and enjoyment; nor would our search be fruitless, so long as the bosom of the earth afforded a receptacle for the germinating seed —so long as the gentle gales of summer continued to waft them from the parent stem—or so long as the welcome sun looked forth upon the ever-blooming garden of nature.

One instance more, and we have done. The "lady rose," as poets have designated this queen of beauty, claims the latest though not the least consideration in speaking of the poetry of flowers. In the poetic world, the first honours have been awarded to the rose, for what reason it is not easy to define, unless from its exquisite combination of perfume, form, and colour, which has entitled this sovereign of flowers in one country to be mated with the nightingale; in another, to be chosen, with the distinction of red and white, as the badge of two honourable and royal houses. It would be difficult to trace the supremacy of the rose to its origin; but mankind have so generally agreed in paying homage to her charms, that our associations in the present day are chiefly with the poetic strains in which they are celebrated. After all the pains that have been taken to procure, transplant, and propagate the rose, there is one kind perpetually blooming around us through the summer months, without the aid or interference of man, which seems to defy his art to introduce a rival to its own unparalleled beauty—the common wild rose. Blooming in the sterile waste, this lovely flower is seen unfolding its fair leaves where there is no beauty to reflect its own, and thus calling back the heart of the weary traveller to thoughts of peace and joy—reminding him that the wilderness of human life, though rugged and barren to the discontented beholder, has also its sweet flowers, not the less welcome for being unlooked for, nor the less lovely for being cherished by a hand unseen.' To these elegantly-expressed sentiments nothing need be added by the writer of these pages.

MODES OF LAYING OUT.

Flowers are cultivated in the borders and parterres of gardens of a mixed kind along with kitchen vegetables and fruits; and this may be said to be the general plan in those grounds of limited space belonging to persons of moderate means, and limited in the extent of their possessions. Many, however, cultivate flowers in gardens exclusively appropriated to them, and also in isolated clumps for the decoration of lawns. In whichever way, the method of culture is the same; and therefore it is unnecessary to enter into particulars with reference to the various sizes and kinds of gardens in which flowers may be grown.

The directions given in the previous sheet on the laying out, shelter, and exposure of kitchen gardens, apply also to flower gardens. The soil should be rich, dry, soft, and partially improved with decomposed peat and leaf mould; the exposure should be full and uninterrupted towards the sun; a free air should be allowed to play over the ground; and means should be at hand for procuring a plentiful supply of pure soft water for irrigation. Every flower garden, also, should possess a small store of fine washed sand as a restorative, and for scattering beneath the finer kinds of flowers when in bloom, as a protection from creeping vermin. Besides the utensils usually employed, the flower gardener should have a pair of small scissors to clip off decayed leaves, and some painted stakes and strips of bast for tying up drooping plants.

The greatest difference of taste prevails on the subject of disposing the various parts of a flower-plot or garden. Straight-lined borders, ovals, circles, and fancy figures, have each their admirers; and we should advise every one to adopt that form which will be most effective in striking the eye. If the garden is seen from a parlour window, as is often the case, the plan most agreeable is to lay out the foreground as a patch of well-shaven green, which is fresh both winter and summer; on its further side there may be a semicircular border; then a walk; and next parterres of such form and size as will suit the extent of the ground. If the garden contain kitchen vegetables, they should be out of sight of the windows of the dwelling-house, or at least not brought ostentatiously forward. 'It is more difficult,' says the author of the 'Florist's Manual,' 'than may at first appear, to plan, even upon a small scale, such a piece of ground; nor, perhaps, would any but an experienced scientific eye be aware of the difficulties to be encountered in the disposal of a few shaped borders interspersed with turf. The nicety consists in arranging the different parts so as to form a connected glow of colour; to effect which, it will be necessary to place the borders in such a manner that, when viewed from the windows of the house, or from the principal entrance into the garden, one border shall not intercept the beauties of another; nor, in avoiding that error, produce one still greater—that of vacancies betwixt the borders—forming small avenues, by which the whole is separated into broken parts, and the general effect lost. Another point to be attended to is, the just proportion of green turf, which, without nice observation, will be too much or too little for the colour with which it is blended; and lastly, the breadth of the flower-borders should not be greater than what will place the roots within the reach of the gardener's arm without the necessity of treading upon the soil, the mark of footsteps being a deformity wherever it appears among flowers.'

Whether all the flowers of a class—such, for instance, as violets, hyacinths, &c.—should be cultivated together, or interspersed and mingled with others, is another matter for taste to decide. The preferable plan seems to be to form a choice variety in borders and other spots, but also to cultivate a quantity of certain sorts in compartments by themselves. Neill judiciously observes, on the choice of flowers for borders—'The plants are arranged in mingled flower-borders, partly according to their size and partly according to their colour. The tallest are planted in the back part, those of middling size occupy the centre, and those of humble growth are placed in front. The beauty of a flower-border, when in bloom, depends very much on the tasteful disposition of the plants in regard to colour. By intermingling plants which grow in succession, the beauty of the border may be prolonged for some weeks. In a botanic garden, the same plant cannot be repeated in the same border; but in the common flower garden, a plant, if deemed ornamental, may be often repeated with the best effect; nothing can be finer, for example, than to see many plants of double scarlet lychnis, double sweet-william, or double purple jacobea.'

The Dutch, who are among the best flower gardeners in the world, have lately begun to copy the English in ornamenting turf lawns with plots of various kinds of flowers; but in all their large and regular gardens they still dispose each kind of flowers by themselves. 'We ridicule this plan,' says Hogg in his 'Treatise on Flowers,' 'because it exhibits too great a sameness and formality; like a nosegay that is composed of one sort of flowers only, however sweet and beautiful they may be, they lose the power to please, because they want variety. It must undoubtedly be acknowledged, that a parterre, no matter in what form—whether circular or square, elliptical or oblong—where all the shrubs, plants, and flowers in it, like the flowers in a tastefully-arranged bouquet, are variously disposed in neat and regulated order, is a delightful spectacle, and worthy of general imitation. Yet still, in some particular cases, I am disposed to copy the Dutchman; and I would have my bed of hyacinths distinct, my anemones, my ranunculuses, my pinks, my carnations distinct, and even my beds of hollyhocks, double blue violets, and dwarf larkspurs distinct, to say nothing of different sorts of roses. Independently of the less trouble you have in cultivating them when kept separate, you have beauty in masses, and you have likewise their fragrance and perfume so concentrated, that they are not lost in air, but powerfully inhaled when you approach them.' Leaving this question to be settled according to taste and other circumstances, we have only to recommend that no flower or herb of any kind should be sown or planted in figures resembling familiar objects. Some persons, for example, will be seen sowing annuals or planting crocuses in the figure of a letter of the alphabet, a ship, a house, a human profile, a crown, &c.—a practice so essentially vulgar that it cannot be too loudly condemned.

As to front-plots in towns and suburbs, if they be limited to a few square yards, it will be better not to attempt the growth of flowers at all, but to lay them down in green sward or clean gravel, with perhaps a variegated holly, box-tree, laurel, flowering currant, sweet-brier, rose, or some other hardy shrub, to enliven them. Nothing, however, can be more wretched than a few sickly plants struggling for a miserable existence amid the dust and smoke of a town; and a person of good taste will never attempt the growth of flowers unless he can command the requisite amount of air and sunshine. In laying out little front-plots of this description, circular, oval, oblong, and other simple forms should be preferred; for nothing looks more ridiculous than the imitation of labyrinths and intricate designs on so small a scale. A few plain forms, in keeping with the front of the building and size of the plot, may produce elegance; but intricate divisions, with lines of gravel between, scarcely broad enough for a human foot, are toyish and trifling in the extreme. Neat and simple edgings of box, daisy, Virginian stock, privet, and the like, should be preferred to showy borders, which are only adapted for large flower-gardens and ornamented lawns.

An error not uncommon in deciding which flowers shall be planted, is to select numbers merely for their rarity or novelty, without reference to what will be their appearance when in bloom, and which generally leads to disappointment. Unless for botanical illustration, make a choice of flowers on two principles—those which will be beautiful when in bloom, although common, and those which will bloom at the particular seasons required, to insure a succession of variegated beauty from spring to autumn. The true amateur gardener takes a pride in improving even the commonest flowers—urging them by careful culture to the highest state of perfection, as to size and brilliancy of colouring, of which they are susceptible in our climate.

CHARACTER AND TREATMENT OF FLOWERS.

All flowering plants belong to the division *Phanerogamia* in the vegetable kingdom; but it is only those in which the blossom is conspicuous, beautiful, or odorous, that are the objects of garden-culture. The part of the plant which constitutes the flower, bloom, or blossom, is the *corolla*; it consists of several divisions or leafy parts, called *petals*. The corolla encloses the *stamens* and *pistils*, or organs of reproduction (see VEGETABLE PHYSIOLOGY); and to bring these to perfection, so as to effect the development of the seeds, is the prime object of vegetable growth. When the seeds are perfected, or in the way of being so, the corolla languishes and dies. The design of the flower gardener is less to produce size and strength in his plants, than to cause them effectually to bloom: he wishes a fine corolla. It is proper, then, to mention, that whatever tends to give excessive vigour to the stems will prevent the formation of flower-buds; and the same result will follow from stunting or starving the plant. To induce flowering, the plant must be fully exposed to sun and air; at a lower temperature than 50 degrees the blooms cannot be expected to open; but from that to 65 degrees the sap will ascend, and the buds, if duly provided with moisture and fresh air, will be rapidly developed. When freely exposed to seasonal influences, flowering plants appear withered and nearly gone in winter; they begin to shoot up in spring, come to perfection in their bloom in summer, and languish and yield their seeds in autumn. But if treated properly in the artificial climate of a greenhouse, they will be found, after proper training, to disregard seasonal influences, and perhaps to bloom in winter or in spring.

It has been remarked that when plants have been slightly checked by frost or dry cold air, they sooner come into bloom. 'This,' says Mr Rennie in his 'Alphabet of Gardening,' 'arises evidently from the pulp being concentrated instead of being expended in the production of new leaves and branches, while perhaps part of the effect may be owing to increased excitability. On this principle the early potato, which does not flower freely, may be made to do so by removing the tubers; and, on the other hand, the tubers are increased in the late sorts by picking off the flower. The greater the quantity, then, of good healthy pulp which can be prepared by the leaves, the more really vigorous and healthy will the plant become; and as flowering and fruiting exhaust a great quantity of this pulp, and of course tend to weaken the general system of the plant, it follows that the artificial prevention of flowering must preserve in the plant the digested pulp which would have gone to nourish the flower and the fruit. Thus by pruning off the luxuriant shoots of melons, &c. the pulp induces the shoots to spring into flowers and fruit. Upon this principle is founded the practice of treating bulbs so as to cause them to bloom vigorously, by cutting off the flowering stem as soon as it appears, in some cases, and in others so as to have the blossoms evolved when placed in water, taking care to encourage the growth of the leaves by rich soil and free exposure to air and sunshine. In this way the greatest quantity of strong pulp is stored up in the bulbs, and luxuriant blossoms are produced the succeeding season. The practice, consequently, of some unskilful gardeners, of trimming off the leaves of snowdrops, crocuses, and tulips, after the blooming is over, for the purpose of rendering a border or a bed neat, is very bad; and it is not much better to tie up the leaves, as is also preposterously done, for in this way they cannot be duly exposed to the air and the light. The same principle will apply to all other flowering plants. When a flowering branch or stem has been produced, and has begun to show the flower-buds, it must be considered that it can only blow finely in proportion to the quantity of healthy pulp either previously in the branch, or from time to time prepared by the leaves of that branch. Consequently, if there are two or more flowers on the branch, each will require its due proportion of food; but if one or more of these be artificially removed, all the spare pulp will go to feed the one, two, or more blossoms which may remain. On this is founded the practice of thinning out the flower-buds from the bunches of auriculas, polyanthuses, chrysanthemums, and other plants, in order to increase the size and beauty of those which are left to expand. It is in consequence of the same principles that free exposure to air is indispensable for producing fine flowers, inasmuch as they depend for nourishment on the pulp, which without these cannot be formed. The vivid colours and pleasant odour of flowers depend on the same causes—for in the shade these are both feeble.'

Flowering plants are usually divided into the following kinds:—*Annuals*; plants which require to be sown annually, as they live and bloom only one season. *Biennials*, which do not blossom till the second season after sowing, remain a certain time in perfection, and then die; they are produced by seed, but some of the finest double varieties are continued by cuttings. *Perennials* are plants which continue for many seasons to grow and blossom annually. *Indigenous plants*; those which are natives of this country, and may have been perfected by culture from a wild state. *Exotics*; plants of foreign origin, which have been introduced into this country. The greater number of our fine flowers and fruits are exotics. Many of these have been acclimatised, or accustomed to our climate, and rendered hardy by a course of culture; but others require to exist in greenhouses and hothouses, or under glass frames, for at least a part of the year. It would appear that each region of the globe possesses plants as distinctive in their features as the different races of men. On this subject Mr Loudon remarks—'The native countries of plants may often be discovered by their features, in the same manner as the national distinctions which are observable in the looks and colour of mankind, and which are effected chiefly by climate. Asiatic plants are remarkable for their superior beauty; African plants for their thick and succulent leaves, as in the case of the *Cacti*; and the American plants for the length and smoothness of their leaves, and for a singularity in the shape of the flower and fruit. The flowers of European plants are but rarely beautiful. Plants indigenous to polar and mountainous regions are generally low, with small compressed leaves, but with flowers large in proportion. Plants indigenous to New Holland (or Australia) are distinguishable for small and dry leaves, that have often a shrivelled appearance. In Arabia they are low and dwarfish; in the Archipelago they are generally shrubby, and furnished with prickles; while in the Canary Islands, many plants, which in other countries are merely herbs, assume the post of shrubs and trees.'

The different kinds of plants generally cultivated for their blossoms are either *herbaceous*—that is, succulent, and full of juice; or *shrubby*—that is, having ligneous or woody stems. A *deciduous* tree or shrub is one which sheds its leaves every winter, and is recovered in spring. An *evergreen* is a shrub which retains its leaves during winter, but casts them in spring as the new buds come out. A *fibrous-rooted* plant is one whose roots send out small fibres; polyanthuses are examples of this section. A *tuberous-rooted* plant is one whose root forms small tubers or lumps; dahlias, peonies, ranunculuses, and anemones, are examples among flowers, and the potato among kitchen vegetables.

The prevailing colours of flowers are yellow, orange, white, pink, scarlet, red, blue, purple; and many are variegated, or composed of different tints. Proper culture, with pure air and sunshine, increase the brilliancy of the tints, and give massiveness to the corollas. Plants of a kindred species may likewise be improved by hybridising or crossing, the general principle of which is the artificial application of the pollen of one plant to another (see VEGETABLE PHYSIOLOGY, p. 80). By this means some of the most beautiful flowers have been originated. Change of soil and climate, however, are the great means of improvement. As long as it is confined to its native habitat, the corolla of the plant and all its other appurtenances are meagre and generally unattractive; but when nourished in a cultivated soil, and all its wants supplied, the whole plant strengthens and expands, and the corolla flashes on the eye with new brilliancy of colour. The changes effected on the daisy, the rose, and the violet, will here occur to remembrance, as striking instances of metamorphoses by culture and change of habitat. Speaking of the laws by which a change of colour is produced, Dr Lindley, in his 'Introduction to Botany,' observes—'A blue flower will change to white or red, but not to bright yellow; a bright yellow flower will become white or red, but never blue. Thus the hyacinth, of which the primitive colour is blue, produces abundance of white and red varieties, but nothing that can be compared to bright yellow; the yellow hyacinths, as they are called, being a sort of pale yellow-ochre colour, verging to green. Again, the ranunculus, which is originally of an intense yellow, sports into scarlet, red, purple, and almost any colour but blue. White flowers, which have a tendency to produce red, will never sport to blue, although they will to yellow; the rose, for example, and the chrysanthemums. It is also probable that white flowers, with a tendency to produce blue, will not vary to yellow; but of this I have no instance at hand.' (See No. 5, pp. 77–8).

Improvement in the brilliancy or change of colour is not effected without a certain loss in the odorous properties of the plant. It is remarked that cultivation generally renders the odour less intense, and sometimes altogether destroys it. Thus the fragrance of the wild violet is not to be found in the heart's-ease.

Propagation.

Flowering plants are propagated in various ways—by sowing seeds at the proper seasons, by dividing the root, by suckers, layers, pipings, cuttings, and bud-grafting:—

Dividing the Root.—This is one of the most simple methods of propagation. The root of the growing plant is partially uncovered, and one or more portions are removed; the root is then covered up, and the detached parts transplanted in soft earth prepared to receive them. Nine-tenths of herbaceous perennials may be treated in this way.

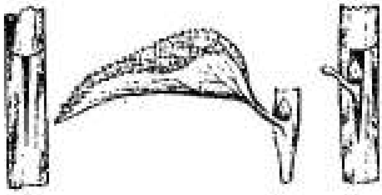
Suckers.—These are young shoots thrown up from the roots of the main plant, round which they cluster. They may be removed by taking up along with them a part of the root. They should be removed in spring, after the plant has begun growing, and immediately planted out. If any flower-buds be developed on them, take them off, so as to give strength to the leaf and root-developing principle of the plant.

Layers.—Some plants, as, for instance, strawberries, send out layers or runners along the ground; these have joints, if we may call them such, at certain points; and where any joint strikes the earth, it takes root, and becomes the centre of a new plant. Thus a running plant will speedily cover, as with a network, a large space of ground. Nothing is more easy than to propagate by causing the layers of some plants to take root. In the case of the carnation and similar plants, fix a stem at one of its joints to the ground, with a hooked stick or peg, covering it slightly with mould, and giving it a little moisture. Roots will in general strike out in a few weeks; and at the end of the season the plant is ready for being cut from its parent, and transplanted. Where layering is tedious, propagation by division of the root may be adopted.

Pipings.—Propagation by piping is an expeditious mode of raising young plants. The following is the method prescribed in a small and useful work entitled 'Every Lady her own Flower Gardener:'—'Take off the upper and young part of each shoot close below a joint, with a sharp knife, and cut each off at the third joint, or little knob; and then cut the top leaves down pretty short, and take off the lower and discoloured ones. When you have piped in this way as many as you require, let them stand a week in a tumbler of water, which greatly facilitates their doing well. Indeed I never failed in any pipings, slips, or cuttings, which I allowed to soak and swell in water previous to planting. When you plant the pipings let the ground be newly dug, and raked very fine; dibble no hole, but gently thrust each piping half-way down into the soft earth round each, to fix it in the bed. Water them often, if the weather is dry, but moderately, just to keep them moist; and shade them from the hot sun in the day. If pipings are covered with a hand-glass, they root earlier by three weeks than those which are exposed. Laying, piping, and slipping, are done in June and July. The plants will be well rooted and fit to plant out in October.' Slips are shoots wrenched off at a joint, instead of being cut, and are treated precisely in the same manner as pipings.

Cuttings are strong shoots of last year's growth, cut from the parent stem or branch, and set in the ground. The cutting should be about six inches long, and cut off slantingly and smoothly. The soil in which the cutting is inserted requires to be dry, or not too moist. Roses and honeysuckles are among the plants usually propagated by cuttings. The operation should be performed in January or February, so that the cuttings may root and vegetate in the opening of spring; but several months are required to bring the cutting to a state fit for transplanting. Some cuttings of flower-stalks may be set as late as May and June.

Budding is a method of propagation chiefly used in connection with fruit-trees; but as it is likewise applicable to rose-bushes, it may here be described. It is a species of grafting, and consists in inserting the fresh-cut extremity of a small twig or bud beneath the bark of another plant. A leaf-bud, easily known by its tapering point, should be alone selected, and not a bud on which a flower is developed. The leaf on the selected bud is to be taken off, for if it remained, it would exhaust the sap, and the bud would in all likelihood wither and die. Along with the bud, a small slip of bark is to be taken; and if this bark separate freely, it is a test of there being pulp enough to form a union. The slip of bark is to be inserted beneath the bark of the other plant, in a slit made for the purpose, and the whole tied with a strip of mat to keep out the air. The subjoined cut represents the various parts in budding: *a* is the bud cut out, with a



b a c

shield of bark attached to it; *b* the stem, with a slit in the bark to receive the shield attached to the bud; *c* the bud inserted, and the leaf cut away.

Shrubby plants are also propagated by *in-arching*; but a notice of this, and also of ordinary *grafting*, will be more appropriately given under FRUIT GARDENING.

SELECT FLOWERS FOR THE GARDEN.

Flowering plants are now so numerous, both as respects species and varieties, that a bare list of them would more than fill the present sheet. All, therefore, that can be reasonably expected from us is a few hints as to those which are most approved, and cultivated chiefly in the open air. A person with little experience should stock his garden only by degrees—a small number of different sorts every year, according to fancy, and what he finds to be the capabilities of the soil and exposure. In commencing to make a choice for a moderately-sized garden, or for still smaller plots of ground and borders, we should also recommend the plan of cultivating a mixed variety of different colours and different heights—those which are smallest being in front, and nearest the eye, and the other rows rising in height and massiveness as they recede. With as few as four colours, four sizes, and six different periods of coming into bloom, a mingled border may be established with ninety-six sorts, which will present a pleasing assemblage to the eye.

Annuals.

Some annuals are called *hardy*, and others *half-hardy*. The hardy kinds will grow and blossom in open borders, without artificial heat or protection; those which are more tender will also grow in the open air, but are improved by being brought forward under hand-glasses. Of the delicate class of annuals which must be constantly kept under glass frames, it is not our purpose to speak. The greater number of annuals may be sown at the end of March or beginning of April. The soil should be fine, and have a warm exposure; and on being sown, cover the seeds with only about half an inch of mould; peas and lupines should be an inch below the surface. If the weather be dry, irrigate with pure soft water occasionally. Take care that the seed you sow is fresh and good: the way to test its quality is to throw it into a glass of water; if it be worthless, it will swim; if good, it will sink to the bottom.

Among the vast number of annuals that offer themselves to the choice of the gardener, the following, each having varieties as to colour, may be mentioned as taking the lead in the *half-hardy kinds*:—African marigold, French marigold, China aster, marvel of Peru, chrysanthemum, sweet sultan, Indian pink, love apple, gourds, bottle gourd, convolvulus, yellow balsam or touch-me-not, amaranthus, ten-week gilliflower, white ten-week stock, cannacorus, and Chinese hollyhock. *Hardy kinds*:—Adonis-flower, candytuft, larkspur, lupines, sunflower, lavatera, poppy, convolvulus major, nasturtium, Tangier pea, sweet pea, winged pea, Lobel's catchfly, dwarf lychnis, Venus's looking-glass, Virginian stock, heart's-ease, snapdragon, mignionette, xeranthemum, purple jacobæa, Clarkias.

If annuals are required on a more extended scale, the best plan is to leave the selection to a respectable nurseryman. Such a person will at least present a copious list to make your choice from, and mention the size or height to which the plants will respectively grow. Mr Loudon, in his 'Encyclopædia of Gardening,' quotes a list by Mr Swinden, a Brentford nurseryman, consisting of nearly ninety hardy annuals, distinguished in ranges according to heights. From this we make the following extract—for the sake of simplicity, leaving out the Latin names:—

'*First Range—from 8 to 12 or 14 inches high.*

Cape marigold; purple and white. Large caterpillar; yellow, and singular pod. Venus's looking-glass; light purple. Ram's horns; yellow: the pod is its beauty. Round snails; yellow, and singular pod. Dwarf variegated lychnis; crimson and white. Heart's-ease; purple and yellow. Half-moons or moon-trefoil; white, and singular pod. Blue meadow lychnis; sky-blue. Dwarf virginian stock; purple. Small hedgehogs; yellow, and singular pod. Woodroof; light blue. Red hawkweed; pale red. Large hedgehogs; yellow, and singular pod.

Second Range—from 12 to 18 or 20 inches high.

Oak of Jerusalem; yellowish, with fragrant smell. Small white candytuft; clear white. Long-horned devil in a bush; yellow, and singular pod. Convolvulus minor; bright blue, with yellow eye. Large purple candytuft; light purple. White Lobel's catchfly; reddish white. Annual snapdragon; purple and yellow. Scarlet or wine peas; dark and light red. Large white candytuft; clear white. Striped convolvulus minor; blue and white. Red Lobel's catchfly; bright red. Dwarf nasturtium; deep orange. Broad Spanish nigella, with brown seed; deep blue. Red flos Adonis; dark red.

Third Range—from 20 to 24 or 22 inches high.

Spanish nigella, with black seed; light blue. Spanish hawkweed; pale yellow, and purple eye. Blue Moldavian balm; deep blue, and fine scent. Annual rest-harrow; pale red. Double Roman nigella; white mixed with blue. Small running nasturtium; dark orange. Nettle-marjoram; yellowish, no smell but to the over-curious. Rocket larkspur; pink and white. Sweet-scented lupines; bright yellow. White Moldavian balm; fair white, and fragrant smell. Dutch lupines; fine blue. Annual hare's ear; pale yellow. Purple jacobæa; purplish-red and yellow eye. Dutch ranunculus-marigold; sulphur-colour. Red-topped clary; pale red, and pink leaves.

Fourth Range—from 2 to 2½ or 3 feet high.

Belvidere; yellowish—a handsome plant. Small variegated corn-poppy; various, red and white, &c. Double upright larkspur; blue, blush, &c. Cyanus minor; blue, crimson, &c. Thorn-apple; white, and singular pod. Prince's feather; dark crimson. Crown larkspur; pale pink, spotted, &c. Honey scabious; pale blue, and globular pod. Portugal lychnis; pale red. Small blue lupines; bright blue. Love-lies-a-bleeding; light red. Ranunculus-marigold; deep orange. Honeywort; dark purple. Strawberry spinach; bright-red fruit.

Fifth Range—from 3 to 4 feet high.

Venetian small-flowered mallow; purplish-white. Double crimson jagged-leaf poppy; dark crimson. Tall narrow-leaf wallflower; bright yellow. Arach; deep crimson. Double striped carnation poppy; red and white. Blue sweet trefoil; lead-colour. Red lavatera; light changeable red. Branching larkspur; blue and white, &c. Tall white lupines; clear white. Double black carnation poppy; rose-colour. Small Peruvian nasturtium; dark orange. Lord Anson's peas; fine blue. White lavatera; snow-white. Dwarf double and quilled yellow sunflower; deep yellow. Bladder ketmia; pale sulphur and purple eye.

Sixth Range—from 5 to 7 or 10 feet high.

Tall double yellow sunflower, with black seed; deep yellow. Painted lady sweet-scented peas; pale red and white. Arach; sulphur-coloured. Purple sweet-scented peas; dark and light purple. Tall Indian persicaria; bright crimson. Painted lady crown peas; black and white. Convolvulus major; fine purple. White crown peas; clear white. Large Indian nasturtium; dark and light orange. Tall double brimstone sunflower; sulphur-coloured. White sweet-scented peas; clear white. Plain Tangier peas; fine crimson. Tall oriental mallow; purple. Painted lady Tangier peas; pale red and white. Scarlet beans. Curled leaf, upright mallow; white, tinged with purple.'

Whether tender or hardy, all annuals should be carefully trimmed, and kept from straggling. Some will require thinning. Preserve the strongest blossoms for seed; and remove withered and imperfect blooms, to add vigour to those which remain.

Biennials.

The difference between biennials and perennials is in many instances very ill defined. A biennial is said to be a plant which, when sown, does not bloom till the following spring, and dies out in the course of autumn. This is true as respects some biennials, but it is equally certain that many will survive and bloom year after year, the same as perennials. For instance, carnations are called biennials, although it is notorious that these plants will grow and multiply by roots in the same spot, year after year, with only ordinary culture. Another circumstance requires notice. No treatise on gardening that we have seen sufficiently recognises the power which biennials and other plants possess of continuing themselves by dropping their own seeds on the spot where they grow; by which means, in point of fact, many biennials, and annuals also, possess much of the virtue of perennials. In all treatises, far too much stress is laid on the necessity of artificial propagation. In most instances, biennial and perennial flowering plants simply die off from the top to the bottom of the stems at the beginning of winter, and the roots remain dormant in the ground till revived by the warmth of the ensuing spring. Except, therefore, as respects thinning, and propagating by a division of roots, and transplanting occasionally for the sake of change of soil, the unprofessional gardener has little or nothing to do in the way of multiplying the number of his plants, or artificially keeping up the species during winter. Of course we here refer to gardening operations in the British islands, where the winters are generally so temperate, that every kind of root is safe in the ground, excepting certain bulbs, and those of a tuberous nature, such as potatoes, dahlias, ranunculuses, &c. which the frost would reach and destroy.

Among biennial plants suitable for ordinary flower gardens are included the following, each having several varieties:—Canterbury bells, carnations, French honeysuckle, globe thistle, hollyhocks, scabius, sweet-william, rose campion, wallflowers, lavatera arborea, purple digitalis, and stock gilliflowers. Some of these are very beautiful, and none more so than carnations.

The *carnation* is an elegantly-formed flower, with a slender stem and blossom at top, each blossom consisting of a convolution of petals like the rose. As a number of stems grow up together, the show of brilliant heads is considerable. There are many varieties of the carnation, but all are arranged in three classes—flakes, bizarres, and piquettees. Flake carnations possess but two colours, with large stripes through the petals. Bizarres are variegated in colour, with irregular stripes and spots. Piquettees have a white ground, spotted with purple or some other colour, and are serrated on the edges: they are the most common. According to amateurs, the finest carnations should have a flower at least three inches in diameter, with the edges of the petals waving or smooth, not serrated. The petals must fill the calyx, but not to bursting; if a calyx burst, the flower has been imperfectly cultivated. 'The calyx,' says Hogg, 'should be at least one inch in length, terminating with broad points sufficiently strong to hold the narrow bases of the petals in a close and circular body. Whatever colours the flowers may be possessed of, they should be perfectly distinct, and disposed in long regular stripes, broadest at the edge of the lamina, and gradually becoming narrower as they approach the claw of the petal. Each petal should have a due proportion of white, one-half, or nearly so, which should be perfectly clear, and free from spots. Bizarres, or such as contain two colours upon a white ground, are esteemed rather preferable to flakes, which have but one, especially when their colours are remarkably rich and very regularly distributed. Scarlet, purple, and pink, are the three colours which predominate in the carnation. When the pink flake is very high in colour, it is customary to distinguish it by the appellation of rose flake.'

The following, which we copy from an agreeable horticultural treatise, 'The Manse Garden,' are the plainest directions we have seen respecting the culture of carnations:—'The best soil for carnations is good loam, enriched with well-rotted stable dung, and quickened with a little sand. The quantity of manure can only be determined by the previous strength of the ground: if made too rich, the flowers will lose their fine colours; if left too poor, they will want vigour. No recent manure should ever come near a fine plant. Let the ground be prepared before winter with dung, and a rough furrow laid up to the frost. In April give a fresh digging, and plant in rows three feet by two. This width is to make room for layers, without which a fine blow of carnations cannot be maintained above one year. As the plants shoot up, they must be tied to neat green rods; and in order to have a fine blow, superfluous flower-buds must be pinched off, leaving only three or four to each stem. The young shoots near the ground, which do not run to flower, are denominated grass; and from these the layers are selected. The operation is somewhat nice, but when rightly done, is always successful, and good flowers are thus preserved and multiplied from year to year. Towards the end of July, stir up the ground about the plants, and mix with the soil a little old well-wrought compost. Have at hand a sharp penknife, a trowel, and a number of small pegs with an angle at the head: pieces of fern will do, or wood of no more strength than to bear pushing into the ground. Scoop out the earth in the form of a basin around each plant; select the strongest grassy shoots for layers, and remove such as are in the way; crop the top leaves an inch from the heart, and pinch off all the rest, taking care not to peel the stem. Begin an incision on the under side of the shoot, a little below the second joint from the top, and cut upwards till the joint is slit in the middle. Set the pointed extremity made by the slit into the bottom of the excavation, and there fix it with the peg; place the head of the shoot erect, fill in the earth, make it firm, and finish the work with a good watering. The young plants will be ready for removal by the end of autumn, when they may be set in flower-pots if the soil is too damp, and apt to cause rotting in winter; but if sufficiently dry, the layers may remain till spring, and it will be of use before winter to earth them up, sloping and beating the mould about them so as to throw off the rain. Although the propagation of this plant by pipings (as the grass shoots taken off and stuck in the ground are called) is by no means so sure as the above method, yet of a number some will take root; and as pipings are more easily procured than plants, the experiment may be made. If carried to some distance, steep the slips in water till they swell to their proper size; trim them as above directed, and set them firm into old elastic compost; water plentifully, and set over them a hand-glass, first throwing water on the glass, and then earth to darken it, and let it not be stirred for some days, it being found that a deficiency both of light and air promotes the striking of slips—probably on this principle, that the sick, having no appetite, must avoid the exertion which requires food as well as that which food requires.' We may add that carnations require room to expand and blow; and when fully grown, the stalks should be tied with a strip of bast to a small stake thrust into the ground at their side.

The *hollyhock* is a splendid flowering plant, and exceeds all others in tallness. With good soil, shelter, and proper exposure, it will attain a height of twelve or fourteen feet, and generally reaches seven or eight. It is a substantial herbaceous plant, with a thick stem, along which, to the top, are the broad showy blossoms; and from this attractive appearance it is very suitable to ornament fronts of cottages, edgings to shrubberies, or the centre of clumps in lawns. The colours are very various, as pink, dark purple, yellow,

&c.—the double sorts being the richest and most esteemed. The seeds of hollyhocks are sown in May; and in September or October the young plants are transplanted into the ground where they are intended to blossom. Although classed as biennials, the plants will spring and bloom for a number of years.

Wallflower.—There are several sorts of this fragrant plant, those flowers which are dark and most massive being most highly esteemed. Every cottage-garden should have two or three wallflowers, as their perfume is very pleasing, and their culture no way troublesome. 'To insure,' says the author of the 'Manse-Garden,' 'a succession of the best breed (and the method applies to the double flowering, which yields no seed, and cannot otherwise be preserved), about the beginning of July pinch off a hundred slips or young shoots of five or six inches in length, taken only from the finest stocks; crop the leaves, and strip the rest of the stem bare; dibble the slips so prepared into a bed newly dug, and shaded by trees or a north wall. Sprinkle them with water, and shade any part to which the sun has access. Not one will go back; and in this way a profusion of one of the sweetest flowers, and the best of its kind, may be had from year to year.'

From what are usually called biennials, we turn to the copious list of *perennials*, which may very properly be sectioned into those with bulbs, those with tuberous roots, and those with fibrous roots—the latter by far the most numerous, and including plants of a herbaceous and shrubby nature; to these may be added climbing and aquatic plants.

Perennials—Bulbs.

In this class are included the hyacinth, narcissus, iris, lily, tulip, snowdrop, crocus, and others:—

The *hyacinth* has a tapering bulb, shoots up long green leaves, and in the centre is a stalk on which the bloom, in the form of bells, grows all round, causing it to droop or bend. There are several varieties, differing in colour—as blue, red, and white; but the blue is the most common. The hyacinth is a favourite of the Dutch, by whom it has, like the tulip, been brought to great perfection. The best kinds have double flowers with brilliant colours. A sandy soil and saline atmosphere, with a warm exposure, are favourable in developing these properties. In the British islands they will endure the winter in the ground, and are among the earliest blossoming plants of spring. In Holland, the bulbs are lifted and carefully stored during winter.

Of the *narcissus* there are many varieties, which include daffodils, white narcissus, jonquils, and polyanthus narcissi. The chief difference is in colour and size of petals. Most have a lightish-yellow flower, with a deeper yellow cup. A fine narcissus has tall and firm leaves, and from the centre springs the round tube-like stalk, on the top of which is the bright yellow bloom, with petals spreading out like rays from a star. Some send up two flower-stalks; and the criterion of excellence is massiveness and distinctness of colour in the corolla. Of the polyanthus species there are at least a hundred sorts, sulphur-coloured, single and double, white, &c. Like hyacinths, the bulbs may remain in the ground during winter.

Of the *iris* there are various sorts, some low, and others tall, but all of them beautiful from the delicacy of colour. The Persian iris is low, with delicate blue and violet blossoms: the Chalcedonian is taller, and distinguished by the great size and magnificence of its flower, which is a purple-blue striped with white: the English is of still greater height, and has flowers double the size of the former. None requires much sun.

The *lily* is a plant equally tall with the larger iris. There are many species, with different colours—white, orange, and carmine. The orange, speckled with dark dots, is the more common. This plant will grow and bloom with little sun, or under the shade of trees. The effect of the orange blossom is pleasing among green plants which require to be set off by a contrast.

The *tulip* is the pride of the garden, or at least stands pre-eminent in general estimation. Like most other bulbs, it is a native of the Levant, and was brought to its perfection in Holland, where tulip-fancying was at one period a mania, and the bulb is still a large article of trade. The finest tulip-gardens are at Haarlem, which has a warm and saline climate, with a soil light and rich. Round the roots and over the beds sand is freely scattered, so that the tulips seem as if growing from a sandy beach. In planting in this country, follow the same practice. Before planting, take off the brown outer rind. Plant in October, or early in November, so that the plant will blossom in April. In forming a bed of tulips, the bulbs should be set at a distance of seven inches apart, and in straight rows, taking care to mix the different colours. To raise from seed, or to improve the varieties by crossing, are works of time, and not to be thought of in ordinary circumstances. Bulbs can be obtained from nurserymen at a price ranging from five shillings a dozen to five guineas a bulb. Half-a-crown each is a common price for tolerable bulbs; but of course all depends on taste. The following is Hogg's criterion of a fine variegated late tulip:—'The stem should be strong, elastic, and erect, and about thirty inches above the surface of the bed. The flower should be large, and composed of six petals: these should proceed a little horizontally at first, and then turn upwards, forming almost a perfect cup, with a round bottom, rather widest at the top. The three exterior petals should be rather larger than the three interior ones, and broader at their base: all the petals should have perfectly entire edges, free from notch or serrature; the top of each should be broad and well rounded; the ground colour of the flower, at the bottom of the cup, should be clear white or yellow; and the various rich-coloured stripes, which are the principal ornament of a fine tulip, should be regular, bold, and distinct on the margin, and terminate in fine broken points, elegantly feathered or pencilled. The centre of each leaf or petal should contain one or more bold blotches or stripes, intermixed with small portions of the original or breeder colour, abruptly broken into many irregular obtuse points. Some florists are of the opinion that the central stripes or blotches do not contribute to the beauty and elegance of the tulip, unless confined to a narrow stripe exactly down the centre, and that they should be perfectly free from any remains of the original or breeder colour. It is certain that such appear very beautiful and delicate, especially when they have a regular narrow feathering at the edge; but the greatest connoisseurs in this flower unanimously agree that it denotes superior merit when the tulip abounds with rich colouring, distributed in a distinct and regular manner throughout the flower, except in the bottom of the cup, which should be a clear bright white or yellow, free from stain or tinge, in order to constitute a perfect flower.'

In order to have tulips in anything like perfection, they require a vast deal of care. As strong sunshine injures them, they must either be placed in some shady situation, or covered with a slight awning from the sun's rays. They must also on no account be allowed to go to seed, for in that case the bulb is exhausted and done. To prevent this catastrophe, they should be watched when they approach perfection, and the head and stalk cut off. A usual signal for cutting is when they cease closing at sunset, or when the edges of the petals exhibit the slightest appearance of withering. They should be cut rather too early than too late. After cutting, admit the sun to the stems; and when these wither, which may be in June or July, lift the bulbs and lay them aside in a dry airy situation; there let them remain till the period for planting, which is the end of October or beginning of November. If the bulbs require to be sent to a distance, twist each separately into a piece of paper; in this state, and kept dry, they will remain dormant, yet fresh and ready for planting, for several years.

The *crocus* and the *snowdrop* are two small bulbous plants, so well known for their hardy growth, that little need be said of them. Crocuses are very various in colour—blue, yellow, white, and so forth; and the principal thing in planting is to dispose these colours in a pleasing variety. When the bloom withers, remove it, but do not cut away the numerous small green leaves. Crocuses, like other bulbs, require occasional transplanting: this may be done in October.

Perennials—Tubers.

In this group the *Dahlia* (named from Dahl, a Swedish botanist), both from its beauty and size, deserves the first place. It is a native of the temperate plains of South America, and requires a dry and airy situation for its growth. The tubers at the root resemble long potatoes, and as they spread to some distance, the plant should have a free space of from two to three feet all round. The stems, at and near the top of which are the rose-like blossoms, rise to a height of four feet, and require to be supported by stakes. A new plant may be procured by separating a part of the root, to which a stem is attached. Frost at once blights the green stalks; and when these seem utterly withered and dried, carefully lift the tubers and place them in a dry situation for the winter. In May they must be sprung on old manure under a glass frame, and then planted out and occasionally watered. Dahlias are now found of almost every colour—the *Acmé*, a white variety edged with crimson; Amanda, rosy lilac; Ariel, white and lilac; Augusta, purple; Countess of Liverpool, scarlet; enchantress, creamy-edged cherry; Lord Althorp, dark puce; yellow perfection; peerless white; and so on—every year adding its novelty.

The *ranunculus* is a stock beauty in all gardens, and it has some hundreds of varieties. The tubers are small, and require to be treated like those of the dahlia. The blossom resembles a compact small rose of a flattish form. The soil in which the plants are placed requires to be fine and in good heart. In planting ranunculuses and dahlias, the colours should be arranged so as to produce an agreeable variety.

The *marvel of Peru* is a very fine tap-rooted plant, rising to a height of two or three feet, and bearing beautiful transient flowers, differing in colour, as pink, white, and yellow, according to varieties. There is a succession of blossoms daily, the old ones dropping off and a new set advancing. In its native climate, the blossoms do not open till after the heat of the day is over, about four o'clock; the plant is therefore viewed as a kind of time-measurer, and is sometimes called the *West India four o'clock*.

Fibrous-Rooted Perennials.

The genera, species, and varieties of flowering plants with fibrous roots include the greater part of vegetable productions. A few of those most prized are all we need notice. Take, first, the humble *daisy* (day's-eye), which has been cultivated up from the wild *gowan* or daisy, the 'wee modest crimson-tipped flower,' and is now found in two principal varieties—the mottled crimson and white, and the pure crimson. This plant is the hardiest of the herbaceous tribe, keeps longest in bloom of any, and may be propagated to any extent by simple separation of roots.

Pinks are another universal favourite; they may be viewed as an inferior kind of carnation, and are divided by florists into the three classes—damask, cobs, and pheasant's-eye. The criterion of a fine pink is clear white petals, laced with crimson-purple, and finely serrated on the edges. The branches of stalks require tying to stakes; and they should be cultivated, so as, if possible, to avoid bursting the calyx.

The *primrose* family includes several pretty flowering plants—all, as is believed, sprung and cultivated up from the wild primrose (*primula vulgaris*) and cowslip. There is no great beauty in the primrose as a garden plant, but it is useful as an early spring flower, and succeeds the crocus in giving colour to the borders. The highest cultivated of the race is the *polyanthus*, which sends up stems loaded at top with a bunch of peduncles brown, red, and yellow. The colour most admired is that shaded with a light and dark rich crimson, resembling velvet, relieved by a bright golden hue. The *auricula* (*primula auricula*) is a larger plant, but varying in colour, and more delicate in many respects. It flourishes best in rich soil from old turf and rotted cow-dung. The chief colours are red, pink, crimson, white, blue, apple green, and mulberry. On the petals there is a fine meal, which is injured and marked by drops of rain or artificial irrigation; and therefore flower fanciers take care to shelter the plants with frames, and allow no drops from the watering-pot to touch them. When treated with attention, a bed of auriculas may be rendered very beautiful.

The *anemone*, when double, is a pretty flower, with a number of flattish petals forming a cup, in the centre of which is a great number of long small petals clustering over each other. The *lobelia*, in its different varieties, is a fine tall showy flower; that which is most common is the cardinal flower, with splendid scarlet blossoms. The *lychnis* is another pretty scarlet flower, but small in size. The *sweet-william* is deserving a place in every garden; it may be had of various colours, shading from deep crimson to light pink. The *campanula*, or pyramidal bell-flower, in its different varieties, blue and white, is a graceful flower, with pendant bells, which should also be found in all tastefully laid out borders. It may be kept long in flower, by cutting off the blooms as soon as they begin to wither. The large herbaceous *peony*, with its brilliant and deep crimson disk, is another choice flower; it requires little care beyond supporting with stakes.

The *violet* family, which now embraces what are termed *heart's-ease* and *pansies*, is a cultivation from the original wild violet (*viola odorata* and *viola tricolor*). By the French, the cultivated violet or heart's-ease is called *pensée* (thought); hence our name *pansy*. No flower in the garden has lately engaged so much attention as the heart's-ease; and by means of culture and hybridising it has attained a most extraordinary degree of perfection as respects size and richness of colour. We cannot do better than offer the following intelligible directions on the subject from Harrison's 'Floricultural Cabinet':—'The most approved method of propagation is by taking off young slips in the autumn, which is the best time, as then the ground and weather are most suitable for the formation of rootlets, on account of its dampness and dulness. About the first week in October a bed is prepared of light but rich soil, raised a little above the path, in order to drain off all superfluous moisture. The cuttings are then made ready, by stripping them of their under leaves, and cutting close below the bottom joint, from which the roots must spring; for if this is not done, the cutting will decay to that joint, which frequently destroys the whole. After the bed is prepared, the cuttings are arranged according to their varieties, each sort being marked by a tally-stick, numbered or named according to the pleasure of the owner. The cuttings will be found to be well rooted in about six weeks, when they may be planted out for blooming in the spring, or potted to keep over winter in a frame.

The soil in which the pansy is found to flourish best is a compost of cow-dung one-half, fresh loam one-quarter part, leaf mould one-eighth part, and coarse sand one-eighth; but peat soil should on no account be intermixed, as it burns up the pansy completely. These ingredients should be well mingled together, and purified from worms and slugs by having lime-water frequently thrown over the heap, and in a short time it will be fit for use. The situation best adapted for the heart's-ease is one which is sheltered from the mid-day sun, but which receives a little in the morning, as it is then not so powerful as to injure the colours. Transplanting may be performed at any season, but in doing so an error is prevalent. We see the plants taken up with a ball of earth around them, and planted again with it. Now, as everything deteriorates the soil in which it grows, and as the pansy entirely pierces every particle of earth its roots can reach, therefore that which we take up with it must be entirely exhausted. When replanted, the pansy can receive very little food from its new situation, as its roots do not by nature struggle far from the stem. To prevent this starvation, it would be much better to wash away all the soil from the roots, and replant the flower with its roots unconfined; then it would be able to seek food for itself abundantly, and thereby produce much larger blossoms.

The following list contains some of the best varieties in cultivation:—Argo, Augusta, Anne Eliza, British Queen, Colonel Dundas, Captivation, Dandie Dinmont, Eclipse, Feronia, Haidee, Henrietta, Imogine, Jewess, Livia, Laura, Magnet, Miss June, Miss Towers, Paul Pry, Peter Dick, Platonia, Penelope, Queen of the Whites, Reliance superb, Triumph, Victoria superba, Wycomb Abbey, Westminster Abbey, Windsor Castle, White Perfection, Liberal, Acme of Perfection, Ringleader, Revenge, Victory, Miss May, Glory of North Durham, Beauty of the Wear.' To this we may add the Fair Maid of Perth, and Lord John Russell.

Shrubs—Evergreens.

Among these the *rose* unquestionably deserves the first place, having from time immemorial been a favourite in every garden. There are some hundreds of species and varieties of roses, among which are included China roses, hardy climbing roses, moss roses, select double Scotch roses, red and white roses. The China rose is delicate, with few petals in the flower, and yields a succession of blossoms monthly through a great part of the year; it is hardy, and is green and flourishing in winter. Among red roses, the moss rose is the most beautiful, and next it may rank the cabbage rose; but both are excelled in fragrance by the leaves of the *sweet-brier*, a rose shrub, which, for the sake of its delicious odour and hardy green leaves —a thing of moment in making up a bouquet—should have a place in every garden. All kinds of rose-bushes are exhaustive of the soil, and should be frequently manured, if not transplanted to fresh mould. In order to keep them in bloom, cut off all blossoms which seem about to wither. The branches require careful pruning. For adorning the walls of summer-houses, cottages, &c. the *honeysuckle* excels, and should, both for its beauty and fragrance, by all means have a place in every garden, however humble. The honeysuckle is a *twining* plant, and has a tendency to climb in a spiral direction from right to left, which requires to be accommodated. The *hop*, which is sometimes grown in gardens, and allowed to climb on tall poles, twines in an opposite direction, or left to right, or with the sun, and this peculiar tendency also must not be frustrated, but assisted by strips of bass. In point of massiveness of green surface, the honeysuckle is surpassed by the *jasmine*, a tall running shrub, growing up in numerous branches, which, being well covered with small narrow leaves, is very suitable for leading up to verandas or concealing pieces of wall. It does not adhere, and requires nailing; when carefully treated, its massive green and elegantly-drooping small branches have a pleasing effect. *Ivy*, the most pertinacious of climbing plants, will grow almost anywhere, and only requires pruning to keep it within bounds every winter or spring.

Among the various tall bushy shrubs most appropriate as an ornamental background in gardens, are the different species of laurustinas, azaleas, rhododendrons, and lilacs. The *laurustina* yields a plenteous crop of small variegated blossoms. The *arbutus* is likewise a beautiful shrub, but more suitable as an embellishment in lawns; it has small whitish bell-shaped flowers, and yields a strawberry-like fruit in warm exposures. Perhaps all out-of-door exotic shrubs should yield the palm of beauty to the *ribes sanguineum*, a plant profusely adorned with small red blossoms, which appear in spring. It resembles the common currant, and matures its berries in our climate.

Evergreens constitute a class of shrubby plants, more suitable for the ornamental front-plots of dwelling-houses, or for approaches and lawns, than for gardens; because although the green of the leaves is pleasing in winter when other vegetation is dead, these plants are very exhaustive of the soil; often prevent the sun from getting to the borders; and keep the ground in a litter with fallen leaves at a time when trimness is expected. Many species of evergreens are now cultivated in gentlemen's grounds; but those which are most generally esteemed for ornamental plots or other limited situations, are the various tribes of *laurels*, *alaternus*, *arborvitæ*, *holly*, *juniper*, and *box*. With proper care, any of these may be lifted and transplanted into situations more agreeable to the eye, either at the beginning of September or May, when young shoots are preparing to burst forth. The plan is to dig all round them, at a distance equal to the compass of the branches, sinking the trench to a point beneath the sole of the plant; then lift them bodily with the whole mass or ball of earth round the roots. A pit must be prepared for the reception of the ball, and when placed in its new situation, fill in the rest of the pit with fine earth, laying the rootlets straight, and packing in all neatly to the surface. A copious stream of water must now be poured from a watering-pot upon the newly-placed mould, round the stem; this carries the particles of earth to the rootlets, surrounding each with its proper nourishment, and giving solidity to the whole. If likely to be exposed to winds, the plant should be supported till thoroughly rooted in its new abode.

Concluding Remarks on the Garden.

The preceding are the principal flowering plants, annual and perennial, herbaceous and shrubby, usually grown in open gardens in Great Britain; and we now wish to impress on the minds of the unprofessional flower-culturist three main principles which should govern his labours:—1. Let him, by every reasonable attention to soil, culture, and other circumstances, endeavour to produce the finest corollas of which any given flower is susceptible: 2. Produce these flowers only in their proper season, and throw away as little time as possible in forcing blooms at unnatural periods: 3. To maintain a garden as far as possible in continual beauty, try to keep up *successional variety*, for in that is exhibited the experience and foresight of the gardener. The directions given in the foregoing pages, and in the floricultural calendar appended, it is hoped will assist in leading to this arrangement, on which so much beauty depends; and as a farther aid, we offer the following hints furnished by a correspondent to the 'Gardeners' Chronicle:'—' It is the desire of every one who possesses a garden, to have as much variety of colour and succession of gaiety throughout the season as the situation and means of the possessor can accomplish; yet in viewing most gardens, even where expense is not an object, borders devoted to the cultivation of particular plants may frequently be observed to be attractive only when such plants are in blossom, and looking bare, if not unsightly, after the bloom is over. Supposing equal skill in the cultivation of plants in general to exist among gardeners, the great superiority in effect of one garden beyond another consists in the distribution and arrangement of the plants themselves, so that a succession of blossom, and a due contrast of colour should, where practicable, keep every border furnished even to the end of autumn. In this respect most gardens are deficient. Succession is not attended to, except for the more limited space and favoured spots near the mansion, or in front of the conservatory. In most gardens it is considered sufficient to keep any border where plants have blossomed free from weeds and neatly raked. To the mind of the gardener this border tells its own history, of the beauty of which he had boasted but a few weeks since; but the visitor or casual observer who walks through the garden, only seeking to please his eye with varied gaiety, makes no allowance for the past which he has not seen; and remarks, that though some parts are beautiful, a great portion of the ground has nothing worth looking at.

By the subjoined method, the comparative gaiety of the scene may be kept up, and a relief to the eye, not without interest to the observer, preserved. Mix the seeds of the following well-known annuals:—

Mignonette,	Heart's-ease,
Carnation poppy,	Clarkia pulchella,
Papaver amœnum,	Do. white,
Dwarf Dutch poppy,	Godetia of all sorts,
French poppy,	Antirrhinum majus,
Branching larkspur,	Do. sparteum,
Eschscholtzia Californica,	Do. versicolor,
Do. crocea,	Collinsia bicolor,
Campanula speculum,	Coreopsis tinctoria,
Candytuft, varieties,	Convolvulus minor,
Nasturtium,	Gilia tricolor, and other species.
Centaurea Cyanus, various.	

Then let this mixture of seed be very thinly scattered upon the borders early in the spring; it need not interfere with any ordinary work on the borders that may be required afterwards; and in places where the ground may be disturbed, many of the seeds will only appear at a subsequent period, and consequently flower later in the autumn. Most of these annuals will continue flowering until the frost kills them, and if not removed too soon, will leave behind them sufficient seed for years to come. Every gardener has remarked the strength, the beauty, and the effect of single plants of self-sown annuals that spring up occasionally in a flower-border, and have escaped that destruction which the merciless hoe, in the hand of the undiscriminating labourer, inevitably entails upon them; yet if the intelligent labourer is properly instructed, he will soon learn to confine his extermination to weeds, and his skilful eye will spare the annuals at proper intervals.

One case yet remains of much consequence to present as well as to future effect, though generally but little attended to: this is the frequent examination of all annuals as they expand their first flowers, and the pulling them up, unless in habit, form, and colour, they are fit to remain for stock. Crowded as annuals generally are in the patches sown in gardens, their true character and beauty are seldom seen; and if among the mass sown some few blossoms appear more striking than the rest, and the seed of these is considered more worthy of preservation, it is generally too late to take away the worthless without destroying the plants most desired; and the seed so saved from the most select variety is but little better than that from any of the other plants.

The system now recommended gives the advantage of separation and a power of selection, with the certainty that a selected plant will, by its position as a single plant, not only blossom in beauty and vigour, but afford that abundant harvest of good seed which will amply repay in future years the trifling care thus proposed to be bestowed upon it.'

Garden-Walks.—In the previous sheet on the KITCHEN GARDEN we recommended walks to be three feet broad, laid with gravel, bedded on hard cinders, and edged with dwarf-box. As an improvement, some place a bed of stones beneath the cinders, or at least the upper gravel, and on this point all must, less or more, be governed by circumstances. Where it can be afforded, asphalte pavement may be employed instead of all other materials. In the neighbourhood of London, where fine yellow Kensington gravel can be obtained at little cost, it is largely employed, and forms a beautiful walk, the yellow contrasting finely with the green of the plants. On the subject of garden-walks and borderings, the author of 'The Manse Garden' offers the following recommendations, in which we unite:—' In making walks amongst shrubs and flowers, dryness and variety of edging are the chief things to be promoted—there not being here, as along a fruit wall, for the sake of the trees, any scruple as to the burying of stones, and there ought to be none as to the trouble of a two-feet excavation; for every cart-load of earth so saved is worth money, and the convenience of depositing stones in place of the earth will save a great expense of carriage. Box, though tiresome, if there be no other, is by far the best edging for general use; but the planting of it is often bungled, or done at a needless expense. Take up with a spade a portion of the edging that has grown too old, and part the roots: one yard of the old will serve for ten of the new—a supply that is not obtained from the nurseries without cost. In parting, tear all the old bush down into the smallest shreds; throw away every one that is thicker than a crow-quill, and cut off all the roots beneath the uppermost tier of fibres; a single fibre is enough; with none the plant may do, but it is not necessary to try it. The plants so trimmed should be about four inches in length. Having filled the excavation with stones, all to four inches left for gravel on either side of the walk, dig the surface, set the line to a nicety, using many pins at every turn, to make the windings easy; bring the level exactly to the line, and beat all smooth and firm, so that the earth may stand cutting. With a trowel, cut by the line to the depth of three inches, pulling the earth towards the walk, and lay the green tops of the plants to the line, setting their heads above it, not more than one inch, and all touching one another. The roots will vary a little in depth, but let a few plants be held exact at the top with one hand, whilst the earth is applied to the unequal roots with the other. The reverse rule of evenness, providing for the roots and not the tops, is frequently adopted; hence the straggling appearance that ensues—some leaning out, and others in; some set like a tree, having a stem from which branches proceed, and others having branches sunk up to the middle. Box may be planted in September, October, or November; in February, March, or April. To wet clay, brought up by new trenching, coal-ashes may be added; and to avoid rotting by moisture without growth, the plants may be set in May.

For other edging, sea-pink is very good, but it soon gets deformed with blanks, unless taken up and replanted: whereas box, annually clipped in autumn, will serve for the half of a lifetime. London-pride admits of paring, and will last for five years; coarse polyanthus or primrose does well beneath trees. Should the root of an old tree come in the way, it is easy to keep up the green line by planting periwinkle, which needs little soil, or ivy at some distance, and leading the runners past the tree, where they will take root all the way, and being clipped, make a handsome appearance. The propensity of ivy to run up the tree is easily counteracted; but should it be indulged, few things are more beautiful, and the tree is there rather for ornament than for the value of its timber. Double-daisy and cowslips may be used, and may be kept any length of time by occasional lifting and parting of the roots. Hepatica, blue and red mingled, make a beautiful edging, and will last an age: but the most brilliant of all is dwarf gentian; it lasts long, but must have half a foot in breadth, to secure plenty of its bright sky-blue flowers. The pansy or tricoloured violet is also fine, but must be replanted every year. For any place where the walk gets amongst high shrubs or trees, or where a sloping bank is of difficult keeping, there is nothing so fit for a low hedge as butcher's-broom; it suffers no injury by drip or shade, and grows immovably strong; and not agreeing with the shears, it is in such a place more suitable in the natural sluggishness of its growth.'

PLANTS FOR THE GREENHOUSE, &c.

These are of various kinds, both herbaceous and shrubby, and require to be distinguished from the preceding only because they are exotics, too delicate for open-air exposure in all weathers, and require to be kept in a temperature above the freezing-point. This is done by placing them in a conservatory or greenhouse, which is a light fabric, covered with glazed frames, and, if necessary, heated a slight degree in winter by means of flues or pipes of hot water. The most approved situation of a greenhouse is against a wall with a southern exposure; and, if possible, placed in connection with a range of artificial vineries or hot-houses. In many instances a conservatory is connected in a very agreeable way with the parlour of a dwelling-house, by which its beauties are enjoyed without the trouble of going out in bad weather or during the inclemency of winter. All the plants are in pots; and whenever it can be done without risk of injury, the frames are opened, and free exposure permitted. At the country seats of various English noblemen conservatories are formed on a magnificent scale, so as to allow the free growth of even tall trees, such as the palm and other large tropical plants.

The most beautiful greenhouse flowers usually cultivated are camellias, geraniums, fuchsias, orchids, and those of the cactus tribes, to which has lately been added the *Azalea Indica*. The camellia, or *Camellia Japonica*, is a woody shrub, yielding splendid rose-like flowers, of colours varying from white to red. The geranium is a well-known herbaceous exotic, with clustering bunches of flowers of different colours. The fuchsia, introduced from Chili, is a handsome shrub, of different varieties, yielding exceedingly beautiful flowers, of a bright crimson hue; and the manner in which these flowers depend from the branches, like drops of ladies' earrings, has a singularly graceful effect. The cacti are an interesting kind of exotics, distinguishable by their thick and substantial leaves or fronds, on which usually grow small and sharp prickles; the flowers are splendid. Besides these, we may enumerate, either for their great beauty of blossom or fragrant odours, the nerium, jasminum, gardenia, daphné, heliotropium, acacia, mimosa, eucalyptus, diosma, gnidia, xeranthemum, bignonia, passiflora, amaryllis, gladiolus, and calceolarias; the latter very beautiful, and suitable for open air in summer.

An airy parlour or drawing-room, with windows facing the sun, may be considered a domestic greenhouse; and these apartments, as is well known, may be furnished with flowering plants, which will bloom and thrive if certain precautions be adopted. Flowers of nearly every kind may be thus treated, and made to form an elegant ornament, and means of delightful recreation in a dwelling-house. According to their nature and size, they are planted in earthenware pots, or small wooden tubs or boxes, filled up with the appropriate mould, which requires occasional renewal, at least in part, with the removal at the same time of the outer rootlets. Bulbous plants will grow and blossom in glasses filled with water; but the plants are necessarily weakened by the process. The glasses should be dark-coloured, for roots are injured by light.

On the subject of the cultivation of flowers in windows we find the following useful observations in the 'Gardeners' Chronicle:'—'The three principal things requiring consideration are *air*, *light*, and *moisture*. Plants kept in windows naturally extend their branches and leaves to the light, and they thereby become one-sided; and it is wrong to endeavour to make them otherwise by frequently turning them, as the plants will as constantly turn their growth to follow the light, which not only weakens them, but spoils their appearance. As for plants receiving no perpendicular light, it is more natural to spread them out, forming one good face or tier of healthy foliage to the window; for well-balanced heads under such circumstances are almost out of the question. Place them as near the glass as possible; of course windows having a south aspect possess the greatest advantage.

Judicious watering of plants in rooms is perhaps the most important feature in their management; and it is unfortunately in most cases ill understood, being too often given mechanically, as it were at stated times, whether required by the plants or not; and by a too eager desire for their welfare, they are frequently surfeited to death with water, which is justly termed "killing by kindness," and is practised with success, especially by ladies, from a false apprehension of their wants. In summer, this cannot be easily accomplished, unless the plants are allowed to stand in saucers constantly filled with water, which, by overloading them with juices, will soon engender sickly soft growths, unsuited for the production of flowers or healthy foliage. An exception to this rule is the growth of annuals in pots during summer: they, if well drained, may stand in feeders; but these, whenever used, should be half-filled with fine gravel or sand, which may be kept in any state of moisture. The best and only general rules that can be adopted are—in *winter*, keep plants not then growing fast rather dry; in *spring*, increase the quantity with their activity and the sun's power, keeping them in a medium state of moisture; in *summer*, water daily; and in *autumn*, decrease with the length of day and the returning torpidity of the plants, until the dry state of winter is again reached. All this resolves in the following:—Plants, when growing fast, may have free supplies of water, which must be lessened as their growth approaches maturity, and cease, or nearly so, when that is attained, until the return of their growing season. As regards *air*, similar rules to those given for watering may be followed; and indeed they are analogous. In *winter*, when the plants are not growing, large supplies of air are not so important, enough being usually given by the room door. As *spring* advances, increase the quantity, carefully guarding against the cold of mornings and evenings, or cutting winds; and if the plants are placed out in the middle of fine days, take care to bring them in before the chill of evening comes on. After the first or second week in May, they may be set outside for the summer; and towards the end of September, or as soon as heavy cold rains occur, they should be placed again in their quarters for the winter, setting them out of doors when fine, or supplying them with plenty of air by the window, until the cold weather and decrease of moisture at the roots bring them to a state of comparative rest. It should be remembered in spring and autumn that the plants must not go out to-day because they were placed out yesterday, but the weather alone must determine: sudden changes must at all times be avoided. The leaves of plants act as lungs, by which they breathe; if they become dirty, their respiration is impeded; therefore an occasional careful sponging will be useful to them. In spring and summer allow them the full benefit of genial showers, which will do them more good than any artificial watering. Never use spring water if soft or rain water can be had; and always let it be about the same temperature as the air in which the plants are growing. It should hardly be necessary to mention the removal of decaying leaves and flowers; the last are exhausting as well as unsightly.

One principal potting is usually required, and afterwards as often as the plants may fill their pots with roots, or seem to require it. The most important thing is good soil, which, if composed of three parts loam of a fibrous open texture, with a fourth dung, most plants will thrive in, using plenty of drainage to allow water to pass off readily. Never suffer the surface-soil in the pots to become hard or moss-grown, but let it be loosened occasionally with a piece of stick.

Succulents are well suited for growing in rooms, as they are not so impatient of either air or water as most other plants; and the abundance of their beautiful flowers renders them objects of interest. Cactus speciosus, Jenkinsonii, flagelliformis and speciosissimus, mesembryanthemums, and flowering aloes, deserve especial notice.'

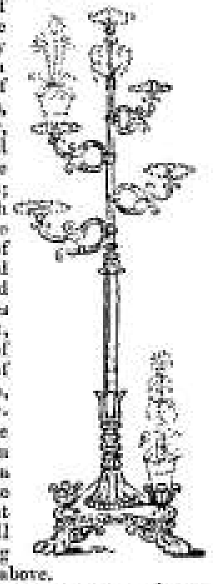
To the foregoing is added the following list of flowers for pots, with the period of their blossoming:—'*Spring*.—Snowdrops, Russian violets, early tulips, crocus, narcissus, hyacinths, heart's-ease, mignionette, mimulus, moschatus, ranunculus, anemone, myrtle. *Summer*.—Pelargoniums, mignionette, ten-week stocks, China roses, double wallflowers, pinks, carnations, cactus, aloes; annuals, as nemophila, schizanthus, collinsia, &c.; myrtle, heliotrope. *Autumn*.—Pelargoniums, lobelias, campanulas, salvias, hydrangeas, verbena, fuchsias, petunias, calceolarias, myrtles, heliotrope. *Winter*.—Chrysanthemums, pelargoniums, heliotrope, myrtles, fuchsias, aloes, cactus.' We mention the preceding as suited for open pots; but there are many others of long and well-established repute to be had from ordinary greenhouses, or even in slips from private cultivators.

All that is necessary for successful in-door culture is attention to the general directions previously given. If plants have sufficient air, light, warmth, and moisture, and be potted in proper soil, nothing else is needed, save a little care in keeping them clean, occasionally stirring the upper portion of the soil, turning them regularly to the light, loping off old wood, pruning unseemly shoots, and removing decayed leaves. It may sometimes happen, notwithstanding all ordinary care, that a few, such as the pelargoniums, may be infested with small green insects, or may otherwise take disease and languish. The former are generally destroyed by a sprinkling of powdered lime, the fumes of tobacco or sulphur, or even, where the nature of the plant will admit, by a thorough drenching with pure water. Disease is almost always the result of inattention, of too much or too little water, of confined pots, or of forcing into unnatural growth, and can only be remedied by recurring to proper treatment; such as removal into larger pots, a supply of new soil, cutting asunder and replanting matted roots, or by giving small doses of active manures, as nitrate of soda, ammoniacal water, liquid guano, and the like. When slugs or other vermin infest the soil in which plants are grown, the above manures will in general kill them; if not, a drenching with lime-water—allowing it to pass off through the holes in the bottom of the pot or box—is sure to prove effectual, the same time that it is likely to add to the vigour of the plants.

Another direction to be borne in mind is, never transfer a plant from one situation to another of a widely different character without some previous preparation. Vegetables no doubt possess wonderful powers of accommodation, but there is a limit to this principle; and a plant reared in the hothouse will no more endure the exposure of an open pot, than the animals of India could live and propagate in Iceland. Thus many of our rarest exotics are permanently injured by sudden removal from the stove to the open stand, or from the open air and conservatory to the drawing-room. Plants intended for transferences of this kind should either be taken at the period of their repose, or immediately before their breaking into blossom, if their flowers be the object in view. For example, is it wished to bring some showy orchid from the stove to the drawing-room, it ought to be kept as dry as its actual wants will permit some time previous to its flowering, and to be removed to its destination as soon as the first flowers make their appearance. On the other hand, it should not be returned to its original destination till the flowers have withered, and even then not till the soil has become pretty dry.

Pots and Stands.

Since the main object of domestic floriculture is to improve the taste for what is lovely and ornamental, it should be the aim of all growers who can afford the outlay to procure pots of as handsome shapes as possible. The common earthenware pot is often very clumsily made, though not of itself an inelegant object; but others may be constructed with ornamental mouldings in relief, or in the form of vases, urns, and the like, which would add greatly to the grace of a flower-stand. Pots may also be constructed of stone, of polished slate, as recently manufactured by Mr Beck of London, of cast-iron, wood, and the like, and in highly elegant fashions, either to be set on plain shelving or on ornamental stands. Elegance, however, does not consist in exuberance of ornament; the plainer often the better; and correct taste will avoid all grotesque and fantastic shapes—such as representations of plants and animals in postures and situations in which they are never to be found in nature. There is an endless variety of pots; some intended to afford better drainage than the common sort; others by being double—that is, a pot within a pot, and the space between filled with water—to afford a more equable supply of moisture; and many whose main object is display and ornament. Whatever be their form, the amateur should remember that gardeners do not speak of flower-pots as large, middling, small, or very small, but distinguish them by numbers, thus:—The smallest ones are called *thimbles*; the next *sixties*, which are 3½ inches deep, and 3½ inches wide at top; *forty-eights* are 4½ inches deep, and 4½ inches wide at top; *thirty-twos* are 5½ inches deep, and 5½ inches wide at top; *twenty-fours*, 6½ inches deep, and 6¼ inches wide at top; *sixteens* are 8 inches deep, and 7½ inches wide at top; *twelves* are 8½ inches deep, and 8½ inches wide at top; *eights* are 9 inches deep, and 9 inches wide at top; *sixes* are 10 inches deep, and 10 inches wide at top; *fours*, 11 inches deep, and 11 inches wide at top; *twos*, 12 inches deep, and 12 inches wide at top—all inside measure. It must be remembered, however, that these dimensions vary more or less in the formation of what are called *flats* and *uprights*; the former are of greater diameter than depth; the latter of greater depth than diameter; but all are made to contain nearly the same quantity of soil.

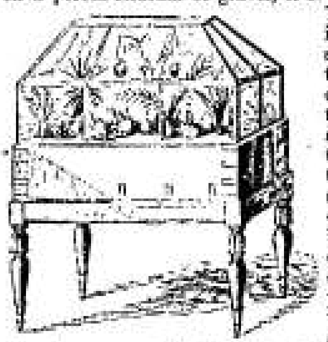


Stands are commonly made of wood or cast-iron; but we have also seen very cheap and pretty ones constructed of a wooden upright, with suspension arms of stout iron wire. Wooden ones, with plain shelving, of circular, or semicircular, or quadrantal forms, make very handsome stands for recesses and corners; those on single uprights, with branches for the support of the pots, are usually constructed of iron wire, or of cast-iron bronzed or painted, and are best adapted for central situations in lobbies and drawing-rooms. It may not, however, be in the power of some to procure flower-stands of either description; and for such, one board placed in the window-recess, so as to bring merely the top of the first row of pots within influence of the light, and a second level with the top of the first pane, will make no inelegant display; the effect of which will be heightened by suspending some light pots from the lintel above.

Of plants for suspension, a great variety can always be easily obtained, and as easily nurtured. Some require to be grown in pots, and watered; but many will send down their graceful pendants and blossoms for years with no other supply of moisture than what they absorb from the atmosphere. Indeed, a number can be grown without the aid of soil; a wet rag, a ball of moss, or of fresh turf, being the only protection their roots seem to demand. Pendant plants form very handsome appendages to a dwelling apartment, and no amateur should be without a variety to grace his collection. Of these may be mentioned, as worthy of adoption, saxifraga sarmentosa, linaria cymbalaria, fuchsias radicans and decumbens, Russelia juncea, lantana sellowiana, the epiphyllous sorts of cacti, ferns, lycopodiums, &c.; and with a little management, the prostrate verbenas, lobelias, and mimuluses, the trailing mesembryanthemums, with campanula rupestris, fragilis, hirsuta, and a multitude of plants which resemble them in their habits. Even some annuals, flowered in early spring, as nemophila atomaria and insignis, nolana atriplicifolia, &c. create a good display when suspended in pots; and many of the tender creepers hereafter mentioned (p. 541) may be trained pendant as well as erect,

Ward's Cases.

It may happen, from the vitiation of the air in towns, and in dwelling apartments, or from other circumstances, that it is impossible to grow the plants we most wish in open pots. To remedy this, a plan was some years ago devised by Mr Ward, a surgeon in London, of keeping the plants under close glazed frames, in which situation they grow and flourish in perfection. These frames are generally known by the name of Ward's Cases, and may be seen in almost every large town, constructed of every shape and size, according to the taste or means of the grower. By aid of these, any one, whether inhabiting the most humble or the most splendid dwelling, provided it be freely exposed to the sun's light, has it in his power to cultivate a miscellaneous collection of plants, at an expense so trifling, as to be within the reach of the most moderate circumstances. One of these cases, of a very complete structure, is represented, with its collection of plants, in the following figure. On the stand or table is a strong box, lined with zinc or lead, and filled with well-moistened loamy soil, underlaid by a thin subsoil of turfy loam, and this resting on a porous stratum of gravel, or broken earthenware.



This composition is meant to represent a natural fertile soil, which it does to perfection, the water lodging among the gravel till the wants of the plant in the superior mould require it. Over this box is placed a close-fitting glass cover, which completes the apparatus. The lighter and thinner the glass frame, and the finer the glass, the better are the plants exposed to view, and the more readily to receive the sun's light. This plot of soil, with its glazed framework of air above it, forms a little world of itself, in which the plants grow and flourish. When the moisture of the soil within is vaporised by the heat of the sun, it collects on the inside of the glass, and trickles down again, so that the plants are never subjected to irregular or capricious watering, while their own respiration and decomposition of water afford them nearly all the atmosphere they require. The case, however, is not absolutely air-tight; if it preserves a certain regular amount of moisture, warmth, and air, the while it excludes dust, soot, smoke, and other noxious fumes, it does all that is required. It must be evident that a Ward's case may be of any size or shape. It may be made like a lantern or bell-glass, to cover a single plant, or large enough to become a domestic conservatory.

Cases of the kind described may be used either for in-door or open culture; and answer as well for a little front plot, or back-court, as for a drawing-room. They can be also conveniently put up in balconies, or even over the entire window, so that the panes may serve for one side of the conservatory. Many such are now to be seen in our large towns, even in the smokiest and least inviting quarters. This sort of double window, if we may so speak, is admirably adapted for tall plants and flowery shrubs, or for suspending pots, and is altogether a very pretty annexation to a dwelling. Lofty and partially close cases of this sort are fitted for almost every species of greenhouse plant; but the moistened and shaded atmosphere of a small and closely-fitted case is destructive to flowering exogens. Plants of a succulent nature, and especially those having fleshy leaves, like the cactus and aloe, and all natives of damp and shady situations, grow and bloom in them to perfection. Among these are many lovely and rare plants, which will amply repay the attention of the case-grower, such as the melocactus, mammillaria, echinocactus, opuntia, epiphyllum, rhipsalis, and other varieties of cactaceous and epiphyllous genera; the aloe, cycas, agavé, cereus, side-saddle flower, Venus's fly-trap, sun-dew, nepenthes, lycopodium, &c.—all remarkable either for the beauty or peculiarity of their habits and structures.

Rare exotics need not, however, be sought after. 'The plants to furnish it,' says Mr Ward, 'can be procured abundantly in the woods in the neighbourhood of London. Of these I will mention a few. The common ivy grows most beautifully, and can be trained over any part of the case, agreeably to the pleasure of the owner. The primroses, in early spring, will abundantly repay the labour of fetching them, continuing for seven or eight weeks in succession to flower as sweetly as in their native woods. So likewise does the wood-sorrel, the anemone, the honeysuckle, and a host of other plants, independently of numerous species of mosses and of ferns. Some of these latter are more valuable than others, in consequence of the longer duration of their fronds, such as *Lastrea dilatata*, and its numerous varieties. There are likewise many cultivated plants procurable at little or no cost, which grow without the slightest trouble, such as the *Lycopodium denticulatum*, the common musk-plant, myrtles, jasmines, &c. All the vacant spaces in the case may be employed in raising small salads, radishes, &c.; and I think that a man would be a bad manager who could not, in the course of a twelvemonth, pay for his case out of its proceeds. These remarks apply chiefly to situations where there is but little solar light. Where there is more sun, a greater number and variety of flowering plants will be found to thrive, such as several kinds of roses, passion-flowers, geraniums, &c. with numerous beautiful annuals—namely, *Ipomœa coccinea*, the species of *Nemophila*, *Convolvulus*, and a host of others: the vegetation, in fact, can be diversified in an endless degree, not only in proportion to the different degrees of light and heat, but likewise by varying the quantity of moisture; thus, with precisely the same aspect, ferns and bog plants might be grown in one case, and aloes, cactuses, mesembryanthemums, and other succulent plants in another.'

Case-grown plants, after the first preparation, require little or no care; the case need only be opened for the removal of dead leaves, or for a little trimming when required. Plants in open flower-pots are exposed to the vicissitudes of change of climate, and require constant watering; but the plants in these cases seem to be independent of any change of temperature in the air, and water themselves. The moisture rises by the sun's influence from the moistened earth, cherishes the leaves of the plants in its aërial condition, and during the cool of night falls to the earth again like rain or dew. In this manner there is a constant succession of rising and falling of moisture, in imitation of the great processes of nature daily going on in the fields around us. The plant-case is a little world in itself, in which vegetation is supported solely by the resources originally communicated to it.

Walls and Trellises.

Where it is objectionable to fasten climbing-plants to walls, a light trellis-work of wood or iron wire may be employed; permanently fixed where the climbers are perennial, but movable where they are grown merely for summer purposes. By being removed in autumn, and kept dry, a wooden trellis, originally of small cost, will last for a long number of years; the while that its removal, along with the withered branches of the plant, is a positive improvement to the appearance of the dwelling. Nettings of string or wire make very convenient leaders when other material cannot be had; and these may be woven along the outside of doors and windows, where other frameworks might not be permitted. In trellising, the lines should be easy and graceful, in order to give scope to the free and rambling habits of the climbers.

Among the *hardy* species adapted for this purpose, there are the honeysuckle, the ivy, many varieties of the rose, the jasmine, the small white clematis, the pyrus Japonica, lathyrus, chimonanthus, cydonia, lonicera, or even the humble hop, where an easily-nurtured and quick-growing climber is wanted. For summer purposes merely, a selection from the following genera may be made, descriptive particulars being easily obtained in any catalogue:—Campanula pyramidalis; cobæa, several species; convolvulus speciosus; lathyrus, several; loasia lateritia; lophospermum, several; manettia cordifolia; maurandya Barclayana; pentstemon argutus; rhodochiton volubile; Thunbergia, several; tropæolum, several; passiflora cœrulea; Tweedia cœrulea. Two plants appear in the above list, which, though they cannot be called climbers, make a handsome display when fastened to a trellis or a wall; these are campanula pyramidalis, and pentstemon argutus.

It has been often remarked that, of all flowering plants, climbers present the most graceful forms which can be contemplated under the open sky; but true as this may be, the tender varieties are not the less graceful when cultivated in the greenhouse or drawing-room. Grown in pots, and sustained by appropriate frameworks, they can be trained to almost any shape, be it urn, vase, obelisk, or pillar—a screen of living network, or a fairy arbour. Trellises affixed to the outside of pots can be had of a thousand designs; and where purchase is objectionable, they may be constructed of wicker, slender painted rods, cord, or varnished copper wire, which is one of the most pliable and durable of materials. By the adoption of this plan, with frequent prunings in particular cases, climbers may be made to clothe a trellis not more than four feet high, and so requiring no larger space than a small shrub; flowering more profusely when of three or four years' standing than if they had been three times that age, and had covered a sixfold greater surface over an arbour or veranda. Indeed, climbers are not of difficult culture; for we have seen a cottager's window shaded within by a screenwork of leaves and blossoms, more effectually than it could have been by the costliest Venetians.

Rock-Work and Aquariums.

If space and means permit, a flower garden may be much improved by introducing a piece of artificial rock-work, and a small pond; because, in connection with these, certain highly interesting plants may be reared or kept, which would not answer in a plain earthy soil or surface. In order to increase the effect, the pond should be at the base of the rock-work, and receive from it the trickling of water which has been conveyed to the summit in pipes. Let the rock-work possess a natural appearance, with rugged sides, and perhaps be ten or twelve feet high. Rocks of the same kind and colour should be placed together; if intermixed, they seldom wear a natural appearance. A dark cave, penetrating into the thickest part of the erection, is not very difficult to construct; and when encircled with ivy, and inhabited by a pair of horned owls, which may be easily procured, it will form a most interesting object. Rock plants of every description should be profusely stuck around, and in one short twelvemonth the whole scene will exhibit an impress of antiquity far beyond anticipation. The undertaking, when completed, will present a field of varied and interesting study, and more than compensate for all the attention and outlay bestowed upon it. The aquatic and rock plants, which formerly were 'far to seek and ill to find,' will thus be brought within the range of every-day observation; the wagtail, oxeye, and stonechatter, will be attracted to the spot, not perhaps because they are lovers of the picturesque, but because they find everything here suited to their nature; and colonies of the wild-bee will soon be seen and heard around the interstices of the rocks, and heavily laden with their winter store. A weeping-willow adjoining, and one or two mountain-ashes, will add materially to the beauty of the scene; and if the spot be airy, there might, with advantage, be planted, on or about the top of the eminence, a variety of what is usually called the *Scottish thistle*. This elegant plant will not thrive in low or damp situations, and prefers a bracing to a warm atmosphere; hence, though a beautiful object in borders, it is difficult to bring to perfection in some situations.

Among the plants suitable for growing from the crevices of the rocks may be mentioned various heaths and mosses, the Valeriana diœcia montana, trifolium alpestre, thymus vulgaris, epilobium alpinum, campanula cervicaria, alyssum calycinum, and viola banatica. Many plants might be mentioned as suitable for the marshy borders of the pond, as the acorus, littorella, lychnis flos-cuculi, saxifraga irrigata, epilobium angustifolium, primula farinosa, and so forth. We should recommend the unprofessional gardener, in replenishing either a rock-work or pond with appropriate plants, to consult a nurseryman skilled in the subject; as soil, air, climate, moisture, and other circumstances, require careful consideration.

GARDEN PLOTS IN TOWNS.

The attempt to have a neat and flourishing garden or garden plot in populous towns is very often defeated by the abundance of smoke and other impurities in the atmosphere; for, as repeatedly mentioned, pure air is essential to the proper growth of plants. It is found, however, from experience, that certain kinds of shrubs and flowering herbs are less delicate in this respect than others; and that, with a reasonable degree of care, open plots in towns may be made to yield a surface of vegetable bloom and beauty. On this branch of flower-culture, so important to many town residents, there appeared some time ago a well-written paper in 'The Magazine of Domestic Economy,' describing the experience of an amateur florist. We take the liberty of extracting from it the following passages:—

'When I first took possession of my garden [in town], I found it encumbered with old lilacs and laburnums, the common aster, and other ordinary plants. These I immediately removed: by my west wall I planted a buddlea globosa and a Virginian creeper; and by my south wall, which was partly covered by a vine, I planted the jasminum revolutum, the small white clematis, and the pyrus japonica. The latter grew luxuriantly, and bore an abundance of flowers, which, glowing upon the light wall, enlivened my prospect in winter. I had a great deal of the south sun in my garden, but none of his morning beams reached it, and there was a corner which never had a gleam at all. In this spot I planted a quantity of roots of the lily of the valley, and they flowered well, although late. The laurustinus also grew well with me; and I should strongly recommend this pretty shrub, together with the laurel, instead of those deciduous shrubs which we see in town gardens. The latter become very shabby as they grow old; neither the lilac nor syringa flower well in confined situations; besides this, the untidy appearance of their falling leaves is a great annoyance. My jasmine grew quickly, and, with the clematis, soon covered as much wall as I could afford to them; the great inconvenience of the latter plant is, that it requires frequent attention as to nailing up, and this, where there is not a gardener always at hand, is troublesome; as, although the stem should be cut down within three feet of the ground every autumn, yet the young shoots soon grow beyond a woman's reach. However, it is worth while putting ourselves to a little trouble for the sake of the delicious scent of the flowers of this pretty trailing plant. As regards perennials, I daresay all who are fond of flowers have endeavoured to nurse the China rose, and induce it to flower in the town. I have grieved over many a healthy plant which refused to show a single bud, and watched the gradual wasting away of others, notwithstanding my unceasing care. The common Provence roses, both white and red, flower well in the town; but it is vain to attempt the China—it requires a very pure air; and I do not know any flower whose colour varies so much with the quality of the atmosphere. I am but slightly acquainted with the names given by botanists to the numerous varieties of roses; but I have tried many of them, and found the Tuscan, the rose de Meaux, the Tudor, the little early crimson, and one surpassing them all in beauty, the Bengal celestial (I believe), flower extremely well.

With regard to spring flowers, the snowdrop I could not tolerate in the city—the smoke robbed it of all its beauty; the crocus, either the mice or the sparrows would not leave undisturbed; and after replenishing the edge of my border several times, I gave up the matter. The hepatica and gentianella flowered well with me; anemones also I had of very good colours. Heart's-eases pined away after the first year, but they were easily replaced, and they were too ornamental to be relinquished. Then followed the white lily, and a variety of irises, all of which increased fast, and flowered abundantly. The peony I could never persuade to flower; in the first place, it does not blossom well until it has been for years settled in a garden, and I believe its beauty even then is greatly dependent upon the purity of the air. My buddlea was every spring covered with its golden balls, and grew so quickly that I scarcely knew what to do with it. I am surprised this beautiful shrub is not more common: it is perfectly hardy, even as a standard; it will remove well, even when it has attained a considerable size; it is very easily raised by layers; and there is an air of grandeur about it, both as to leaves and flowers, that raises it above the common flowering shrubs of our gardens. But we go on in the old-fashioned manner of planting our gardens. The same varieties of deciduous shrubs are taken, without considering with how much advantage their places might be supplied by those more lately introduced. The magnolia, for instance, grows quickly and flowers abundantly in the city upon a south wall; and the arbutus is not at all particular with respect to situation. The bignonia grandiflora also does not withhold its scarlet trumpet-like blossoms in the immediate vicinity of a steam-engine. To return to my garden, the glory of which in the autumn was the lobelia fulgens, I managed it thus: I sank in the ground, up to the rim, a large and deep seed-pan; this I filled to about three quarters of its depth with rich soil, properly mixed, and planted my roots. As soon as the shoots appeared, I supplied them plentifully with water, and from time to time added more soil. The plants grew luxuriantly, furnishing tall and thick stems, with large and highly-coloured blossoms; indeed, the gardener who had assisted me said that he had never seen finer flowers. The sweet-scented marvel of Peru thrived well with me, and the tiger-flower also. Carnations and picotees I tried one year, but was so much disappointed in the result that I gave them up, although very reluctantly, as I believe carnations do not require a very pure air; and I have fancied since that my failure with them arose from some other cause than the smoky atmosphere. Dahlias also, although they flowered very well, I gave up. The amaryllis lutea flowered well with me when once established, and the hemerocallias cerulea and flava did the same.'

After condemning annuals in general, the same writer goes on to say—'I own I am willing to make some exceptions myself in favour of the coreopsis, and such brilliant flowers particularly; the French marigold, too, and the scarlet zinnia, I could scarcely give up. The lupinus mutabilis blossoms well in the town, but it is very liable to be destroyed by a caterpillar; the easiest method of preventing which is to strew a little soot around the plant. The grub, I suppose, will not rise through this: I found it more effectual than tobacco, which I also tried. The scarlet colutia is much eaten by an insect: I found the same method succeed in this case. I had forgotten to mention that all bulbs of the narcissus and jonquil tribe flowered well with me: the primrose and polyanthus gave miserable-looking blossoms. I planted the double pomegranate against my south wall, and it grew well: I left the house before the plant was old enough to flower. I should notice one great recommendation which American shrubs possess to those who are likely to change their residence—they may be removed without danger at almost any size. Mine were planted in a border of common earth, in a hole filled up with peat and loam fit for them; and when a rhododendron, four feet in height, was removed, it was found that the roots formed a complete ball, none of the fibres having penetrated beyond the soil which was proper for them. The common and Portugal laurel may be removed when very large: I have myself seen one of the latter, which three men and a boy could with difficulty lift, transplanted with success. Of course it was carefully tended as to water. The scarlet lychnis does not mind the corrupt air of the town; but it will not grow to so great a height in such a situation as it does in the country. There are many other plants which might be treasures in a town garden; experience, however, is the best teacher in this as well as in more important matters, and if a garden be stocked with the plants I have mentioned, experiments may be made as to others; should they all fail, the garden will still be *gay*.' To the foregoing we need only add that much may be done to keep garden plots neat by frequent trimming and raking, and particularly by keeping the plots in grass close shaven.

FLORICULTURAL MONTHLY CALENDAR.

January.—Little can be done in the flower garden except the weather be open and dry; but advantage ought to be taken of favourable intervals to render the plots and borders neat; to protect by coarse screenings of leaf-mould, fuchsias, China roses, and other choice shrubs; for though they may not perish by frost, the mulch tends to enrich the soil, when forked in. Propagate by division of roots daisies and thrift; protect the beds of hyacinths, anemones, ranunculuses, and tulips, by a covering of coarse litter. Top-dress auriculas, using a compost of light loam and two year-old cow-dung, mixed with a twelfth each of sea or river sand, and rotten wood. Plant all the bulbous roots that are still out of the ground. In heat, sow mignionette, annual stock, pentstemon, diffusus, gentianoides, and other half-hardy annual and perennial plants, using the propagation-pot, by which means the entire number of seedlings (allowing for previous thinning out) can be transferred, with roots undisturbed, to the plots or borders. Commence sowing in the last week, for hothouse culture, seeds of gloxinia and gesneria; these, if obtained from impregnated plants, may yield new and striking varieties. Sow also (broken up and mixed with sand) the berries of psidium cattleyianum; this plant is one of the choicest evergreens of the stove, or even greenhouse, for it is not tender.

February.—Attend to the foregoing general directions, and now cut turf for lawns; fork and clean the flower-borders. Plant anemones, gladiolus, perennial herbaceous roots; and transfer others, dividing the crowns, to multiply the species. For examples of this division of roots, select the primrose, single, double, and the polyanthus. Transplant the rooted layers of carnations, also the divided roots of campanula, lobelia, lychnis, mullpink, and dianthus sinensis. Sow in mild heat any annual flower seeds, and of auricula and mimula, in boxes or pans. We include the beautiful primula sinensis. Excite choice dahlia roots, placing them in hotbed frames, or in troughs or pots of old tan, or any light moist substance, on the floor of a stove or vinery at work.

March.—Sow annuals, including balsam seed, collected from the best double flowers. Plant box-edgings, using much pit-sand; also evergreen shrubs of every description. Transplant autumn-sown annuals into pots, and protect them, till fresh-rooted, under glass; as clarkia of every kind, calliopsis, œnothera lindleyana, mignionette, schizanthus pinnatus, and porrigens. Sow in the last week, in the open ground, and at the same time, a pot of each in heat, or at least under glass, stocks, foxglove, china-aster, clarkia, dahlia, campanula, larkspur, pentstemon, amaranthus, tobacco, and all the hardy annuals. Take cuttings of hydrangea from the tops of the shoots. These, if the buds be full, sometimes will produce a fine flower-head, and the effect is striking. Soil, pure heath-mould, or leaf-mould and sand.

April.—Plant dahlia roots in richly-manured loam, hollyhocks, carnations, biennials and perennials: at this season every herbaceous plant is almost certain to succeed. Campanulas (the tall pyramidal), raised by cuttings of the roots in autumn, may now be transferred to pots of loam and leaf-mould; and as the plants grow, they are to be constantly shifted, till they come into pots, wherein they will bloom profusely. If placed in the borders, they will require no peculiar treatment. Sow in a pot the seeds of this variety of campanula (seedlings frequently produce the finest plants; they require profuse watering); also the seeds of the pansy or heart's-ease, to procure varieties. Propagate by cuttings, as directed for geraniums, or by single eyes, the Erythrina crysta Galli, and laurifolia. In propagation pots, using the same soil, all the salvias, verbenas, rockets, double wallflowers, and every species of fuchsia that has produced young wood. Try every plant by cuttings placed in ounce phials, three parts filled with rain-water. Bud China, noisette, and moss-roses, on dog-rose stocks. Divide the roots of dahlias, either retaining one single tuber with a sprouting eye, or twist out very cautiously a single shoot, so as to detach its base and the latent bud it contains, planting it in the smallest pot of sand and leaf-mould; a gentle hotbed will facilitate the protrusion of roots.

May.—This is the season to stock the flower-garden with those plants which have been prepared during autumn, winter, and spring; and therefore transfer, from the propagation pots, annuals raised in them, by lifting the whole mass, and depositing it in a spot prepared in the border: thus trouble and loss of time are obviated. Sow a few annual seeds in the open ground for succession. Plant the parterres with groups of fuchsias, calceolaria, petunia, Neapolitan violet, verbena; and at the latter end form masses of the scarlet and variegated geranium, and many less-prized but beautiful fancy varieties; such are Diomede, conspicuum, succulentum speciosum, Moore's victory, Dennis's rival, &c. &c. Propagate by cuttings the China roses of every kind; plant them two joints deep, in a shady situation; also calceolarias of the shrubby kind, Peruvian heliotrope, &c.: by division of the roots, Neapolitan violet, placing them in beds of manured loam, twelve inches apart; the heart's-ease of the best varieties, in shady situations; the soil, rich loam and leaf-mould. These favourite prize-flowers require a frequent renewal of soil; they dwindle if retained in one site, and degenerate to the condition of the poor weak flowers of former years. Propagate by slips lychnis, double rocket, and wallflower; thin out the superabundant shoots of asters, antirrhinums, pentstemons, phlox, and all luxuriant herbaceous plants.

June.—Propagate, as during the last month, and plant young side-shoots of the best lobelias, in shady borders, under a hand-glass. The pipings of pinks, placed in sandy earth, are to be closely covered in the same way, till completely rooted. Salpiglossis succeeds best in the open air; the plants should be now turned out of pots, and set in a dry border. Greenhouse plants may now be arranged in a north aspect; the pots to stand on a deep stratum of coal-ashes. Azaleas, acacia armata, and some such plants, are greatly improved by being turned out of pots, and planted with the entire balls in an open peat-border.

July.—Bud roses on wild stocks. A pretty effect is produced by inserting one or two buds of the deep-red China in the common China rose. The former is strengthened in its habit, and the different tints of the two roses are very pleasing. Propagate by cuttings the Chinese azaleas, half-shrubby calceolarias, linums, pelargoniums, fuchsias, myrtles, and other exotic shrubs. Layer carnations in sandy earth, with a little chalk; peg them near the incision with hooks of fern-leaves. Sow mignionette in small pots for winter; also annual flower-seeds for bloom in September.

August.—Bud, as before, but not the China rose. Plant seedling herbaceous plants, cyclamens of every kind, offset bulbs to gain strength; repot auriculas, removing the suckers, and detach the black ends of old roots with the finger and thumb. Sow the seeds of all the annuals mentioned under that head in a previous page. Use gentle heat; add any other favourites, as madia elegans, mimulus, the white night-flowering petunia, tall and dwarf larkspurs. Sow the seed of the best pansies. Take cuttings of all the fine pelargoniums that are out of flower early in the month; also of calceolarias, shrubby and half shrubby; of antirrhinum caryophylloides, pentstemon gentianoides, &c.; these require no heat, but should be placed in a cold frame.

September.—Plant the crocus and some other bulbs. Transplant herbaceous perennials and pinks to permanent beds, if perfectly rooted. Propagate by cuttings China roses in the open borders; and by slips petunias, heliotrope, salvias, gerania, calceolaria, &c.; they require only a hand-glass and light soil. Sow auricula seeds in pans in the greenhouse; also clarkia, collinsia, chelone, and other annuals, to be preserved in pots all winter. If the pyramidal campanula be out of flower, take up one of the finest roots, blue and white; break it to pieces, and half filling a large pot with loam, place the pieces on the earth; fill the pot with loam, and keep it merely protected from frost all winter. Raise every geranium or other greenhouse plant now in open ground, and repot them in soil suitable to each. Cut back to low buds, well situated, the horse-shoe geranium, and place all the plants under glass, to recover from the removal; make cuttings of the best amputated shoots of geranium. Gradually diminish the watering of all greenhouse plants.

October.—Plant towards the end bulbs of hyacinth, narcissus, and tulips, the common jonquil, and daffodil, and anemone roots, &c.; also shrubs of every description, though evergreens generally succeed in spring: cuttings, as before, if not completed. Hyacinths in pots, filled with a compost of light loam, sand, and vegetable earth, should be plunged to the rims in ashes, or light earth, under the glass of a cold frame; and when the plants begin to grow, the pots should be raised, cleaned, and placed in the greenhouse. Greenhouse plants must now be taken in, and be gradually inured to winter treatment by the free admission of air and abatement of water. Take up the Persian cyclamen, and pot it in loam, sand, and leaf-mould. There is a geranium which merits much attention; it is called the scarlet globe, and appears to be a seedling variety of Pelargonium zonale: cuttings of it strike freely in the open border early in summer; the handsomest of these taken up in September, and carefully potted in poor loamy soil, will flower throughout October and November, placed in the window of a south room: the flower-head assumes the figure of a Guelder rose.

November.—Bulbs; plant all, employing much sand about and above the bulbs. Protect fuchsias, if frost threaten. Screened leaves form the best substance to be placed as mulch. Dahlias should be taken up in airy and dry weather, when quite dry and clean: preserve the tubers in well-dried sand.

December.—Protect beds of tulips, hyacinths, and other choice bulbs or roots, with a layer of sawdust mixed with sand, or with ashes. Sawdust alone has been found the most effectual protector to the roots of potted plants in frames, the pots being plunged in it to the brims. If dry weather permit, lightly fork the surface of plots and borders; but at anyrate, if it be frosty, scatter some light manures around the stems of shrubs and the more tender plants; it will tend to enrich the ground at the first spring regulation. Secure begonias and other plants which die down by placing the pots in a temperate dry cellar.

THE FRUIT GARDEN.

The fruits produced in ordinary gardens under the climate of Britain are of three leading kinds—*kernel fruits*, of which the apple and pear are the principal; *stone fruits*, including the peach, apricot, plum, and cherry; and *berries*, of which there are many species, as the gooseberry, currant, raspberry, and strawberry. The kernel and stone kinds are produced from trees, the others from shrubs or from herbaceous plants. All the garden fruits, of whatever sort, have been greatly improved by a long course of cultivation from a wild state—this being a branch of vegetable economy which has engaged the unremitting attention alike of men of science and practical gardeners from a remote antiquity till the present time. Of the best means which experience has suggested for culturing fruit-bearing trees, and bringing their produce to perfection, we now propose to treat.

GENERAL MANAGEMENT.

Fruit-trees are grown as independent plants in an orchard, in which case the tree is suffered very much to assume any height or bulk that nature permits; also trained upon walls, or constrained to grow in a particular manner upon artificial palings called *espaliers*. In whatever manner the tree is planted, or designed to grow, the tendency of the main stem and branches of the plant is upwards into the atmosphere, and of the chief roots downwards into the soil. In general, the depth and spreading of the roots are proportional to the height and spreading of the branches, because the roots are the anchorage and food-seekers of the plant, and require a depth and compass of soil corresponding to the bulk of the tree and its demands for nourishment. On these accounts, it is of the first importance not to stint fruit-trees of a depth and breadth of good sound mould adapted to their expected dimensions.

Trees planted close to walls should have a depth of soil in proportion to the height of the wall. If the wall be six feet high, the border beneath will require to be trenched two feet deep; and so on to a ten-feet wall, which should have at least three feet of free penetrable soil. The principle is, the deeper the soil, the less will the roots straggle. As already said, their tendency is chiefly downwards; and it is only because they cannot get far enough down that they range abroad. Their object is to absorb nourishment wherever it can be obtained; and, abstractly considered, it is of little consequence whether this nourishment be procured beneath the main stem or at ten yards' distance. But, practically, the gardener is concerned in keeping the roots from straggling, and interlacing, as with a network, the under strata of his borders, thus impeding his operations, and perhaps robbing his culinary vegetables or flowering shrubs of a portion of their food.

It will therefore be observed that depth of available soil is as essential in fruit-tree culture as in any other department of gardening. If possible, a depth of three feet should always be obtained. Should the garden, when first taken possession of, not have more than eighteen inches or two feet of soil, our recommendation is, not to plant fruit-trees upon it at all till the ground be trenched, as directed in No. 32, to a depth of three feet, and till, by annual digging, the substratum be incorporated with that immediately above it. In the course of these preparations let the soil be well cleared of stones, meliorated by winter frosts, and enriched with old manure. Bear in remembrance that fruit-trees must never be excited by new and undecomposed manure. The material applied both before planting and also while the tree is growing, should be loam, mixed with a thoroughly-rotted compost of dung, leaves, and the like. Some persons, following an old prejudice, place a paving-stone at a certain depth beneath, to prevent the root of the tree from penetrating into the subsoil; but this is only waste of labour; for if the descent be counteracted, the roots will proceed laterally, and penetrate downwards as soon as they can conveniently do so. By giving a proper depth of soil, and keeping that soil in heart, no fear need be entertained for the tree receiving that injury from the subsoil which it was the object of the paving stones and lined pits of our forefathers to prevent.

When we say that depth of soil is advantageous, it is necessary to guard against an impression being formed that deep planting is also required. In general, the roots of trees should be placed near the surface. Mr M'Intosh, in his very beautiful work, 'The Orchard,' offers the following caution on this subject:—'Deep planting is an evil much to be guarded against; and many of the disappointments which have attended the fruit-grower may be traced to this cause. As some criterion for the guidance of the amateur, we would say, let every young fruit-tree, of whatever kind, be planted at least three inches above the ground-level; that is to say, let the part of the stem which was level with the surface while in the nursery, be kept three inches above the general surface of the ground when it is planted, and let the earth be heaped up to that height around it, for a couple of feet or so, in the form of a little hillock. Trees of larger size may be rather more elevated. This applies to soils of the ordinary description; but in damp soils the elevation should be still greater. When trees are set in a pit—which should always be a third larger in diameter than that of the extent of the roots, so that they may be all spread out to their full extent, without being doubled or turned round—they should be spread as regularly as possible, and the bottom should be made perfectly level; by this means the roots will have a horizontal direction given to them, which they will afterwards maintain. The intention of this arrangement is to induce them to extend themselves near the surface, and to prevent their extending downwards into a bad or cold subsoil.'

Propagation—Impregnation.

Fruit-trees may be propagated by seeds, layers, cuttings, budding, suckers, or grafting. By any of these methods, a main object of the culturist is to improve, or at least not to deteriorate, the quality of the plant. In a state of nature, every fruit is inferior to what it will become by cultivation. This disposition to improve is taken advantage of by gardeners; and by attending to various circumstances in the economy of any individual plant, they are able to produce and propagate the best varieties. The principal means employed is to select such varieties as have attained a certain degree of perfection, and then crossing two of the most nearly allied, in order to produce an intermediate variety. The discovery of the sexuality of plants, as established by Linnæus, has rendered this a comparatively simple operation to skilled gardeners. The following is a short exposition of the method given by Mr M'Intosh, who quotes from other authorities:—'The means used in the process of artificially fecundating the stigma or female parts of the blossom of one flower with the pollen or male dust of another, have been beautifully described and explained by Knight and others. That eminent pomologist has obtained thousands of apple-trees from seeds, many of which are of first-rate quality, by cutting out the stamens of the blossoms, to be impregnated before their own pollen was ripe enough for the purpose, and afterwards, when the stigma was mature, by introducing the pollen of the other parent, either by shaking the pollen of it over the flower containing the stigma only, by introducing the flower when deprived of its petals or coloured leaves, or by transferring the pollen upon the point of a camel-hair pencil from the one flower to the other. By these means he prevented the possibility of the natural fecundation of the blossom within itself, and thus greatly increased the chances of obtaining intermediate varieties by making use of two distinct parents.

'This process is called cross-impregnation, and is in its nature highly curious. Dr Lindley describes the action as follows:—"Pollen (the male dust) consists of extremely minute hollow balls or bodies; their cavity is filled with fluid, in which swim particles of a figure varying from spherical to oblong, and having apparently spontaneous motion. The stigma (the female organ) is composed of very lax tissue, the intercellular passages of which have a greater diameter than the moving particles of the pollen. When a grain of pollen comes in contact with the stigma, it bursts, and discharges its contents among the lax tissue upon which it has fallen. The moving particles descend through the tissue of the style, until one or two find their way, by routes specially destined by nature for their service, into a little opening in the integument of the ovulum or young seed. Once deposited there, the particle swells, increases gradually in size, separates the radicle and cotyledons, and finally becomes the embryo—that which is to give birth, when the seed is sown, to a new individual. Such being the mode in which the pollen influences the stigma, and subsequently the seed, a practical consequence of great importance necessarily follows—namely, that in all cases of cross fertilisation, the new variety will take chiefly after its polliniferous or male parent; and that, at the same time, it will acquire some of the constitutional peculiarities of its mother."' According to modern phytologists, the character of the female parent predominates in the flowers and organs of fructification of the hybrid; while the foliage and general constitution are those of the male parent.

Illustrating these principles by reference to the propagation of varieties of apple-trees from seeds, Mr M'Intosh observes, that 'the kinds of apples that it would be advantageous to cross by artificial impregnation, appear to be those which have a great many qualities in common, and some different qualities. Thus it would be proper to cross the golden pippin with other pippins, and even with some rennets, but it would be improper to cross it with codlins or the larger growing kinds. The numerous varieties of pippins raised by Knight and others have been obtained by the above rule. It is no doubt true that a small apple—say, for example, the golden pippin—crossed with a much larger sort, will produce a variety sufficiently distinct from the other; but it is almost equally certain that this new variety will be of inferior quality to either; "the qualities of both parents," as Mr Loudon has very justly observed, "of so very opposite natures being, as it were, rudely jumbled together in the offspring."'

Grafting—its Theory.

Grafting, which is a practice of great antiquity, is the union of two plants in a growing state, through the medium of the circulating juices. It is now a well-known fact in surgery, that if a piece of a finger which has been accidentally chopped off be immediately applied to the stump whence it was severed, and the wound properly bandaged, it will adhere, and become part of the living member, as formerly. This, then, is grafting in the animal economy, and it is analogous to the grafting of one vegetable on another. The only dissimilarity is, that the piece of finger is restored to its own stump, whereas the vegetable union is between parts of two distinct trees. But this is a point of no consequence; for it is probable that if two persons, in equally good health, were to have a finger chopped off at the same time, the pieces might respectively be changed, and each individual might have on his hand part of the finger of his neighbour.

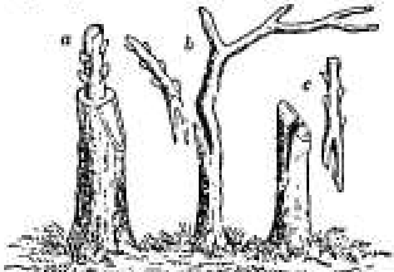
Gardeners assign five reasons for grafting:—1. The perpetuation of varieties of fruit, which could not be insured by sowing seed; 2. Increasing, with considerable rapidity, the number of trees of any desired sort; 3. Accelerating the fructification of trees which are tardy in producing their fruit; 4. Improving the qualities of fruits; and 5. Changing the sorts of fruit of one tree, and renewing its productiveness.

When a tree becomes old, but has still healthy and vigorous roots, and it is thought advisable to renew or improve its fruitful qualities, it is cut off across the lower part of the stem, and forms the *stock* on which *scions* are ingrafted, which scions taking root, become in time the fruit-bearing branches of the tree. As a general principle, the sorts to be united require to be considerably alike as respects disposition of woody fibre and sap and pulp vessels, so that no decided interruption may take place in the ascent or descent of the juices. Yet to effect any improvement in fructification, there must be a certain difference between the varieties. For example, the wild apple-tree, which bears only crabs, too sour to be eaten, forms one of the best stocks on which a graft can be made; and for that reason alone it is grown by nurserymen from seeds. The notice of this remarkable fact leads to a consideration of what are the radical principles on which improvement is effected by grafting. On this intricate subject we subjoin the scientific explanations of Dr Lindley:—'In proportion as the scion and stock approach each other closely in constitution, the less effect is produced by the latter; and, on the contrary, in proportion to the constitutional difference between the stock and the scion, is the effect of the former important. Thus when pears are grafted or budded on the wild species, apples upon crabs, plums upon plums, and peaches upon peaches or almonds, the scion is, in regard to fertility, exactly in the same state as if it had not been grafted at all; while, on the other hand, a great increase of fertility is the result of grafting pears upon quinces, peaches upon plums, apples upon white thorn, and the like. In these latter cases, the food absorbed from the earth by the root of the stock is communicated slowly and unwillingly to the scion; under no circumstance is the communication between the one and the other as free and perfect as if their natures had been more nearly the same; the sap is impeded in its ascent, and the proper juices are impeded in their descent, whence arises that accumulation of secretion which is sure to be attended with increased fertility. No other influence than this can be exercised by the scion upon the stock. Those who fancy that the contrary takes place—that the quince, for instance, communicates some portion of its austerity to the pear—can scarcely have considered the question physiologically, or they would have seen that the whole of the food communicated from the alburnum of the quince to that of the pear is in nearly the same state as it was when it entered the roots of the former. Whatever elaboration it undergoes must necessarily take place in the foliage of the pear—where, far from the influence of the quince, secretions natural to the variety go on with no more interruption than if the quince formed no part of the system of the individual.' Referring the reader to VEGETABLE PHYSIOLOGY for an account of the functions of the ascending and descending sap, we need only remark, that although increased fertility is produced by a decided difference between stock and scion, it is at the expense of durability; and that the practice is eligible only where it is wished to diminish the vigour and growth of the tree, and where its durability is not thought important.

All things considered, therefore, it is preferable to ingraft the scion of any approved variety on a sound stock, properly prepared for the purpose. As already observed, crab stocks are often grown to form the foundation of good apple-trees, and so are several other stocks propagated by professional gardeners from seeds and layers. We may now describe the different modes in which grafting is performed.

Scion-Grafting—Budding.

Grafting is performed in two principal ways—scion or slip-grafting, and grafting by approach, or in-arching. Of the first kind we have examples in the accompanying figure. Three modes are shown—*a*, *b*, and *c*, in each of which the process consists in placing a scion in an opening or cleft of a growing stock: *a* is called



whip-grafting, *b* side-grafting, and *c* tongue-grafting. By either method, the scion may be a shoot of a single year's growth, cut from a tree in a healthy condition. The season for the operation is about the middle of March, when the sap is rising and the buds beginning to be developed. The grafting should not take place immediately on cutting the scion: after removal from its parent stem, place it in the ground for a few days, so that it may be partially exhausted of its juices, and be more ready to receive the ascending sap from the stock. Keep it in dry ground, and not exposed to the sun. A scion may be brought safely from a distance by being stuck in a raw potato. Before applying to the stock, cut the extremity of the scion afresh.

Tongue-grafting, by which a tongue or slice raised in the sloping cut of the scion is inserted in a corresponding notch of the stock, is the more common method of procedure. It is performed when the stock is young, so that the scion which is added forms the stem of the future tree. The cut in both pieces requires to be smooth, and the joining so neat, that the bark on one side of the scion must be even with the bark of the stock. Having joined the two pieces, bandage them together with a flat strip of mat, but not so tightly as to prevent the circulation or expansion of the fibre. Over the bandage, plaster all round a handful of soft adhesive material, formed of clay, cow-dung, and chopped straw, taking care not to disturb the united edges. This mass will form a hardened lump, and may remain till the end of summer, when, the union being complete, it may be removed.

The principle upon which the external plaster is applied to the junction, is that of excluding the atmosphere from the wound, and is thus scientifically explained by Rennie:—'It is to prevent the oxygen of the atmosphere from getting to the fluid pulp at the joining, where it would unite with the carbon, and form carbonic acid gas, and thereby rob the pulp of its solidity. The exclusion of light is necessary on the same account; for, as in the case of a finger cut, the oxygen would unite with the carbon, and prevent the thickening of the matter of the blood. On the same account moisture, by supplying oxygen, would be injurious; and dryness might act both by exhausting the pulp, and by causing the edges of the bark to shrivel and gape, which would facilitate the entrance of the air with its oxygen. It must be obvious, from the simple principle (never, as far as I am aware of, before stated with reference to grafting) that no composition, whatever may be said of its peculiar power of healing, can act in any other way than this, any more than the farrago of plasters and salves for healing flesh wounds and cuts, which are only advantageous in so far as they keep the lips of such wounds together, and exclude oxygen and light.'

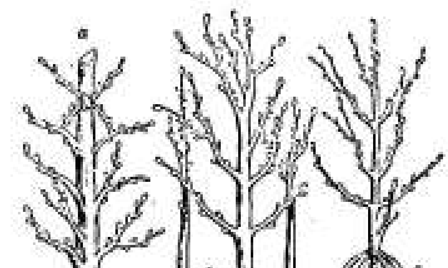
If the grafting has been properly performed, and other circumstances be favourable, the scion in two years will be in blossom, and yield a crop of fruit. What its quality will be, must depend on the nature of both stock and scion. If the scion be of a fine variety, that it will remain; and if the stock be equally fine, the quality will be improved. The excellence of the scion, however, is the prime consideration, for it is the part which is immediately concerned in the elaboration of the descending sap or proper juice, upon which depends the flavour and quality of the fruit.

Speaking of the descending sap, it may be here observed that the thickening of this juice, which is necessary for its accumulation, does not take place without the aid of heat and solar light; and thus, in cold wet situations, plants seldom produce so much fruit as in warm and dry ones. Abundance of carbon and nitrogen is further necessary; and scientific cultivators, having observed these facts, take advantage of them when they wish to throw trees into fruit, by keeping the roots so near the surface as to be within the reach of atmospheric air, from which they obtain carbonic acid and nitrogen. They also bend the branches in training them against a wall, so as to prevent the too rapid descent of the sap, and to force it to accumulate in those places where they wish flower-buds to be produced. If a ring of bark be taken off a tree in spring, the sap will rise just the same as usual; but when the sap begins to descend, a protuberance will be formed just above the ring, which will be occasioned by the accumulation of the sap; its further descent being stopped by the removal of the liber, which contains the vessels of the latex. This theory also explains why gardeners sometimes ring the branches of trees in order to throw them into fruit.

For an account of the process of *budding*, which is analogous to grafting, we refer to the previous sheet.

In-Arching.

This is an ingenious mode of grafting, by which one growing plant, without removal, is made to strike upon another plant, and thus form a union. It may be performed in various ways, as represented below. For



example, two branches of a tree (*a*) may be bent so as to meet and strike upon a wound in the main stem, by which a gap will be filled up; one growing tree (*b*) either from the ground or a pot, may be led to unite with another; or several suckers (*c*) may be led from the ground archwise to strike upon a point in the stem, thus bringing fresh aid to the productive part of the tree. By means such as these, quickset hedges might be thickened like a network, so as greatly to improve their appearance and protective qualities.

KERNEL FRUITS.

Kernel fruits, or *pomes*, as they are scientifically named (see VEGETABLE PHYSIOLOGY), include the apple, pear, quince, and others: those which require any notice here are the varieties of apples and pears.

The Apple.

The apple-tree is of universal European growth, and is believed to have been introduced into Britain by the Romans. It was greatly cultivated in the gardens of monasteries during the middle ages, and from that source the greater number of our cultivated varieties have drawn their origin. The *crab*, or wild apple is the type of the fruit when left to degenerate, and to which it would speedily return, but for constant culture and crossing. Culture, without crossing or grafting, is found to prevent an immediate return to the crab; and therefore, when an improved variety is obtained, it will yield seeds productive of a similar variety. The extent, however, to which varieties may be preserved without crossing, has never been accurately determined, as the practice among professional gardeners is not to risk degeneracy in the fruit; and they uniformly resort to one or other of the methods of grafting above mentioned. The apple-tree, if favoured by a good soil and climate, will live to a great age, two hundred years being not an unusual duration in a fruit-bearing condition. Some orchard apple-trees now existing in Herefordshire are said to be a thousand years old; and many were undoubtedly brought over by the Normans in the time of William the Conqueror.

The varieties of cultivated apples are now innumerable. In 1834, the catalogue of the garden of the Horticultural Society of London described 1400 varieties, and there are now in all probability several hundreds more. The numerous varieties are of three sorts—apples for the *table*, or to be eaten raw; apples suitable for *baking* and other culinary purposes; and apples for *cider*. Table apples are again subdivided into those which will keep, and those which will not. The choice kinds at present include Ribston pippin, which will keep till March, but is in its prime about Christmas; the Dowton nonpareil, scarlet pearmain, and Blenheim orange. The Keswick and Kentish codling and Hawthornden are early ripe, but the fruit will not keep beyond October. The nonsuch is a fine apple, and remains good in October. The old nonpareil is in every respect deserving of its title; its flavour is high and musky, and it keeps long; few apples bring such a high price in the market in February. Other choice long keepers to be named are, the scarlet nonpareil, the golden harvey or brandy apple, the winter pearmain, and the Easter apple, commonly called French crab. The best baking apples are the Colvilles for early use; the rennets and pearmains for autumn; the russets and Padley's pippins for winter and spring. To this short list hundreds might be added; but those who can grow what we have enumerated, and bring them to their full complement of bearing, can require no others as stock-trees. It must always be borne in mind, however, that what will succeed well in one garden may not do so in another, and that experience as to soil and climate, independently of advice from skilled neighbours, will in every case be necessary in the proper and profitable conducting of the fruit garden.

Mr London, in his 'Encyclopædia of Gardening,' mentions, that for *cottage gardens*, where the soil and situation are favourable for the production of the apple, the following sorts are recommended by Mr Thompson:—'Where the space will admit of only one tree, the best is the Ribston pippin; where two, the Ribston pippin and Dutch mignonne; where three, the Wormsley pippin, Ribston pippin, and Dutch mignonne; where four, the Wormsley pippin, king of the pippins, Ribston pippin, and Dutch mignonne; where five, the Wormsley pippin, king of the pippins, Ribston pippin, old nonpareil, and Dowton nonpareil; where six, the Wormsley pippin, king of the pippins, Ribston pippin, Alfreston, old nonpareil, and Dowton nonpareil; where seven, the Wormsley pippin, king of the pippins, Ribston pippin, Alfreston, Dutch mignonne, old nonpareil, and Dowton nonpareil.' Beyond this, Pennington's seedling and any other good sorts may be added. The same writer continues:—'It often happens that one or more trees can be trained against a cottage wall or roof, or against some wall appertaining to a cottage; in these cases, the proper sorts are, Ribston pippins, old nonpareils, and if a large kitchen apple be required, the Bedfordshire foundling. In situations liable to spring frosts, which so often kill the blossoms of the generality of apples, the Court pendu plat is recommendable, as its blossoms expand very late in the season. Under less favourable circumstances, where the Ribston may not succeed, the Bedfordshire foundling will be a hardier substitute, or the king of the pippins, which is still hardier; the northern greening may be planted for late kitchen use. For an autumn apple, perhaps none in this case is more to be recommended than the Keswick codling.' To these observations we need only add, that the cottager will do well in all cases to prefer one or two copious-bearing trees to a number of fanciful and fickle varieties.

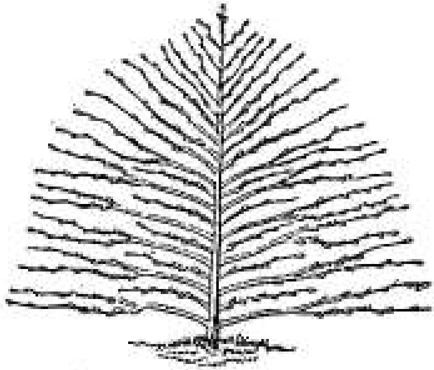
Standards.—Pruning and Training.—Standards are those trees which grow independently in open ground, and are classed as Large and Dwarf Standards. The proper object of cultivation is to give figure to the tree, of whichever kind, and bring it to a fertile or mature condition. Apple and pear-trees, as they approach to maturity, develop short *spurs* along the entire extent of the branches, and those spurs are the best in every respect which are produced naturally without the aid of the pruning-knife. But in addition to fruitful spurs, the trees produce a great number of superfluous wood-shoots, which, if not entirely removed, or at least so curtailed as to convert them to bearing spurs, would render the tree almost useless; in short, to effect prolific fruit-bearing, the shoots must be kept in subjection, or in the state of spurs. A recent writer on this subject observes:—'If a tree be a free grower, on a free stock, as the crab, or a strong pippin, from seed, all the leaders will be checked by shortening them back every year to a distance from the point of origin, which varies according to their strength; where they are very strong, the leading shoots should not be reduced more than within twelve or fifteen inches of their base; but when they are weaker, they may be cut to within nine inches. By this means the onward growth of the branch is momentarily arrested, the ascending sap is impelled into the lateral buds, some of which will be sure to grow so slow as to become productive.'

The foregoing directions comprise a view of the theoretical principles of pruning, and it affords an excellent groundwork for practice; but those who are strangers to the cultivation of fruit-trees, and, as such, undertake the management of an orchard, will be surprised and perplexed at the anomalies which continually present themselves; it will then be self-evident that gardening cannot, in its routine, be learned from books; that one tree assumes a certain mode of growth; another produces developments in an order which has not been foreseen or contemplated; another forms its fruitful spurs spontaneously, without solicitation or the adoption of means; while a fourth, in despite of the most rigid foreshortening, continues for years to yield nothing but growing shoots. We have seen numbers of spur-trees purchased at the same period, and treated upon the same principles, every one of which evinced a habit or constitution to a greater or less extent peculiar to itself; thus it is with trees as with the human genus—to be in any degree known, they must be individually and diligently observed and studied. This experimental fact being admitted, we may safely adduce the practice of pruning recommended by Mr George Lindley for dwarf standards, in his 'Guide to the Orchard,' &c. He observes that 'dwarfs on *crab-stocks* are much more adapted for large and ponderous fruit than standards, as they not only produce larger fruit, but are less likely to be blown down by high winds. Trees for this purpose should have their branches of an equal strength: those which have been grafted one year, or what are termed by nurserymen maiden plants, are the best; they should not be cut down when planted, but should stand a year, and then be headed down to the length of four or six inches, according to their strength; these will produce three or four shoots from each cut-down branch, which will be sufficient to form a head. At the end of the second year, two or three of the best placed of these from each branch should be selected, and shortened back to nine, twelve, or fifteen inches each, according to their strength, taking care to keep the head perfectly balanced (if the expression may be allowed), so that one side shall not be higher or more numerous in its branches than the other; and all must be kept as near as may be at an equal distance from each other. If this regularity in forming the head be attended to, and effected at first, there will be no difficulty in keeping it so afterwards, by observing either to prune that bud immediately on the inside next to the centre of the tree, or that immediately on the outside. By this means, viewing it from the centre, the branches will be produced in a perpendicular line from the eye; whereas, if pruned to a bud on the right or left side of the branch, the young shoot will be produced in the same direction; so that if the branches formed round a circle be not thus pruned to the eyes on the right successively, or the left successively, a very material difference will be found, and the regularity of the tree will be destroyed in one single year's pruning.'

What is here said refers only to the leading shoots which form the figure of the tree; others—side shoots (*laterals*)—are developed, and these require constant regulation. 'In pruning these laterals or supernumeraries, they should be cut down to within an inch of the bottom, which will generally cause the surrounding eyes to form natural blossom spurs; but where the tree is in a vigorous state of growth, branches will probably be produced instead of spurs; if so, they must all be cut out close, except one, which must be shortened as before. In all winter prunings, care must be taken to keep the spurs short and close, none of which should at any time exceed three inches; cutting out clean all the blank spurs, which have produced fruit the previous summer, to the next perfect bud below.'

It would perhaps be impossible for any writer to improve upon these directions generally; they comprise all the essentials for producing a balanced dwarf standard—that is, a tree low in stature, furnished with ten or twelve regular main branches, proceeding at a short distance from one central stem, each branch garnished from base to summit with fruitful spurs. But experience has instructed us to caution a pruner not to expect too much, but to watch the figure which his tree affects, and the course of its supernumerary shoots. If it evince a decided tendency to form short spurs naturally at a very early period, he may prune short, as above directed; but if its habits be so luxuriant as to produce wood-shoots after each pruning, it will be wise to defer the summer cutting of the spring shoots till the middle of July, instead of performing it at or before midsummer; and then either to snap the shoots or to cut them to a bud situated at least five inches from their base. This pruning, late as is the season, will generally cause each shoot to break its leading eye; in August, therefore, this new shoot is to be checked by nipping off its point; and finally, in September the spring shoot is again to be cut at the eye, below the one at which it was first pruned in July. In this way the vigour of the tree will be moderated, and several of the lower buds will probably enlarge, while the leading bud only expands into a growing shoot. If these hints be understood and acted upon, a young pruner will experimentally be taught to apply them, and thereby acquire the tact to discover the constitution of his trees individually, and to coax them into a condition of maturity. At the winter regulation, when the buds begin to swell, it will be easy to discern the fruitful eyes; and where any of these are discerned, the shoot projecting beyond them must be entirely amputated; and this may be done with safety, for spurs, when once fully formed, rarely break into barren shoots, though one of the eyes may do so.

Wall-training.—The circumstance of apple-trees producing fruit only on the outer parts, which are freely exposed to the sun and air, has led to numerous contrivances for exposing the inner as well as the outer stems. One method, as is well known, is the training of the tree in a flat shape against a wall—a plan also advantageous for enjoying the heat, which the wall radiates as a reflector against the branches. A difference of opinion exists as to the comparative merits of training the main stem in a serpentine or in a straight upright direction, and also whether the branches should be led perfectly horizontal or with an upward slope. If the height of wall permit, the upright stem and fan shape, as represented beneath, seems the most advan-



tageous, and certainly the least troublesome plan; and we would recommend unprofessional gardeners to attempt no other. Where the wall is low, the branches should proceed more horizontally; and the tip being restrained by pruning, those lateral stems will gain greater vigour. In either case, the branches, great and small, will require to be held in their appointed situations on the wall by stripes of list and nails. The nailing should not be so tight as to prevent expansion in growth, or be otherwise injurious. Iron nails rust and disfigure the wall, therefore nails made of zinc, where they can be driven home, are preferable. When a branch at any time becomes loose, it ought immediately to be refastened.

Espaliers.—These are rails generally formed of upright and crossbars of wood, but sometimes made of cast-iron. The best are of wood, and of from four to five feet in height. To these the trees are trained as on a wall, with this difference, that instead of being nailed, the branches are usually tied; the fastenings are soft hemp cord or strips of bast; but twigs of willow answer much better. The situation of espaliers is generally along the sides of walks; and if the trees be carefully trained, they have a neat effect. Care must be taken that they do not prevent the sun and air from reaching the kitchen vegetables. 'When properly managed and well exposed, espalier trees, observes Neill, 'generally produce excellent fruit, the sun and air having access to both sides of the tree: they commonly afford abundant crops, and the fruit is not apt to be shaken by high winds. Farther, they tend to hide the crops of culinary vegetables from the eye, and to render the kitchen garden as pleasant as an avenue in the shrubbery.'

The following hints on espalier training, by the author of the 'Manse Garden,' appear so eminently useful, that we take the liberty of giving them a place here. First, as to cultivation: 'Have the ground well trenched and manured [taking a crop of vegetables the first season], and plant the trees three or four feet from the walk, and twice as near to one another as they should afterwards be when full-grown. The reasons for this close planting are, that the value of a few crops is more than the expense of the trees; your rails are sooner covered; and when the trees begin to meet and incommode one another, you can then, having ascertained their various qualities, give scope to the best, by diminishing or rooting out the less worthy. For one or two years after the meeting has taken place, you may delay the pain of execution by allowing the young shoots to pass one another on the opposite sides of the rails. To incur no more expense than is necessary, the stakes may be placed two feet apart, in which case the annual shoots will require to be conducted from one resting-place to another by pieces of lath or wild brier, or willow of two years' growth. These conductors require a firm and separate tying, distinct from that which fastens more loosely the living wood; they thus give strength to the rails, and provide for straighter training than is commonly done by having the stakes twice as thickly set, and consequently at double the expense of timber.

Supplementary to both wall and espaliers is the following device, which has proved eminently successful:—Supposing that you have more garden ground than is necessary for the supply of vegetables, and that some part of it may be spared for a green shady walk amidst shrubs mingled with standard fruit-trees, on the south side of a row of evergreens, impervious to the eye, let a dry stone-wall be raised to the height of four or five feet, and coped with large stones, merely for strength and durability. Plant this on the north side with ivy, to assist the screen of shrubs, and in a short time not one stone will appear. From the south side take away all the good soil to a depth of two feet, a breadth of five feet, and a length equal to that of the wall, which may be sixty or a hundred feet, as you find convenient. This excavation, it is to be understood, runs close by the building, the foundation of which must of course have been secured by perhaps a foot of depth, and which will yet be uninjured, as the stones that cast up in removing the earth will immediately be thrown to the base in room of the materials taken away. Thus an effectual provision is made against the springing up of docks, nettles, or other troublesome weeds; the earth removed will be an invaluable treasure, whether for making compost or helping a thin soil; and the excavation itself will afford a most convenient receptacle for the immense quantities of stones which occur in trenching or raking the garden. Suppose the filling up in this manner to be nearly completed, let a row of large thin stones, set on edge, run along the southern boundary, and rise two or three inches above the surface of the ground. This will serve to keep the mass of stones distinct from the earth, that there may be no mingling in the process of digging. You have then on the one side of this excavation the low edging, and on the other a wall of four or five feet; and the design is, in the course of time, to fill up, with the riddlings of the garden or with clean stones, in whatever way, the whole space from the summit of the low edging to the top of the wall, to present an inclined plane facing the south, and nearly at right angles to the rays of the sun. On this [which is, in reality, a mound leaning against a wall] fruit trees are to be trained. Before the bank is completed to its proper slope, the trees may be planted along the southern boundary, and trained for two or three years upon poles laid from the edging to the top of the wall, according to their future destination. When the surface of the sloping bank is raised within an inch or two of its proper height, let a layer of coarse sifted gravel be laid on the top. This will much improve the appearance, and increase the reflected heat; and being free from small sand and earthy particles, will give no birth to annual weeds.

For the purpose of training, should peaches or apricots be planted, a close trellis will be requisite; but apples or pears will require nothing more than common espalier rails laid on the gravel, and held in their places by two slight spars running across, one at the top, and the other at the bottom. In the meantime, the ivy produces a beautiful and beneficial effect, surmounting the wall, and adding to the closeness of shelter caused by the evergreen shrubs. It should be clipped along the top after the manner of box-edging. Nothing can exceed the real snugness of the trees so placed, or the beauty of their glowing blossoms spread out under the eye; and the quality of the fruit comes fully up to the theoretic advantages with which it is favoured. The heat is undoubtedly much greater than that of the best wall; and the open flowers find, in their humble height, a shelter, like the daisy of the field, from the sweeping blast, which often scatters the petals of a higher tree like a shower of snow. Experience has fully proved the suitableness of this contrivance to all elevated situations. In some places very low and warm, the heat, so powerfully reflected, might possibly be too great; but in that case figs and nectarines might be so exposed, and would certainly take all that they can get.'

The Pear.

The pear-tree, like that of the apple, is found in a wild state in all parts of Europe, and has been similarly domesticated and improved into many fine varieties. The tendency of the tree is to a handsome pyramidal form. It is much longer in attaining maturity than the apple-tree; and on a dry soil, it will survive and continue fruitful for centuries. The tree may be propagated by seeds, layers, cuttings, budding, and grafting: it is more frequently raised from seeds than the apple; but grafting on its own species is also common, and is generally successful.

The observations already offered respecting soil for apple-trees apply equally to those of the pear kind, and nothing more need here be said, either on that subject or on general culture. The pruning, however, is different, because the pear is a very independent growing tree, and, as a standard, will assume its own natural figure in opposition to all restraint. All branches which lash one another must be removed; but unless the pruner cut and deform his trees in his attempts to create fruitful spurs, there will seldom be a redundancy of wood. A little foreshortening or disbudding in the spring and summer may be useful; but in general, as the pear can seldom become fruitful under seven or eight years from the grafting or budding, it will be prudent to watch the gradual development of the natural spurs, and to cut back the laterals to them when formed, and not before. Mr Knight pruned very little, shortening the main shoots occasionally, not sooner than July. He thus expressed his opinion in a letter to a professional gardener on the subject, in April 1833:—'I would recommend the knife to be little used upon the young pear-trees, particularly upon the horizontal branches. As a general rule for pruning trees that are to be kept low in gardens, I recommend the upright shoots to be shortened about the beginning of July.'

About 200 varieties of pear are enumerated in recent catalogues, all differing from each other in their qualities, time of ripening, &c. Among the finest sorts may be mentioned the Jargonelle, Marie Louise, Beurré de Capiaumont, Muscadelle, Bonchrétein, St Germain, Rousselet, Wilding, Beurré Diel, Glout morceau, Easter beurré, and Beurré rance. The word *beurré*, which here occurs several times, is from the French word for butter; and that, as well as the other names, show how much we are indebted to our continental neighbours for perfecting this delicious fruit. In selecting pear-trees, the nature of the locality must be consulted, subject to which the Jargonelle and others mentioned, also the Windsor, are general favourites. The summer, autumn, and winter Bergamots are not excelled for rich muskiness of flavour. The pear requires a warmer climate than the apple: hence some of the finer sorts, which grow well as standards in the south and central parts of England, will require a wall and shelter in northern or more keen situations. Any sorts worth the cultivating should have a rich aromatic flavour, and be either of the melting kind (*beurré*), or be firm and crisp, like the winter Bergamots.

Orchards.

An orchard is a piece of ground specially devoted to the rearing of fruit-trees, principally apple and pear, and is frequently an appendage of the English farm and manor-house. It should be a well-fenced enclosure, and if there be room for a choice, its situation ought to be on the side of a dry knoll sloping to the south-eastward; the best soil is a fresh sandy loam, of eighteen inches in depth or upwards, reposing on a subsoil of dry gravel or rock. If the ground be wet, it must be thoroughly drained in the first place, as no fruit-tree can answer its purpose if the soil be otherwise than dry. A damp clayey subsoil must be avoided; and the deep rich soil in the lowest dip of a valley is the worst situation to be chosen; for though it may be sheltered against wind, it is most liable to keep the trees in a growing state too late in the autumn, and to be severely assailed by late frosts in the spring, when the trees are probably in flower.

Shelter is necessary to orchards against the autumnal south-west winds; but this is best obtained by high hedges or forest-trees planted on that side. Winds from any other quarter need not be so much dreaded. Sheltering hills at some distance are an advantage, so as the orchard is not in the lowest dell at their base. Many orchards are almost barren, the trees covered with moss and lichen (a fine harbour for insects), only from their being too much sheltered, and deprived of a free current of drying air.

As an orchard is usually a pasture for sheep, cows, or other cattle, the trees to be planted in it must be standards; that is, trees trained in the nursery, with a clear stem six or seven feet high, from the top of which the branches diverge, and out of the reach of cattle. Sometimes the stocks are first planted, and when fairly established, are *worked*—that is, grafted or budded at the desired height.

If an orchard is to be formed out of an arable field, the ground may be prepared by the plough, laid into bands or ridges of eight yards wide, the trees to occupy the middle or crown of each ridge, these lying south and north. The trees should be planted in right lines, five, six, or eight yards asunder; and the whole area surrounded by a deep ditch and hawthorn hedge. When the trees are planted (which should be about the end of October), the ground may be laid down with a crop of barley or oats, with grass and clover seeds in the spring, and so remain.

If an orchard is to be formed in a grass field, it is drained, if necessary, and enclosed with a hedge and ditch as above; the trees are either planted in trenched pits or in trenched borders; that is, borders six feet wide are traced south and north, and regularly trenched fifteen inches deep, the turf being turned to the bottom. Along the middle of these borders the trees are put in at the distances already mentioned. This done, the broken ground is sown down with grass seeds, and the trees staked and protected against cattle, if they are in any danger. The pits, six feet square, are trenched and planted in like manner. In planting the trees, the ordinary care must be bestowed as well in taking them up as replanting; each should be set on a little mound of the finest of the soil, on which the roots should be regularly spread, and kept near the surface—for deep planting must be carefully avoided; the uppermost fringe of roots should just be within the turf, but no deeper; and they should be encouraged to take a horizontal rather than a downright direction. Orchards planted in either of these methods answer very well, if care is taken of the trees till they are fairly established, and can protect themselves.

The fruits chosen for such orchards are apples, pears, plums, and cherries, and of these such as are known to thrive, and are most fruitful in the neighbourhood of the intended orchard; for all fruits are not equally thrifty in the same locality, and this is a point deserving the consideration of the planter. Orchards of this kind are planted chiefly with a view to the service of a family, any redundance being sent to market, or sold on the trees to the fruit-monger; but when fruit-trees are planted as a special source of profit, a very different plan requires to be followed.

An acre or two of suitable land, with a proper exposure, is fixed on; the whole is trenched fifteen inches deep, and thoroughly drained, if necessary. The surface is levelled and laid into beds ranging south and north, and about twelve feet wide; along the middle of these the trees are planted; and the intervals are occupied by two rows of small fruits, either gooseberries, currants, or raspberries. Some of the intervals may have a rank of filberts introduced, which, when kept as low bushes, and properly spurred on, are as profitable as any other kind of orchard fruit. Such an orchard is intended to be a perfect thicket of fruit-trees: all, whether yielding large or small fruit, must be kept as dwarfs, and trained in the *bush form*. Of course the sorts which are naturally of a dwarfish habit are preferred, and if not dwarfish by nature, they must be made so by art. The bush form is obtained by encouraging the lateral growth of the branches, and depressing by some means or other those which have a tendency to grow upright. A sufficient number of branches is gained by pruning while the trees are young, and so disposed that they may aggregately form a rotund, compact, but not overcrowded head, shading a circle twelve or fourteen feet in diameter, more or less, according to the fruitfulness or individual strength of the trees. This close planting and low stature of the trees render them a shelter to each other, both against the frosty winds at the time of flowering, and against the equinoctial gales of autumn. The surface of this orchard is never dug. In dry summers, a mulching of half-decayed littery-dung is spread under the trees, and hoed in during the winter. Strawberries are introduced when the trees are young, but the ground must not be exhausted by surface cropping.

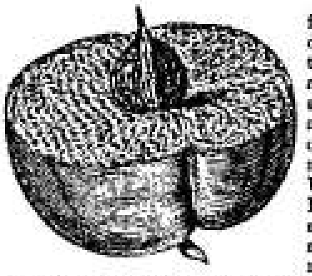
The success of such a fruit garden depends very much on a proper selection of the kinds, and on the skill of the manager in keeping the trees fruitful and dwarfish, without the application of the knife; for this is quite practicable, and is an art which must be had recourse to in the treatment of dwarfed trees.

In Herefordshire, Devonshire, and adjoining districts in England, orchards are maintained principally for manufacturing a beverage from their produce. *Cider* is the liquor made from apples; the trees in most estimation for the purpose being the new foxwhelp, the wilding, the cherry pearmain, and the yellow and red Norman. When the ripened apples have been shaken from the trees, they are allowed to remain in heaps for a month or so on the ground, to become mellow; after which the process of manufacture into cider commences. (See No. 46.) *Perry*, or the liquor from pears, is also a pleasant and wholesome beverage, and in some instances almost approaches the quality of sparkling champagne. The most austere varieties of the pear, unfit for the table, answer best for this purpose; and it is thought that a mixture of the wild pear with the cultivated sorts make a peculiarly fine liquor.

Quince and Medlar.

The *quince* is classed by botanists with the apple and pear, and these are often grafted on quince stocks, which confirms their consanguinity. It is said to be a native of eastern Europe, and to grow wild on the banks of the Danube. It was introduced into Britain from the isle of Candia, and grows readily in our hedges; but is not much used—the fruit in its raw state having a peculiar disagreeable smell, and an austere taste. It is sometimes employed to give flavour to apples in pies and tarts, and is occasionally made into a marmalade, which is much used in the south of France, where the quince is extensively cultivated. The *medlar* is also a native of south-eastern Europe, though long naturalised in Britain. It somewhat resembles a small apple, and possesses considerable flavour, but which is seldom developed, even in its ripe state, on the tree. It is gathered and laid aside until it begins to change or decay, and then only is it fit to be eaten.

STONE FRUITS.



The finest wall fruits of the garden are included in this division; these are, the peach (see section), nectarine, apricot, plum, and cherry, and all their numerous varieties. Under these well-known names we shall take a cursory view of each, referring the reader for minute particulars to the catalogue in Lindley's 'Guide to the Orchard and Kitchen Garden,' and to that of the 'Fruit Cultivator,' a small work of great merit, by the late Mr Rogers of the Southampton Nursery. Besides the familiar term *stone fruits*, botanists refer all the trees which bear fruit with a kernel contained within a hard bony shell, surrounded by a rich and saccharine pulp; this, consequently, would embrace that division (*Amygdaleæ*) which has the almond-tree for its type. The peach and nectarine were, till lately, considered species of the almond (*Amygdalus*), but they have been separated from that family, and constituted into a distinct genus (*Persica*). The nectarine, by some considered as a mere variety of the peach, and by others as a separate species, differs only in the epicarp or outer covering of the pulpy part being smooth instead of downy.

Peach and Nectarine.

Both are natives of Persia, introduced from that country in the year 1562, and extensively cultivated since that period. Each admits of two leading subvarieties—the melting peaches and nectarines, or *free stones*, and those with more solid flesh adhering to the nut, and therefore termed *cling stones*. The French consider them as one fruit, but arrange them under four divisions; but we prefer to simplify our description as above, and shall even dismiss the cling stones altogether from our catalogue, deeming them comparatively worthless, being later in their season, and of a flavour altogether inferior to the true melters.

The peach and nectarine (*P. vulgaris* and *lævis*) can be raised by sowing the stones, and excellent varieties have been so obtained; therefore it is not a fact that the trees raised from seed are wildings; but as there is no certainty of what a seedling may ultimately become, it is not prudent to trust to this mode of propagation; and though we would urge every gardener to make himself intimate with the process of budding—that approved and certain method of perpetuating approved varieties—yet as much time must thus elapse before a wall can be stocked with fruitful trees, we think it advisable that he purchase of a good and trusty nurseryman such varieties as are found to be adapted to the locality. The peach and nectarine are seldom grafted; it is usual to select buds of trees that are approved bearers and of fertile habits, and to insert them into young vigorous stocks of the muscle plum or seedling peach. Nurserymen raise their trees in this way, preferring the plum stock; the operation is performed late in July or early in August. The buds swell, but remain torpid till the spring of the following year, at which time the head of each budded tree is cut back to an inch above the inserted bud, which then expands, and forms one or more shoots. Trees in this condition are called 'maidens,' and many prefer such; but in general the nurseryman prunes and trains them into form during the two succeeding years, when they are sold as trained trees, at a price varying from 4s. 6d. to 7s. each. The mode of training thus commenced is usually that which is called the *fan* or *peacock's tail*. It is formed upon the principle of rejecting a central stem, and of leading all the main branches and their secondaries to assume the figure of an expanded fan. It is to obtain such trees that we recommend the planter to purchase the *trained* plants of the nursery garden. But there is another very excellent method of forming a tree, called the *Seymour training*, from the name of the gardener who introduced it. This plan requires a central stem, from which all the main shoots are trained at angles, varying according to the height of the wall and the vigour of the trees. The branches are led to the right and left alternately, at as nearly equal distances (about nine inches) as possible; and when a tree grows kindly, and the pruner is a man of dexterity and foresight, a handsome well-balanced tree is the result. To obtain these Seymour-trained trees, the planter must purchase 'maidens,' and either train them himself or employ an adroit pruner who is willing to attend to the required directions. We shall now attempt to explain the principles upon which all judicious pruning is founded.

The peach produces its fruit upon the spring wood of the previous year; occasionally, also, if the habit of the tree be very vigorous, upon secondary shoots from that wood; but this is by no means desirable under ordinary circumstances, because it proves that the tree is too luxuriant in young wood, which, being developed after midsummer, can scarcely become duly mature. A tree cannot be expected to produce or support a crop of fruit in a period short of four or five years from the budding; but during that period, the art of the gardener should be employed to lay in six or more regular branches to the right and left, which will form the skeleton or figure of the tree, and remain the permanent supporters of the young-bearing wood. In the fan method of training, secondary fruitful shoots are permitted to form at the under as well as the upper sides of these main branches; but in the Seymour training, the fertile secondaries are led off from the upper sides only; all those which break from the front (called *fore-rights* and *breast-wood*), or from the back next the wall, or from the under side, are obliterated as they appear, either by pinching them off with the finger and thumb, or by amputation with a sharp knife; this process is termed *disbudding*. The quantity of wood to be retained, year after year, so as to obtain a regularly-increasing proportion of fruit, without redundant wood, is chiefly produced by the judicious use of the knife in disbuddings.

We will suppose the example of a tree trained in the nursery during two years, then planted in October against a wall fronting the south or south-east, and cut back in February following, so as to leave all its branches about six inches long. The shoots of the first spring form the bases of the permanent branches, and are to be nailed, as they advance, in the most regular order, leaving them at their full length till February of the second year, when the strength and condition of the tree are to be consulted. As a first rule, we are taught, and experience sanctions the rule, 'that every shoot is to be shortened in proportion to its strength, by pruning to the point where the wood is firm and well ripened, by which all the pithy wood is removed, causing a supply of that which is better ripened for the ensuing year.' But in order to facilitate the ripening of the wood, it must be trained thin, retaining those shoots only that may be required for the ensuing year. After two years' growth in a good soil, we may reasonably expect that six or eight permanent shoots, a yard or four feet in length, will be formed and trained in, on each hand, and that all these branches are furnished with three or more secondaries, laid in at nearly equal distances from one another, and which, by the end of June, may be a foot or more in length. The tree will continue to grow till the end of August; but disbudding must be effected repeatedly, so as to leave it in the form and condition just described.

It has then become a bearing tree, which condition implies a series of strong woody branches of two, three, or more years old, that have produced other shoots in the spring, which, when ripe, are of a deep reddish-brown tint on the sunny side. These latter are the fruitful shoots, and they never bear twice; but if neglected, run on to an uncertain length, sending forth other weak laterals, which might indeed bear a little fruit, but such as could never compensate for the ruin, or at least disfiguration of the tree. It is a maxim among good pruners that a peach-tree should be *green* throughout or all over; that is, every space, even close to the main stem, has one or more leafy and fertile shoots. This maxim would be violated in two seasons were all the shoots permitted to extend themselves, and the tree would be found bare—every part of the centre becoming verdant and productive only at the remote extremities. Hundreds of fine peaches and nectarines can be found in this condition; and in fact the greater proportion of those in private gardens afford irrefragable evidence of neglect or want of knowledge.

The bearing-shoots, therefore, must be shortened to twelve or fourteen inches, if strong, and the weaker to eight or ten inches, or even to half that length, if very slender. The pruner should cut sloping from behind, and a little above a *treble* eye—that is, an eye with a shoot-bud between two blossoms, if there be such; for a branch or shoot not in a mature or bearing state has no treble eyes; but in furnishing a tree, it is not needful to cut away the wood-shoots as useless; because by pruning back to an eye seated rather low on the shoot, two good fertile shoots may be provided in lieu of a barren one. A single sharp-pointed eye is the origin of a wood-shoot; the blossom-bud is more bulky and rounded; but by deferring the winter regulation till late in February, the condition of the two will be no longer doubtful.

When it has once been so pruned, the leading branch will break its extreme bud, which will thus elongate that branch; and the fruitful laterals will also develop several minor shoots. It is from the last that a selection must be made to effect two objects of the greatest importance. The first is, to attract the sap along the entire shoot, in order to nourish the young fruit upon it; and this will require that the shoot at the extreme point, or at least one beyond the uppermost fruit, be permitted to extend itself, and be nailed securely to the wall, when it shall have acquired some strength and toughness. The second object is, to provide a shoot to succeed the one now bearing fruit; and in doing this, the lowest should be selected, because it will, by its situation, replace the present shoot in a manner most conformable with the gardener's maxim before adduced, and tend to keep the tree compact and fertile—*close home*. A third shoot ought also to be retained to guard against emergency or accident; all the others should be removed by disbudding early in May. In July also a general regulation must take place; when, by removing useless shoots, and nailing those retained, the fruit will be duly exposed to the sun's rays. Thus the growth of shoots and fruit proceeds; and if regularity and order be maintained, the tree will, year after year, elongate, and add branch to branch, retaining complete verdure throughout. A few lines from 'The Guide,' by G. Lindley, will suffice to complete our concise directions:—'Should young shoots, indicating extraordinary vigour, anywhere make their appearance, they should be immediately cut out, unless where a vacant part of the wall can be filled up; because an excess of vigour in one part of the tree cannot be supported without detriment to the other. Peach-trees, when in a state of health and vigour, generally throw out laterals from their stronger shoots' [he means *secondary* laterals, before alluded to]; 'when this is the case, they should not be cut off close, but shortened to the last eye nearest the branch' [this is, in fact, to spur them, in the hope to convert the lowest bud into a fruitful one]; 'and if there is room, one or two of those first produced may be nailed to the wall, or the middle shoot may be cut out, leaving the two lowest laterals, and allowing them to take its place—thus frequently obtaining two fruit-bearing branches, when the main shoot would in all probability have been wholly unproductive.

In the thinning of peaches and nectarines, and indeed any other drupaceous fruit, it is necessary to proceed with caution, as they are apt to fall off after having attained a considerable size. In order, therefore, to secure a crop, it will be the best way to thin them at three separate times: the first, as soon as the fruit is of the size of a hazel nut; the second, when of the size of a small walnut; and the third, as soon as the stone has become hardened; after this, it rarely happens that either peach or nectarine falls off before it is matured.' These directions apply in every part to the order of training by the Seymour method; for all the bearing wood of one year must be replaced, if possible, by young shoots proceeding from the base of that wood; this fact, if appreciated, will of itself render any adroit man an able trainer and pruner of the peach-tree.

Peach-trees are but too liable to be molested by insects and mildew; the former are usually some species of the aphis, commonly called *green fly*, though, as in 1840, it was *black*. Some trees doubtless escaped; but those which were attacked suffered to an extraordinary degree, insomuch that the crop dwindled, and the growth of the trees was checked—three distinct broods having succeeded each other between the middle of April and July. They obstinately resisted every kind of wash, though in general tobacco water is effectual. Scotch snuff and fumigation failed; and at last premature close-shortening was resorted to, and thus the new wood was seriously injured. We allude to this fact, as being in strict accordance with the concomitant visitation of the black aphis which locally destroyed the bean crop, and deformed kidney-beans, peas, and even the nettles and other weeds of the fields and lanes. A disease produced by frost, which is called 'the bladder blight,' frequently swells and distorts the leaves of peach-trees: we are acquainted with no other remedy but that of timely hand-picking. By these attacks the regular training and figure of the trees are much disturbed; and occasionally an entire season may be irretrievably lost.

With respect to soil and preparation of a border, what we have said under the head *apple* applies strictly to the peach. As wall-peaches must have a border, we can devise no plan more effectual or simple than that of clearing out a space of the required length, of eight to twelve feet in breadth, the depth of soil at the wall to be twenty inches, sloping to fifteen inches—making a fall of five inches from back to front. To effect ample drainage, the bottom should be paved, as before recommended, with chalk or fragments of stone, &c. rammed hard, and inclining to a rubble or stone drain running parallel with the wall, to carry away the superfluous water from the bed. A natural substratum of chalk or rock would suffice, but in that case depth of soil must be provided. The bed itself should consist of the rich, but not clayey loam and turf, of a common or pasture, having in it no manure whatever. The trees may indeed be top-dressed every winter with littery manure a yard or more round the boles, and so deep as to protect them from frost, just above the collar, at the critical periods of blossoming. It will also be a great preventive of drought in summer; and of this any one may satisfy himself by raising the mulch in the very driest weather, when the soil under it will be seen black and moist, though in other parts it be parched to aridity. The fruit can be one month accelerated, and its value proportionably enhanced, by growing a tree in a pit of 24 feet long, 60 inches deep at the back wall, and 30 inches at the front. The lights will thus obtain a sufficient slope, if their length be seven feet. Hundreds of fine fruit can be produced in July or August by one tree; but great watchfulness will be required about the period of blooming, to check the ravages of the aphides in their earliest approaches; by three days' neglect, we have seen the destruction of a crop, and the ruin of all the bearing wood of the year, in despite of every usual application. A strong lining, twice renewed between February and June, will greatly accelerate the advance of the fruit.

Selection of a few of the finest melting peaches adapted chiefly to the midland counties.

1. *Bellegarde, or Galande.	4. *Noblesse.
2. *Chancellor.	5. Royal George.
3. Late Admirable.	6. Susanna, or Yellow Alberge.

Nectarines.

1. *Elruge, or Claremont.	3. *Violet Hâtive (the best).
2. Fairchild's Early White.	

The trees marked thus (*) are stated by Lindley to be also suitable to the Highlands of Scotland.

The Apricot.

It is believed, upon the authority of Pliny and others, that the apricot is a native of Armenia; whence its present Latin name, *Armeniaca vulgaris.* It partakes of the habits of a plum and peach, and, till lately, was considered a plum—*Prunus Armeniaca.* It is multiplied by budding, either upon the common plum or the muscle plum. Lindley says that it is usual to bud the *Moor-park* upon the former; but he is persuaded that the tree would be better, and endure longer, were it budded upon the muscle; and if he be correct in this, we may safely assert that all the best apricots will succeed upon that stock without having resource to any other. The operation of budding, like that of grafting, may be most readily acquired by observing the practice of a good budder. The season of budding is comprised between the third week of July and the 16th of August, and showery weather is propitious. The buds should be selected from shoots of the spring wood; and in taking them off, a piece of bark one inch and a half long should be retained, from which the strip of wood it contains ought to detach itself freely, without bringing with it the eye of the bud. This eye or point is a vital organ, without which a bud cannot grow. This remark applies to every kind of bud, whether it be that of the apple, pear, peach, or any of their kindred; or of any ornamental tree or shrub which admits of being thus propagated.

The best varieties of apricot are—1. The Peach apricot, fruit high-coloured, and very large; 2. Moor-park, of high flavour, and also pretty large; 3. Brussels—oval, and capable of ripening on an open standard; 4. The Roman, hardy, and an abundant bearer.

As to pruning and training, when the figure of the tree is formed by having three or four branches proceeding from a main stem, each is shortened in the winter regulation, soon after the leaves fall, to six inches, in order to obtain new branches. These are secured to the wall in May or June, at five or six inches' distance from one another, removing all supernumeraries. At the second winter pruning, the leading shoots may be cut back to ten inches, the others growing upon them to six inches, more or less, as position and strength indicate. In May or June following, more wood is laid in from each branch; and thus, by disbudding and winter-shortening, a regularly-formed head is obtained, upon the shoots of which short fruitful spurs are duly and progressively developed. In all winter prunings and curtailments, the longest shoot that is retained ought not to exceed eighteen inches in length; thence diminishing, according to the strength of each, to nine, or even six inches.

These rules comprehend the essence of all the best practical directions; but one remark, which we seldom meet with, appears important: the apricot-tree comes early into bloom, when very few leaves, if any, are expanded; and it frequently fails to set or retain its fruit. This failure we have remarked particularly with low trees horizontally trained. On the contrary, when a tree having a six-feet main stem without a branch is then trained with a central leader to the height of from twenty to forty feet, and suffered to branch obliquely to right and left, the crop of fruit is frequently very great. We also saw, at the end of March, after the severe frost of 1838, one solitary branch of a tree which had been trained upon the breast of a vinery chimney, with fruit larger than nutmegs, and foliage fully expanded, while every other branch remained torpid as any of the exposed trees of the garden. These facts prove that the high wall of a dwelling, and the proximity of a warm chimney, are most favourable to the productiveness of this very fickle tree.

The Plum.

The common sloe of Britain is the type of this genus, *Prunus;* but those rich and luscious fruits which have been so long cultivated throughout Europe are of Eastern origin. Plums are propagated by budding upon the common plum stock; and for standards, Lindley recommends the insertion to be made nine inches from the ground, when, under favourable circumstances, the buds will produce vigorous shoots, standard high the first year. Open standards require little attention; they should be divested of all the superfluous shoots by pruning them out close to their origin, just before the season of spring growth. But wall-trees and espaliers are to be treated as espalier pear-trees; that is, by training them with a central stem, and a series of horizontal branches proceeding from it on each side, nine inches apart. These branches are not to be shortened; and the spurs which form naturally upon them are to be kept short and compact as they advance in length. Artificial spurs may be obtained by July foreshortening; but as fertility is promoted by whatever checks the luxuriance of the wood, it will, we think, be preferable to train in the supernumerary laterals, depressing them below the horizontal level till some natural spurs are formed near their origin, and then to cut the shoots back to the lowest spur.

The plum ripens in September and October. Of the earlier dessert-plums, the green gage and the two Orleans are the best. Coe's golden drop, and the Goliath, come into season in October; and for preserving, we name the winesour, the violette hative, the two varieties of magnum bonum, and the damson or damascene. The Imperatrice is the best late plum, being delicious in November. The soil already mentioned is favourable to the plum, though the tree will prosper in one of more binding quality. Plums are used at desserts, in tarts, and preserves; and, when dried, form the well-known *prunes* of the fruiterer. The fruit of the sloe, when ripe, makes a good preserve.

The Cherry.

The cherry-tree, or *Cerasus*, as it was called by the Romans, has been known as a cultivated tree for at least three centuries; orchards, the produce of which was sold at a high price in the year 1540, existing to a large extent in Kent. This circumstance conferred the name of Kentish cherry on that peculiar species. Lindley enumerates and describes twenty-eight, and Rogers twenty-five, different kinds of cherries; among which the best for general cultivation are the Kentish, the May-duke, the graffion or bigarreau, Harrison's heart, the black heart, and morella. All may be grown as standards, but the May-duke and morella produce larger fruit when trained against a wall.

Standard-trees form their own spurs, and require only a little thinning out of superfluous branches; but wall-trees must be treated as the apricot and plum, avoiding, however, to shorten the leading branches. The morella requires a somewhat different treatment, because it not only bears on spurs, but, like the peach, on young wood of the last spring. Mr Rogers offers some remarks in the form of anecdote, which are deserving of attention:—In the Surrendon Gardens, of which he had the charge, 'a north wall ten feet high had a border twelve feet wide, and very shallow, reposing on loose or rubble rock. The soil was a dark hazelly loam, of rather inferior quality: the roots were very near the surface, those nearest the stem actually above it. Five trees were originally planted, but subsequently the second and fourth were removed, leaving the centre tree at thirty-two feet from the end ones. Even at this distance the branches met; and in their progress, being kept very thin of bearing wood, the crops were magnificent.' The trees were simply planted on the natural surface of unprepared ground, without any manure or deep trenching. 'Neither was this border ever dug with spades, but slightly stirred with blunt forks, and having a little well-rotted horse-dung bestowed every second or third year. There cannot be a more mistaken notion and injurious practice than overloading and poisoning the fruit-borders with rich dung. In the early training of the morella, the knife should be used freely, to gain a sufficient number of leading branches—thinning out the laterals, but never shortening them.'

The cherry-tree grows to a large size, and its wood is highly valued by turners and musical instrument-makers, from its suitableness for being bored and formed into smooth tubes; in the luxurious East it is much used for the tubes of tobacco-pipes. The fruit of the cherry seems less impaired by growing in a wild state than other garden fruits; in Scotland, the wild cherries, called *geans*, are small, but fine-flavoured; and in Germany, the favourite liquor, *kerschwasser*, is distilled from the juice of this species of fruit. The liquor called *cherry-brandy* is made by putting the best black varieties in brandy. *Noyeau* is a liquor flavoured by the kernels of the *C. occidentalis*; and a large black cherry is employed in the manufacture of the *ratafia* of Grenoble. The *maraschino* of Zara is made from a peculiar species cultivated in Dalmatia.

BERRIES.

In this division will be comprised the currant and gooseberry, both members, with all their now innumerable varieties, of the same family or genus, *ribes*—the raspberry, strawberry, cranberry, and grape-vine.

The Currant.

The currant is a native of Britain; nevertheless, we are indebted to the Dutch for the great perfection to which it has now arrived. The Dutch red and white currant are unquestionably the best produce of the garden; the Naples black is preferred. Currant-shrubs prosper only in cool climates, and they are somewhat arbitrary in their choice of a situation even in our own moist country; they grow to an astonishing perfection in the rich moist vales of the middle counties, but the berries dwindle in hot and arid situations. A loam such as has been so frequently mentioned will also suit the currant, but it likes manure; and this can be advantageously and freely applied as a top-dressing in November, to remain on the surface till after the pruning in February, when it should be lightly forked into the soil without disturbing the roots.

Mr Knight raised three or four hundred bushes from seeds in the course of his scientific experiments upon crossings, but of these very few excelled their parents. One of them, the red crystal, is superior in all respects. We have also raised currants from seeds, and have acquired one fine white variety, but have thus been instructed that seven or more years elapse ere the plants become fruitful, and therefore that propagation by cuttings is greatly preferable. Take cuttings of the young spring wood, with a small heel of the older wood attached to it; divest it of all the buds excepting five of the uppermost and those of the heel; dibble holes six inches deep in a shady bed or border, and fix a cutting firmly in each hole, by pressure and watering. They succeed perfectly if planted in August, provided they be kept moist and entirely shaded, or in a north aspect; but the season extends thence to the beginning of March. The soil should be rich and light. Cuttings may be placed at first where they are intended to remain, or they may be transplanted after they become rooted plants, cutting away all but the upper whorl of roots: in either case, cut back to two or three buds the shoots made the first spring, and subsequently prune on every side at an outside bud, to make the bush spread at top, and render it open towards the centre.

Prune for fruit just after the buds begin to swell—never before February, or the birds will reduce the expected crop; and in pruning, shorten all the leaders and spur in the laterals, till the bushes appear like deformed masses of scrubby twigs. The long pruning is comparatively worthless. By these spurrings and shortenings, the trees progress somewhat slowly, but the fruit is produced in massive clusters from the numerous spurs. The skeleton of each bush ought to consist of nine, twelve, or fifteen bearing branches, diverging at equal distances from three lower short limbs, which emerge from one main central stem; this is the best form of a neat bush, and the knife should be exercised to keep it open in the middle. If the spring shoots push very vigorously, the first high wind generally breaks down more than half of them; but this natural pruning is frequently advantageous. The black currant requires a still more moist and cool site, and that the wood be kept young, but never pruned or spurred. Whatever shoots become black and scaly must be cut entirely out, leaving those bearing branches only which are of a delicate brown colour. The trees require frequent renewal, by taking vigorous cuttings, for old wood produces small berries. If the soil and site be congenial, and the trees be young, the berries are frequently as large as small black cherries.

The Gooseberry.

This universally known shrub is a native of Britain, and therefore much more easily cultivated than exotics; it is indeed so hardy, and suitable for even keen climates, that remarkably little fostering is required to keep it in perfection. After a long course of culture, there are now hundreds of varieties of gooseberries; still, the kinds which keep their place in public estimation are few in number. The following is Mr Johnson's list of good-flavoured and very large sized, those of each colour being placed in the order of ripening:—*Reds:* Keen's seedling, Melling's crown Bob, Leigh's rifleman, Boardman's British crown, red Warrington. *Whites:* Taylor's bright Venus, Wellington's glory, Saunder's Cheshire lass, Woodward's whitesmith, Cook's white eagle. *Greens:* Parkinson's laurel, large smooth green, Collier's jolly angler, Massey's heart-of-oak, Edward's jolly tar. *Yellows:* Didon's golden yellow, Prophet's regulator, Prophet's rockwood, Brotherton's golden sovereign and pilot. The following are small, but of very good flavour:—*Reds:* red champagne, red Turkey, rough red, ironmonger, and Rob Roy. *Whites:* white champagne, white crystal, early white, Taylor's bright Venus, and white honey. *Greens:* early green hairy, Pitmaston green gage, and green walnut. *Yellows:* yellow champagne and rumbullion. For *bottling* the best variety is the rumbullion; for *preserving*, the best are the red champagne and the white eagle. The first gives a deep red to the syrup; the latter a slight pink, but imparts as good a flavour, and requires less sugar.

Although the gooseberry can be grown in almost any garden soil, yet if excellence of fruit is desired, the soil must be a rich loam, not less than twelve inches deep, and resting on a well-drained yet cool subsoil. The plantation should be near the bottom, yet on the side of a hill, and be unshadowed by trees; for if these intercept from them the light, the fruit will be neither large, nor full coloured, nor high flavoured. Whether to form an entirely new soil, or to improve that in which the plantation is to be made, the following compost, recommended by Mr Haynes, may be advantageously adopted:—Of fresh or maiden earth from a light loamy rich pasture, take one whole spit-deep, with all the turf; to which add one-fourth of rotten stable litter, preferring that from an old hotbed made in the previous spring, which, from its softness and greater readiness to intermix with new soil, will be found preferable to every other; add one-fourth of the finest soft and black bog earth, or, in default of this, either the same quantity of the darkest-coloured leaf or vegetable earth, preferring that from hard-wooded trees. Mix the whole regularly together, laying it into one narrow heap or ridge, about a yard high, in any situation exposed to the sun and air, there to remain for six, nine, or twelve months, as circumstances may admit; turning over the whole every three weeks, when the weather is favourable. The longer the compost remains in this state, the more advantageous it will prove.

To propagate, take cuttings of any chosen sorts eight inches long, of the last spring's wood, having a small piece or heel of the older wood; they are inserted about the end of October to the depth of three inches. The situation should be shady, the earth rather sandy, and each cutting should be fixed firmly in the soil. It is customary to remove all the buds excepting four or five at the top, which are left to form the head, produced from one central stem; but we prefer to secure the rooting of the cutting by retaining the lowest, and planting it four or five buds deep. It is from these buds that we expect roots; and though none may be developed till spring, nature will not be idle; and whenever the eyes break and shoots elongate, it will be time enough to select the strongest and best as a leader to form a stem, obliterating all the others both below and above the surface. Should three or four eyes break at the upper part of a cutting, it will be desirable to remove all others lower on the stem, as soon as it shall be manifest, from the vigour of growth, that there are good and sufficient roots to support them. A central stem is most desirable, and people think to obtain one, and to prevent the growth of suckers, by destroying the lower buds in the first instance; we believe that the want of success and the loss of the cutting are to be traced to this practice, and therefore we disclaim it. When the head is formed, gooseberry-bushes can be spurred as directed for currants, avoiding to shorten the leading branches; or at each pruning in February, a certain quantity of the last year's wood should be retained, and a corresponding portion of the two and three years' old wood cut out; thus, as it were, renewing the trees annually. Larger berries are thus obtained from strong young wood than by the spurring system. Propagation by seed is the mode for obtaining new varieties; but it is seldom resorted to in ordinary culture.

When the fruit has fully set, the smaller berries may be cut away for tarts, and the fine berries left for dessert. If some of the reds, as the Warrington, and the thick-skinned yellows, as the Mogul, be matted over when the fruit is ripe, it will remain good till nearly Christmas.

The Raspberry.

The raspberry is a native of some counties in England, but has been greatly improved by culture. The choice sorts are—1. Red Antwerp, fruit large, of high flavour, ripe in July; but by being planted behind a north wall, can be retarded, and the season thus protracted some weeks. 2. Yellow Antwerp, light coloured, very bristly wood, of luxuriant growth; fruit admirable in flavour, luscious; peculiarly adapted to the dessert. 3. New double-bearing; it is rather an autumnal raspberry than strictly a double bearer; still, by due and timely pruning, a second crop is frequently obtained in autumn.

The raspberry is propagated by suckers taken up from among those which rise in abundance from strong plants. The fruitful shoots or canes bear but once, and should always be cut down in August, to admit air and light to the young shoots of the summer; and from these suckers (of which four or five are amply sufficient) some should be selected to renew the stock every five or six years, changing the soil or situation. Care should also be taken to remove the disorderly suckers which rise from the wandering roots. The soil for this plant should be a light loam well manured; an occasional dressing of lime-rubbish produces fine canes and very fine fruit. The plants, if placed in row, should stand a yard or four feet asunder. They may be supported by strong stakes, made to slope to the north; and, confining the bearing shoots to them, the successional shoots will rise perpendicularly, without interfering with the others.

To procure a sound and abundant crop in the autumn, Mr Mearns gives the following directions, which he has practised with success:—' Early in, or as late as the end of May, cut off, or even slip off all the young fructiferous shoots from the former years' canes; and in a brief period they will spring again from the same eyes, and instead of one shoot, they will produce two, and if the canes are strong and healthy, three, and often four shoots from the same eye, each equally as fruitful as the former, with the fruit upon all, as fine as upon the earlier single cane, and continue to produce plentifully through the months of August and September. The double-bearing varieties are generally valued for the purpose of late fruiting upon the strongest canes of the same season; but the fruit is inferior, both in size and flavour, to some of the new scarlet varieties. But to improve the strength of the canes, consequently its fructiferous powers, in the pruning season cut away every one of the canes of the former season, as they are not required, as there will be plenty of the choicer kinds at the same season those would be ripe, and they only rob and keep the light and air from benefitting the younger canes intended for autumnal bearing, and if well attended to, will produce fruit till the frost checks them. In the growing season, it is of importance to select only a few of the finest and best placed canes, and clear the ground of all the rest, or any superfluous matter, so as not to obstruct the light, heat, and air.

The Strawberry.

The strawberry is one of the few fruits indigenous to Britain, and is found, like the bilberry and juniper, in a wild state in uncultivated spots, chiefly in woods and on tangled shrubby banks. It is likewise found in all the other northern countries of Europe, particularly in Norway, among whose rocky mountains it grows in great abundance; it prevails also in the temperate regions of South America, and abounds in the colder climate of Canada and Nova Scotia. This delicious small fruit is, in short, very generally scattered over the earth, and was the delight of ancient as well as modern times. In Latin its name is *fragaria*, which is supposed to be significant of its fragrance; and the French, perhaps from this source, call it *fraise*.

The strawberry is one of those plants to which nature has given the means of extensive multiplication. From the main bush or stems there spread forth tentacula or suckers over the surface of the ground, and these fastening themselves by a root at every joint, as many new plants spring up as there are joints. A single bush will in this manner, if not kept within bounds, soon spread over a moderately-sized garden. From this abundant growth of the strawberry, it has been inferred that the fruit is of essential importance as an article of food in summer; but this is scarcely philosophical; for to what plant has nature given the means of propagation more abundantly than the dandelion, and what is so little used or held in less esteem by mankind? Be this as it may, the strawberry is universally acknowledged to be exceedingly wholesome and refreshing as an occasional summer diet, and it is also allowed to possess certain medicinal properties, which give it a still higher value.

In most parts of England strawberries are eaten alone, or dipped individually in sugar before being put into the mouth; and to suit this mode of consumption, they are brought to table with their stems, which form shanks to hold by. But in Scotland they are consumed in a far more wholesale manner. There they are brought to table stripped of their stems, and are ladled out and eaten with a plenteous infusion of cream and sugar. 'Strawberries and cream' is, in fact, one of the grand national treats which strangers may reckon upon seeing set before them in the early weeks of July, and to which generally full justice is done. In the neighbourhood of Edinburgh there are a number of suburban villages, deriving celebrity from their extensive strawberry grounds, and to those parties proceed from town to enjoy the fruit in perfection; that is to say, along with the richest and most delicious cream. In the vicinity of Dublin, the celebrated 'Strawberry Beds' in the same manner attract immense crowds of persons in the summer evenings, when the fruit is in its prime. Those who are accustomed to see strawberries only in the small potties in which they figure at Covent Garden, can form but a feeble idea of the consumption at either the Scotch or Irish metropolis.

Of late years, there have been many changes and improvements in the strawberry world. Fifty or sixty years ago, only about a dozen sorts were known, those of the largest size being called *hautboys*, from the *haut bois*, or 'high woods,' of Bohemia, where they were originally found. According to horticulturists, there are now some hundreds of select varieties, produced by crossing, change of situation, and other circumstances. An old and respectable strawberry, known as the Old scarlet, was introduced from Virginia in 1625, and has been the prolific source of several varieties. The Austrian scarlet, the Roseberry, the Scotch scarlet, the Aberdeen seedling, the Grove-End scarlet, the Downton, Sir George Mackenzie's late scarlet, Nova Scotia scarlet, prolific hautboys, and Keen's seedling, may be noticed among hundreds of others. Latterly, some poor sorts have been banished from the market, and given place to Keen's seedling, which combines good flavour with largeness of size, and is an excellent bearer. The object in cultivating so many varieties is to obtain a succession of fruit through the season, some sorts ripening and being ready for market in May, while others come to maturity in the course of June and July. It should be understood, however, that it is only in the neighbourhood of London that the successive cropping of strawberries, or the forcing of them at particular seasons, is methodically conducted on a large scale. In most parts of the country, the vicinity of Edinburgh included, the fruit in its different varieties comes almost at once into the market, the season lasting about three weeks, and then all is over. The exceeding precariousness of the crop, from the chance damage of rains, makes the rearing of strawberries a business of little profit, and lately it has been abandoned by a number of our market gardeners. This is a circumstance to be regretted; and we should hope that, by a greater attention to the cultivation of *late* sorts, which would not arrive at maturity till late in July and in August, a greater degree of success in rearing might be secured.

The following comprehend the general directions for culture:—The seasons for planting are March or September. The soil that all affect is a rich unctuous loam, trenched to the depth of two feet. The best and strongest-rooted runners of July are always to be preferred; and these should be planted at the periods above-named, with all their roots, into beds or borders recently prepared. Many persons retain their beds or rows, during an indefinite number of years, in a tolerable state of fertility; but the triennial system appears to combine every advantage, while it avoids the two extremes of annual renewals, and of protracted duration. When a bed is formed and in full bearing, it will require an annual surface-dressing of loam and manure, two parts of the former to one of the latter, early in the winter, to protect the plants and receive the new roots, which always are emitted just below the lowest leaf-stalks; in March the old leaves ought to be all cut off, leaving the hearts untouched; and the beds should be cleared of litter by a wooden rake. Prior to the fruit becoming ripe, the mowings of a lawn or of any soft grass laid over the surface will prevent the berries from being soiled.

Triennial System of Planting.—1. A plot or border of earth being trenched, as before directed, select, after the first rains of September, a quantity of strong and well-rooted runner-plants, and with a garden fork or trowel, set them one by one, fresh from bed, in the new ground; if in single border row, a foot apart; if in a bed, at the same distance plant from plant, but the rows two feet asunder. Fix each plant firmly, and give water over it from the rose of a watering-pot. If a set of plants be thus merely transferred without much disturbance, and watered three times, few will fail. Hoe the ground occasionally; and prior to or during the first frost, sprinkle some manure over and around the plants, and lightly pass the wooden rake over them. Suffer no blossom to expand in the following spring, but leave the plants to acquire strength. Stir the ground occasionally, and cut off all runners.

2. In the second September, prepare and complete a corresponding plantation. Manure and dress the plants during winter, and those of No. 1 for the second time; and in March trim off the old leaves, and rake the surface. Let the plants of No. 1 bear their full complement, the fruit of which ought to be early, abundant, and of first-rate quality.

3. In September, repeat the work, and thus complete the plantations. Treat this and No. 2 exactly as directed for No. 1. In the following spring, suffer No. 1 to bear a second crop, No. 2 its first crop, and obliterate the blossoms of No. 3. In the September of the fourth year, dig up all the plants of No. 1, turn the ground, manure, and replant it. Thus the routine will be completed; and thus, year after year, there will be a plot progressing in one of the three stages; and if, with each approved variety, a similar routine course be adopted—and especially if a plantation be formed in the three aspects, east, south, and north, the last under a hedge or fence, to screen it from the south sun—the season of strawberries can be extended between the latter end of May and the middle of August. For the latter period, Knight's Elton is peculiarly adapted; and they who can at that time command a supply of a fruit so fine and beautiful, will have ample cause for self-congratulation.

The Cranberry.

There are two species of this plant, the fruit of which is now so very largely employed as a kitchen article for tarts, and as a cheap and effective antiscorbutic among seamen. The common cranberry (*Oxycoccus palustris*) grows wild in upland marshes and turf-bogs both in England and Scotland, and generally over the northern parts of Europe. It is a trailing plant, with slender shrubby shoots, which are clothed with small linear leaves; the fruit is an austere red berry, about the size of the common currant. It flourishes by the sides of little rills, and not among stagnant water, as its botanical name would imply; hence the difficulty of making it an article of culture. The American cranberry (*O. macrocarpus*) closely resembles the common species, but is a larger and more luxurious plant. Its fruit is also larger, and of a longish shape; hence the term *macro-carpus*, long-fruited. Though growing wild in great abundance, it is a plant of easy culture; and in some parts of the United States, barren wastes, meadows, and coarse herbage are converted into profitable cranberry fields at little expense. The plant grows well on sandy bogs; and if these are covered with brushwood, the bushes should be cleared away; but it is not necessary to remove rushes, as the strong roots of the cranberry soon overpower them. Some old cultivators plough the land previous to planting; the latter process being performed by digging holes, four feet distant each way, to receive the roots of the young plants. In three years the whole ground is covered with the vines; and an acre in full-bearing will often produce two hundred bushels, which bring about one dollar per bushel.

The cultivation of the American cranberry in our own country was first recommended by Sir Joseph Banks, and several gardeners have been so successful in the attempt, that this berry may now be regarded as one of our cultivated fruits. 'Wherever there is a pond,' says Neill, 'the margin may, at a trifling expense, be fitted for the culture of this plant, and it will continue productive for many years. All that is necessary is, to drive in a few stakes, two or three feet from the margin of the pond, and to place some old boards within these, so as to prevent the soil of the cranberry-bed from falling into the water; then to lay a parcel of small stones or rubbish into the bottom, and over it peat or bog-earth, to the depth of about three inches above, and seven inches below, the usual surface of the water. In such a situation the plants grow readily; and if a few be put in, they entirely cover the bed in a year or two, by means of their long runners, which take root at different points. From a very small space, a very large quantity of cranberries may be gathered, and they prove a remarkably regular crop, scarcely affected by the state of the weather, and not subject to the attacks of insects.' Although a moist situation is best suited to the plant, yet, with a due mixture of bog-earth, it will flourish, producing abundant crops, even in a comparatively dry soil.

The Grape Vine.

The vine, from the juice of whose fruit wine is made by a process of fermentation, is a plant of Eastern origin, which, in the course of ages, has been introduced into all the countries of southern and central Europe, also England. Requiring a fine climate, it will not bear fruit in the open air farther north than York; and it is only in fine seasons, and in good exposures, that its fruit is worth eating even in the southern parts of Britain; in general, the grapes grown in gardens about London are small, and not presentable at table. In the north of France and Germany they are little better, and we do not really get fine grapes of a proper size till we reach Italy or Portugal. In England, however, grapes produced in hothouses surpass in size and flavour the fruit of the Portugal vines.

Throughout the continent, the practice is to grow vines in large fields, either on plains or the sides of hills, which are fully exposed to the sun. They are trained in rows, tied to stakes, and are pruned to a height of about four or five feet; on the Rhine, they seldom exceed three or four feet; and at a distance the ground has somewhat the appearance of being covered with staked beans or peas. In Italy, the vines are trained to a greater height, and are made to cling to horizontal palings, as if from the roof of a hothouse.

To those in the southern parts of England who desire to rear the vine in gardens and on walls, we offer the following directions:—The varieties most suitable for culture are—1. The white sweet-water, with round berries, somewhat tinged with yellow, and faintly streaked with red on the sunny side. 2. The white muscadine, bunches rather loose, berries not very large, yellowish, and abounding with saccharine juice. 3. The small black cluster, with berries between red and purple, closely packed, very sweet, and luscious in flavour. 4. Turner's hardy, or the esperione, a fruitful tree, and very certain bearer; berries of medium size, varying from dark-red to deepish purple.

Mr Hoare's treatise on the vine has added importance to the culture of this graceful tree, and has thrown great light upon the treatment it requires. Our limits forbid us to recur to the statements therein given, and we can only observe, that no one who possesses a gable-end, a brick-walled house, or indeed a wall or fence of any kind, need be without a vine; it affects no richness of soil, but will grow on the shallowest ground, over and in chalk or rock of any description; yet if a border can be formed with a dry and well-drained bottom, the tree will be rendered more vigorous though the fruit may not be exalted in flavour.

A sound turfy loam, to the depth of eighteen inches, rendered open by small fragments of old lime-rubbish and a portion of crushed bones, will support any vine, and promote its fertility; and these materials can be introduced by degrees, first near the roots, then at a greater distance, to replace a corresponding quantity of old soil; thus little expense will be incurred, and still less labour. But if a new border be contemplated, and outlay be not considered, it will of course be best to complete the work in the first instance.

Vines are propagated by single eyes, by cuttings, and by layers, placed in pots when it is intended to remove the plants to borders or vineries. The soil should be a light, rich, sandy earth, or perfectly decayed manure and sand in equal parts; but they who wish to raise vines without loss of time, should plant cuttings taken from vines of known fertility, and of the yearling shoots which are themselves actually fruitful. Each should have three bold eyes on the young wood, and each should retain at its base a small piece of the previous year's wood. The season for planting is the month of March, and the method very simple. Dibble a hole from four to six inches in front of the wall or fence, deep enough to receive the entire cutting. Mix together equal parts of black leaf-mould and white sand; put in the hole enough of this to raise the bottom one inch, and ram it hard with a blunt stick; then insert the cutting, and hold it firm in the centre of the hole, while that is filled brimful with the compost, which is brought into still closer contact with the shoot by pouring water into it two or three times. Make the ground quite even, and its surface level with the uppermost bud, then cover the cutting with a small hand-glass. If the ground is kept moderately moist, not two cuttings in a dozen will fail. If more than one shoot break, and attain the height of five or six inches, the stronger only should be retained, slipping the other off below ground. This shoot must grow till its point become spindling, when it should be nipped back; and all future growth should be thus stopped above its lowest leaf, as also the laterals that appear during the growth of the main shoot. Great care must be taken to keep the vine regularly nailed and secured by soft and roomy ties, to prevent accident, and the danger of being snapped by the wind.

As the aspects suitable to the vine are confined between south-east and a small point to the west of south, the cuttings, if not duly supplied with water, may be droughted and perish before they become completely furnished with roots; but when once established, the main shoot will grow rapidly, perhaps attaining the height of a common fence, and ripen their wood early. In the end of September, let each be cut down to an inch above the three lowest buds; mulch the ground around the stems and over the roots as winter approaches, and watch the spring progress of the eyes. If possible, obtain and secure two equal shoots; and if the wall or fence be from eight to ten feet high or more, lead these shoots horizontally right and left about six inches above the soil, and secure them by shreds and nails. If the wall be six feet or under, retain but one strong shoot, and train it perpendicularly. In September, cut back according to the strength; thus if the wood of the single rod last-mentioned measure from one-third to half an inch in thickness, and the eyes be full, and from four to six inches apart, cut the shoot at the top of the fence, removing also the remains of all laterals and tendrils. The two horizontals will perhaps be rather slighter, yet if they be fully ripe, and furnished with bold eyes, they may be left three or four feet long on each side of the short main stem, but all the buds on the under side of each must be cut away; mulch the ground as before, and in March following carefully fork in the manure.

Bearing Condition of the Vine.—The fourth spring will find the vines in a fruitful state; but previously, the trees prepared for a dwarf fence should be so pruned as to retain but three horizontal branches on each side of the main stems, about eighteen inches asunder, the intermediate branches being cut back to their lowest bold eye beyond the stem. This eye is designed to produce a new shoot, to take the place of the bearing shoot, which, after the fruit is taken, must be cut away. Thus the vine will henceforward produce, year by year, two systems of branches, one of which will comprise year-old bearing wood, the other a corresponding series of green wood, which will produce the fruit of the following year. This description would almost suffice to elucidate the habits of the vine; yet to leave no doubt on a subject which involves the entire theory of pruning, it will be understood that this tree bears its fruit solely upon the green shoots of the present year, which spring from the eyes of the pale-brown wood of the previous year. When, therefore, a vine is of age, and has acquired sufficient strength to support a crop of fruit, it will generally be wise to provide a new series of bearing wood every year, because the fruit of new wood (in the white varieties particularly) is always superior. In this horizontal alternate system for low fences, each new branch may safely be permitted to extend itself at least two joints beyond its predecessor, always remembering to cut back, early in the autumn, to a short distance above a bold eye seated on perfectly ripe wood; for thus the tree will acquire strength and extent at the same time; and experience proves that, in ordinary circumstances, the fertility of a tree should be moderated, and kept below the supporting power.

The trees on the second system of training for high walls must be pruned in a similar manner, and upon corresponding principles. In the autumn of the third year, three out of four branches will be cut down to the lowest bold eye, and a few vertical shoots, from thirty inches to a yard apart, will remain; and these also must be pruned to a strong eye situated on mature wood. This system will furnish new bearing wood every year, increasing in length as the power of the tree augments; while also the low horizontal stems will extend gradually in due proportion. At first one, or at most two bunches, must be permitted to remain upon each upright branch. In the fifth season, a greater crop may be taken, always, however, remembering to restrict the fertility of the vine; for by so doing, its vegetating power will keep in the advance, till, in the end, the entire fence will be filled with vigorous branches, annually renewed, from which a very heavy crop may be gathered without tasking the vine in any degree that shall produce debility.

The spur system of pruning back the bearing shoot annually may occasionally be adopted with black grapes, and not without advantage; yet the system of yearly renewal leaves the vine at the entire command of the pruner, and procures large clusters of fruit. The few remarks above offered enter little into minutiæ, but they elucidate general principles; and if applied practically, will, we believe, lead to improvement in grape-growing. We again profess to be much indebted to Mr Hoare, and recommend his treatise to every cultivator of the vine.

The fruit of the vine grows in clusters or bunches, as many, perhaps, as a hundred grapes in the bunch. It is not desirable that so many should cluster together, for when numerous they are apt to be very small, and to be so compact in the mass, that those within do not ripen. Bunches with many grapes, therefore, should be thinned, by clipping out those of the smallest size, which will allow the others to grow to the proper dimensions. In very many instances, grapes grown on walls in gardens are spoiled by vermin, the interstices in the bunches being often filled with spiders' webs and insects of different kinds. All this is a result of carelessness in not keeping the walls clean, and pruning and otherwise attending to the bunches. As a preventive, let the walls in winter be lime-washed, including all branches of the vines, and take some pains to remove all vermin which appear in the fruit season.

Forcing.—Of the growing of vines in hothouses or vineries it is not our intention to speak; but for the class of persons whom we address, the following account of a method for forcing vines in humble edifices, given by Mr M'Intosh, in the 'Orchard,' seems so suitable, that we take leave to offer it:—' In many parts of the continent, and even in some few instances in this country, vines are forced in very humble edifices. The Dutch, Flemings, and Germans use pits, often not exceeding three or four feet in depth. These are sometimes heated by dung or tan being placed within them, which give out a mild, humid heat, serviceable to the vine while the buds are breaking; and this, with the proper husbanding of the solar heat by judicious ventilation, is often found sufficient to produce ripe grapes at an early period. Other instances occur of such pits being heated by a smoke flue, to which very moderate fires are applied. But what is most novel in these pits is, the vines being planted outside—the wood that is to produce the fruit is trained under the glass within, while the young wood for succeeding crops is allowed to grow without, where, under a brighter sunshine than we enjoy, the wood becomes perfectly ripened; and when the crop is gathered, the old wood, or that which produced fruit this year, is entirely cut out, and replaced with the young wood hitherto growing without the pit. Vines are also ripened on the continent by having glass frames placed against the wall on which they grow, about the time the fruit is half or three parts swelled, at which period those glasses are not in use which have been employed in forcing early crops of melons, salads, &c. The solar heat collected by this contrivance ripens the fruit well, and fully matures the wood for the following season. We have it in contemplation, founded upon the success of this mode, which we have often witnessed on the continent with admiration, to erect a portable structure in the new gardens now preparing for his Grace the Duke of Buccleuch, at Dalkeith Palace, and of which the following brief description will convey a sufficient idea:—Supposing a south wall, built hollow, and heated with hot water (as all our walls are to be), be planted with the early ripening sorts of grapes, late peaches, and some of the best late ripening plums, such as Coe's golden drop, &c. The trees not to be excited in spring (which should never be attempted with hot walls), but rather retarded in their blossoming, by keeping the branches as far from the wall as possible till they begin to blossom, at which time they are to be laid in to the wall, and the blossom protected with thin canvas awnings, particularly during night. In July, at which period the roof-sashes of the early forced peach-houses and vineries will be removed, these are intended to be employed to cover the above wall in the following manner:—A permanent stone curb, twelve inches high or more (or a wooden plank of the same height will answer as well), is laid along parallel to the bottom of the wall, and at two feet distance from it. This curb is furnished with a groove an inch and a half deep and three inches wide, to receive the bottom rail of the sashes, the top rail to run in a corresponding groove, in a batten of wood fixed to permanent brackets near the top of the wall, the distance between the top and bottom grooves to be equal to the length of the sashes, the bottom rail of each sash to be furnished with two brass rollers, to facilitate their movement. The glasses, it will thus appear, will stand perpendicular to the wall, and at two feet from it, and ventilation, and the necessary operations of pruning, gathering, &c. can be carried on from without, the lights being made to pass each other in the grooves, as in the manner of what is called barrack windows. The concentration of solar heat in August, September, and October, with the power of applying fire-heat by means of the hot-water pipes in the walls, which may be safely used as soon as the glasses are put, will not only ripen our best autumn fruits, but also mature the wood and buds for succeeding crops. Grapes and plums may be prolonged by this mode, we think, till Christmas, or indeed until the glasses be required to be again put on the early forcing-houses; and our finest Flemish pears, late peaches, and nectarines, which do not often ripen well in England on the open walls, and never in Scotland, will be brought to the highest perfection. Hot walls we have long ago proved to be of little or no value in spring, but their efficacy in autumn no one can doubt, and their utility will be greatly increased by having this covering of glass before them.'

For information respecting the construction and management of hothouses and greenhouses, we refer to Loudon's 'Encyclopedia of Gardening,' also to the beautiful works of Mr M'Intosh.

MISCELLANEOUS FRUITS.

The following are fruits which cannot be strictly ranked among the preceding sections, and are grown almost exclusively in gardens of a high order:—

The Fig.

The fig-tree is a delicate exotic like the grape-vine, and great care is required to bring crops of the fruit to maturity in the open air. There are many kinds of the fig-tree, but the greater number are adapted to culture only under glass. The following are four excellent kinds:—The brown ischia; fruit large, rather globular; brown pulp; purplish-red; very rich in flavour, and melting; ripens in August. Brown Naples; colour brown without and within; a hardy fruitful tree. The large blue or purple fig, like the brown Naples, ripens about August. It is one of the best fig-trees; fruit long, and of regular figure; pulp red; of rich and fine flavour. Lee's perpetual bearer, which is well qualified for gentle forcing in pots. The best soil for fig-trees is a light fresh loam; but the chief essential to promote fertility is a hard and dry bottom of chalk, gravel, or artificial pavement; a dry substratum and little depth of soil (that is, from one foot to eighteen inches) are therefore what the gardener must provide, if he expects to render the trees permanently fruitful.

As to culture and training, both are extremely simple. Rogers says, and very justly, 'that the knife is seldom wanted' [that is, in shortening; though, from the extreme luxuriance of the wood, it is frequently necessary to cut out many entire shoots]; 'pinching off the points of the young shoots during the months of May and June with the thumb and finger is the most effectual pruning.' Mr Knight restricted himself to compressing the points of the green shoots till the substance was felt to yield under the finger and thumb, by which pressure a check is given to luxuriance, and the milky sap is diverted to the embryo, which lies embedded at the base of each leaf-stalk.

But to secure fruit in due season, the pruner must recollect that in Italy and the south of Europe two crops of figs are produced yearly. Those large figs which are seen on fruitful trees here late in summer, are developed in spring, and would ripen early in a warm climate; but our winters check their progress, and generally destroy them. The crop which ripens in August is developed late in the preceding summers, and is extremely minute, almost invisible, in September; it is situated near the terminations of those green shoots which have been pinched or compressed; therefore the large green figs (which have properly been termed *sterilising incumbrances*) should be displaced by mid-August, and then it will frequently be seen that two minute embryos form in lieu of the one; and these, if the tree be protected, will ripen at the season mentioned. As to protection, it will be proper to unnail and bend down the upper shoots, so as to bring them into moderate compass, then to pass a few straw bands among and across them, and finally to cover the whole with a mat or canvas sheet.

In April, train in, straight and regularly, all the bearing wood; and as the trees grow, suffer the breast wood to curve forward at its pleasure, pinching the points as directed. Not one shoot is to be cut shorter; but if the wood become redundant, branches which obscure the fruit should be removed, reserving those which will manifestly be fertile, and which can be duly trained in the following spring.

The Filbert.

The filbert is believed to be an improved variety of the common hazel-nut. Both plants are monœcious; that is, they produce male and fruitful blossoms very early in the year, on the same tree, but separate from each other: the catkins that become visible in autumn are the males or pollen-bearing flowers: the *crimson threads* are the pointals of the fertile nut-bearing flowers. As the trees are pruned—spurred, as it is termed—in autumn, care must be taken to reserve a number of catkins, otherwise the crimson pointals will fail to perfect the nuts. The chief varieties of the filbert are the red-skinned, the white-skinned, and the cob or Barcelona-nut. The following are the methods of culture:—Strong suckers, taken in autumn, are either planted in the nursery, or at once in the places where they are to remain; and these grow three or four years, and are then cut down within a few inches of the ground. From the stems several strong shoots are produced, which, in the second year after cutting down, are generally shortened by one-third of their length. Regular figure and an open head are procured by placing a small hoof within the branches, to which the shoots are fastened at regular distances. In the third year, as the bush approaches maturity, short shoots (spurs) spring from the eyes, and are suffered to grow till the autumn, when they are cut back nearly to their origin, whilst also the leading shoots of the previous year are shortened two-thirds.

In the following spring, several small shoots arise from the base of the small branches which were cut off the preceding autumn, in consequence of the curtailment of the leading trained branches, and upon these secondary spurs the fruit may be expected; these shoots augment in number yearly, insomuch that many must be cast away. The largest are removed; the lesser remain, being more fertile in their habit. Many decay yearly; but whether they do so or not, those which have borne filberts are always cut away, and a fresh succession provided as future bearers. The leading shoot is every year shortened two-thirds or more, if the tree be weak, and the whole height of the branches must not exceed six feet. In order to strengthen the tree as much as possible, the suckers of the roots are eradicated, by exposing the roots, at a moderate distance from the stem, to the frost. The excavation is, in the spring, filled with manure.

The crops thus produced are sometimes enormous, followed, however, by intervals of barrenness. We have not heretofore adopted the method of pruning, leaving the trees more to the order of nature; but it is right to try experiments; and when a row of young trees exists, a comparison might readily be obtained, by pruning alternate trees, or one of every three trees, by the 'spur system;' always, however, observing to keep the head of every tree open, and to cut away its upright central leader.

The Mulberry.

The mulberry is a native of Italy, introduced in 1548. The structure of its flowers and fruit is very singular; like the nut and filbert, the males are distinct from the females; the latter do not always expand at the same time as the males, and therefore are not fertilised. The calyx swells and becomes fleshy; each individual contains one or two seeds; and a congeries of these swollen organs form what is supposed to be a single mulberry. There is but one known species of the black mulberry, and this thrives best in loam, of the quality so often named; but the bed ought to be deep, and to rest on a dry sandy subsoil. The fruit sometimes fails; and on this subject Rogers observes, that fertility may depend very much on the warmth of the weather at the time of blossoming, and on the circumstance of both male and female flowers coming forth at the same time; sometimes also the male catkins drop before the fruit-blossoms expand. Williams of Pitmaston suggests 'that no tree receives more benefit from the spade and dunghill than the mulberry; it ought therefore to be frequently dug about the roots, and occasionally assisted with manure.' Others consider a velvety piece of turf as the best site. When the buds expand in the third spring, it is desirable to obtain four shoots on each side of the upright stem, and all the shoots that will break from the two horizontals, which latter are to be led upright, and secured as they advance.

ARBORICULTURE.

Scientifically, as well as popularly, the term *Trees* includes all those plants which attain a considerable stature, and possess stems more or less solid. They are, as all must know, by far the grandest objects in the vegetable world, and they are not amongst the least elegant. The timber produced in the stems also renders them of very great importance in many of the industrial arts, and in none more so than in that which has enabled man, from ages beyond historical record, to transport himself across the bosom of the deep, and communicate from one land to another the various productions of the earth.

PHYSIOLOGY OF TREES.

Trees are divided, with a regard to their structure, into two great sections. Some, which spring from seeds of more than one lobe, and grow by additional layers on the outside of the stem, are for these reasons respectively called *Dicotyledonous* or *Exogenous* trees, as the oak and beech; others, which spring from seeds of one lobe only, and grow by additions in the interior of the stem, as the palm and sugar-cane, are called *Monocotyledonous* or *Endogenous* trees. As our treatise regards the practice of arboriculture in our own country, where there are few of the latter kind, we must be understood in all general descriptions to refer to the former only, unless the contrary is mentioned.

Referring to Vegetable Physiology for details respecting the organisation and functions of vegetation in general, we may here merely remark that a tree consists of four principal parts—the root, the trunk, the branches, and the leaves. The *root* is that portion which grows downwards into the soil from the vital knot or collar; this dividing it from the stem or ascending portion. It consists of two parts—the body or *caudex*, and the long branch-like fibres, great and small, which disperse themselves abroad into the soil. The structure of the body of the root corresponds in a great measure with that of the stem, with the exceptions that no pith exists in roots, and that there are no regular joints or nodes for the production of buds. The rootlets terminate in slender spongy threads (spongioles), fitted for absorbing the sap of the earth, and sending it up by the fibres, whence it ascends into the trunk; and it is observed that the soil is exhausted of its nourishing matter only in the neighbourhood of those soft extremities of the roots. When the main root descends perpendicularly, it is called a *tap-root*; and when it divides just below the collar, it is called a *branching-root*. A tap-root is always set down first by a seedling plant; but as the plant increases in size and strength, the tap-root seems to disappear, as it either changes its form, or is surrounded by other roots, which soon attain such a size and thickness as to render the original tap no longer distinguishable. This is the case with trees and shrubs which, after the first few years, have in most cases branching-roots.

The *trunk* is called by Linnæus *caudex ascendens*, or root above ground, an illustration perhaps more fanciful than real. In common language, the trunk is often named the *bole*; and it is this part which affords the timber for which most trees are reared. The trunk, and also the branches, are covered with *bark*, consisting of a series of thin layers, one of which is formed (next the timber) every year; while in the outside of all is a very thin layer of a different substance, called the epidermis or cuticle, analogous to the outer skin of the human body. The new inner layer which is formed every year receives the name of *liber*; it was on this substance that the ancients, before the invention of printing, were accustomed to write; and *liber*, it is well known, is the Latin word for a book. Within the bark is the wood, consisting chiefly of vessels, great and small, which may be torn asunder from each other, and which are employed in conveying sap to the upper extremities. In the centre of the trunk is a small space filled with a soft substance called *pith*, which is supposed to be a reservoir of nutritious matter for the development of buds in spring.

The growth of a true exogenous bole is as follows:—The stem of a seedling consists at first only of cellular tissue, surrounded by an epidermis; but as soon as the leaves have expanded, some bundles of woody fibre are deposited, so as to have the appearance of a dotted circle just within the skin. As the tree advances in growth, the cellular tissue in the centre becomes pith, and rays of it extend to the epidermis between the bundles of woody fibre. A membrane, or rather layer of vascular tissue, then forms round the pith or *medulla*, so as to separate it entirely from the bundles of woody fibre, and the pith takes the form of a star with rays diverging from a centre. In the second year of a tree's life, the rays and the central pith both contract as fresh layers of woody fibre are deposited, and they continue to do so every year till the tree is full grown. In the second year's growth of a seedling tree, a complete layer of wood is formed round the pith just within the epidermis, and this is called the *alburnum* or *sapwood*. Another layer of vessels, like those in the medullary sheath, afterwards forms round the sapwood, so that when a second layer of wood is deposited, a distinct ring of vessels remains between the two. This process is continued every year, and as the layers of vascular tissue have always a different appearance from the tissue of the wood, the rings of vessels between the layers of wood, which are called *concentric circles*, and the medullary rays diminished to fine lines, may be always traced in a section of the trunk of a tree. The medullary rays become changed in time into thin hard plates, which still radiate from the centre to the outer circumference of the tree, and which form what is called by the carpenters the *silver grain* of the wood. The central pith in the meantime has diminished to a mere speck in the middle of the tree, or, as is frequently the case, it has entirely disappeared. The layer of wood, which is deposited every summer, always appears soft and white for the first year; and it is called the *sapwood* because the ascending sap rises through it the following spring. This wood is of no value as timber; and carpenters, in their contracts for houses, always agree not to use it, promising that their wood shall be free from sap, &c. The inner layers of wood in the tree form what is called the *heartwood* or *duramen*, which is extremely hard and durable. As the layers of wood are thus distinct, and as one is generally deposited in temperate climates every year, it has been supposed the age of a tree may be found by counting the number of concentric circles; but this rule does not always hold good, for the reasons hereafter explained. The sapwood of regularly-formed wood is always white, but some secretions are conveyed by the returning sap through the medullary rays into the heartwood, which changes its colour to brown of various shades, dark red, or even black, according to the specific character of the tree.

The *branches* require no further notice than that they precisely resemble the trunk in every respect, except that they are upon a minor scale in point of size. The *leaves* consist principally of tissue, like the trunk, with vessels throughout, and an external cuticle enveloping the whole; and they are connected with the branch by a foot-stalk or *petiole*. The leaf is one of the most important parts of the whole tree. By a most curious process, not perfectly known to us, the crude sap rises through the wood, in the manner just described, and is elaborated or prepared into juice of a more nutritious sort by the leaves. That process, according to some, is effected by means of an alternate contraction and dilatation of the sap-vessels, and still more by a respiration, perceptible and imperceptible, through the pores or stomata of the leaves, and by the action of heat, light, and air; but according to others, it is rather the exhalation from the leaves, than what are properly their respiratory functions, that effects the ascent of the crude sap. It is then converted into proper sap or *cambium*, and being fitted for the nutrition of the whole tree, it descends by the returning vessels of the leaf-stalk and the longitudinal vessels of the rind or inner bark. At length it reaches the roots, which originally supplied the crude sap itself. This elaborated sap is, like human food, digested into chyle; and as it forms the only real nourishment of the tree, it becomes apparent that the plant must decay if stripped of its leaves.

It has been already mentioned that the trunk of a tree (of the exogenous kind) consists of a number of cylinders enclosing one another like so many layers or concentric circles disposed round an axis; and that, as a circular layer is deposited every year, it is possible to ascertain the age of the tree by counting the number of the layers. M. Decandolle, one of the most celebrated botanists of modern times, has, as appears from a work on the subject, paid great attention to this method of ascertaining the age of trees. He observes that the method of reckoning now alluded to is not liable to much error, but the inspection must be conducted with the greatest care; for the older circles become condensed into a mass, and their number can only be guessed at by measurement. 'My plan,' says he, 'is as follows:—When I have got a section of an old tree, on which I can see the circles, I place a sheet of paper upon it, extending from the centre to the circumference. On this paper I mark every circle, showing also the situation of the pith, the bark, the name of the tree, the country where it grew, and any other necessary observations. I also mark in a stronger manner the lines which indicate every *ten years*, and thus I measure their growth at *ten years'* intervals. Measuring from centre to circumference gives me the circles, doubling this I have the diameter, and multiplying by six I have the circumference.'

The learned professor then presents a table of the periods of increase in the diameter of various trees, an inspection of which proves that every tree, after having grown rapidly when young, seems at a certain age to take a regular march of growth, which may perhaps be accounted for by supposing that young trees have more room to expand in, are less pressed by the roots and branches of their neighbours, and may not have penetrated down to a hard, arid, or otherwise unfavourable soil; and also that as trees advance in age they still continue to form layers as thick as they previously did subsequently to the period of rapid growth. If such tables were multiplied to a sufficient extent, as we have no doubt they will be in course of time, they would form data from which, by ascertaining the circumference of a tree, its age might be known without having recourse to the destructive process of cutting deep into the growing timber. 'If,' says our author, 'one cannot get a transverse section of a trunk, then one must seek for old specimens of each kind, the date of whose planting is known, measure their circumference, deduce their average growth, and calculate from them the age of other trees of the same kind, always keeping in mind that young trees grow faster than old ones.' Decandolle cites numerous instances of trees whose ages have been ascertained according to the rule here laid down. Some of these appear to be many centuries, if not thousands of years old; and what is remarkable, still exhibit symptoms of verdure and vitality.

The fact that trees of such vast age continue to bear foliage and fruit, affords indubitable proof of a very remarkable circumstance connected with the vegetable kingdom. In man and all other animals we find an organisation and a process of life going on which are destined to cease at a certain period. But it is otherwise with trees. They appear to possess the power of growing on for ever without exhibiting any symptoms of decay, unless from accidental or extraneous causes. We shall quote the words of Decandolle on this point:—'As there is formed every year a ligneous deposit, and generally new organs, there is not among the vegetable creation place for that hardness or rigidity, that obstruction of old and permanent organs, which constitute properly the *death of old age*, and consequently, that being the case, trees can only die from accidental causes. Trees do not die from age in the true sense of the word: they have no fixed period of existence; and consequently, some may be found that have arrived at an extraordinary age.' But although a tree thus possesses in itself the elements of continual strength and youth, numerous causes step in to interrupt or destroy its existence. In corroboration of what we state, we need only allude to the facts, that soil is of limited depth—that below the soil there are usually hard strata, which the feelers of a plant cannot penetrate—that roots intercrossing encumber each other, and check vegetation—besides which, there are other destructive and obstructive causes which we need not occupy the reader's time by specifying. Consequently, although what the French philosopher says is quite true, that 'some trees may be found that have arrived at an extraordinary age,' yet, every circumstance considered, we are not to be surprised if the number of such vegetable patriarchs should prove exceedingly small, compared with the immense extent of the earth's surface which is covered with forest growth.

CLASSIFICATION OF TREES.

In a view of arboriculture, trees may be classified according to their uses; for example—1. Trees which produce straight timber for masts and long planks—as the various tribes of pines. 2. Trees which afford crooked timber for knees or bends in the ribs of ships, &c.—as the oak, sweet chestnut, broad-leaved elm, &c. 3. Trees which give tough pieces of timber—as the yew, holly, thorn, ash, hickory, maple, laburnum, &c. 4. Hard-wood trees—as the oak, beech, plane, walnut, box, and holly. 5. Soft-wood trees—as the poplar, large willow lime, horse-chestnut, &c. 6. Wood grown for flexible suckers and spray, to form hoops, baskets, besoms, poles, &c.—as the dwarf willow, birch, &c. To these may be added woods of foreign growth—as rosewood, satinwood, and mahogany, which are employed for ornamental purposes.

According to another classification, trees are arranged as of three kinds—resinous, hard-wooded, and soft-wooded. Those which are resinous are also termed coniferous, from their producing seeds in cones. For the sake of clearness we will adopt this simple arrangement, confining ourselves to trees which may be propagated under the climate of Britain.

Resinous or Coniferous Trees.

There are three tribes of these trees, one of which, the Abietinæ, has four genera cultivated in the British islands—the Pinus, Abies, Larix, and Cedrus. Of each there are several species, all distinguished by their spicular leaves, their cone-like seed-vessels, and their resinous wood. Any of them may be easily raised in nurseries from seed. The more common species is the

Scotch Pine (*Pinus sylvestris*).—This is a tall and generally straight tree, with few branches on the lower part of the stem, the leaf apparatus being confined to the top of the plant, these forming a massive clump. It is indigenous to the Highlands of Scotland; but the little that is generally used comes from the forests in that quarter, the greater proportion being imported from the north of Europe, where a variety of it attains great perfection. For strong beams and spars required by house-builders, this timber is exceedingly suitable; but for smoothness and whiteness of fibre, it is excelled by a tree of much inferior strength—the Canadian pine (*P. resinosa*). On account of the heavy import duties levied on foreign pine, much of Canadian timber is employed in its stead, being thus devoted to purposes for which its properties no way qualify it. 'With reference to the common Scots fir,' says Brown (of Arniston), 'the best timber-trees for general purposes are raised where they are standing pretty close in one mass; but the most picturesque form of this tree is found when standing singly, and has room to spread out its branches. When grown in one mass close together, the trees are found clean-stemmed, and drawn up to a great height; consequently such trees are available for many purposes, whereas, when standing singly, the tree is generally found short-stemmed, thick, and branchy. No tree, a native of Britain, can with more safety be planted out into any soil and situation, provided only that soil be a dry one. I have seen a crop of good Scots fir taken off almost every sort of soil of an earthy or stony nature, but upon a mossy soil I have never seen good Scots fir timber grow.'

Spruce Firs constitute a well-known genus (*Abies*) of the Coniferæ, the more common being the Norway fir (*A. excelsa*), a tree which attains great height, but no great bulk, and furnishes white deal and spars of inferior size; it is also very suitable for masts and poles of all kinds. North America produces three species of spruce—the white, red, and black—each esteemed for particular uses connected with ship-building. The Norway spruce is now widely planted throughout Britain, particularly in the Lowlands of Scotland, and when enjoying a favourable situation, soon grows to a useful size. It is a hardy tree, and though its timber is softer and less durable than the Scotch pine, yet from the rapidity with which it grows, and its adaptation to a soil rather damp, it is frequently preferred.

The *Silver Fir*, called also the Pitch Fir (*Picea pectinata*), displays a greater depth of branches than the other firs, and becomes a majestic tree on arriving at full age. In this country the silver firs are only seen as objects of ornament on dressed ground; but how they would answer if planted closely together, and pruned up to form clear butts of timber, is uncertain, this having never, we believe, been tried in these islands. The quality of the silver fir timber of British growth is yet to be tested. The common silver fir, the balm of Gilead, and the hemlock spruce, have been long in our pleasure-grounds; but the yew-leaved, Fisher's, Douglas's, and Fraser's double balsam, are seldom seen beyond nurseries or pine preserves. The common silver fir is a hardy tree, even more so than the spruce, and is deserving of wider cultivation in our forests and plantations.

The *Larch*.—Of this valuable genus (*Larix*) there are several species grown in Britain and other countries; the more common is the *L. Europea*. The larch is the most beautiful in figure of any of this class of trees; shooting straight up, its elegant stem tapering to a point, is furnished with pendulous branches, ornamented with delicate drooping spray. Its qualities are rapid growth, flexibility, and durability in situations between wet and dry—a circumstance perhaps attributable to the quantity of resin in its fibre. In many parts of the country it is gradually superseding the common fir, over which it possesses a great superiority in point of ornamental effect. 'There are,' says the authority already quoted, 'two varieties of the larch generally cultivated in Britain—the white and the red. The white is the variety which attains the greatest dimensions of timber, and is the sort most generally cultivated, although they are both often seen growing together in the same plantation, and that by mere accident. It is said that upon the Athol estates the red larch does not contain above one-third the cubic contents of timber which the white larch of the same age does; and this is observable in every plantation where the two varieties are found growing together. No timber-tree at present cultivated in our woods begins to repay the expense of culture so soon as the larch does. It is a rapid growing tree, and is well adapted for almost every country purpose. It generally sells at nearly double the price per cubic foot that Scots fir brings; and besides the price of the wood, the bark is available for tanning. The circumstances which are found favourable to the healthy development of the larch are—as to soil it is not particular, but the roots must have a constant supply of water, in order to keep the earth in which they grow in a pure state, as is the case upon all rugged mountain-slopes where there is a continual descent of water from the higher ground to the lower.' On very arid soils the larch never grows freely, and soon dies off with a stunted lichen-clad bole; and on flat ground, where water is liable to stagnate, though the young trees may succeed for a few years, yet they are never found to prosper, but die away as soon as the mere surface turf is exhausted of its nutritious properties by the radicles.

The *Cedar* (*Cedrus Libani*) is remarkable for its long horizontal and often crooked branches, and the great mass of dark-green spicular foliage with which it is covered. It is a native of the mountains of Libanus and other high adjacent regions, where it attains great bulk, and grows to a very long age. From its solemn aspect, it forms a suitable accompaniment to cemeteries or ecclesiastical buildings, and also for sequestered glens in mountain scenery, or for extensive lawns. Cedars were introduced into Britain as far back as 1683; and there are but few old country seats which do not possess some specimens. Many majestic ones are met with in different parts; but in no situation have they thriven more prosperously than at the celebrated residence of Moor Park, in Hertfordshire. So numerous and large were they upon this estate—according to the British Cyclopædia—that about 1798 scores of them were felled for sale, containing four and five loads of timber in their butts only. These fine trees were mostly purchased by London builders for quartering, at a low price, the timber being found far inferior to the common Scotch fir. Cedars are trees of very striking character, and give an air of grandeur to every scene in which they appear. There are two or three varieties: some assume the conical figure of the other coniferæ; others extend their branches horizontally from the top of a short thick trunk, forming a dense canopy overhead; while others, again, are very much divided, near the ground, into many upright stems, which, with their horizontal spray, form, in the course of years, a vast bush.

Cedars may be raised from seeds which ripen in England, or from seeds imported from the Levant. When got from the cones, which is a work of some difficulty, they are sowed in deep seed-pans, or boxes; and when fit for removal, the seedlings are nursed and placed in pots, until they are large enough to be planted out in the open ground. While nurslings, many of them require a stake, to which a leader must be constantly kept trained, in order to insure a regular growth.

The *Yew* (*Taxus baccata*) is more frequently grown as an ornamental than a forest-tree, and, like the cedar, it forms a plant suitable for places consecrated to solemn feeling. Its timber is very tough, and is adapted for making bows and staves; hence it is commonly ranked among hard-wooded trees. As an ornamental tree, it should be fenced round, or otherwise placed beyond the reach of cattle, as its foliage is highly poisonous; and being evergreen, is very apt to be browsed upon during the winter.

Yews are believed to be the most ancient trees of Great Britain; and no doubt can exist that there are individuals of the species in England as old as the introduction of Christianity, and there is every reason to believe very much older. It is the opinion of Decandolle, that of all European trees, the yew is that which attains the greatest age. The following are some of the more remarkable British specimens to which the attention of the curious has been directed. Those of the ancient Abbey of Fountains, near Ripon in Yorkshire, which yews were well known as early as 1155. Pennant says, that in 1770 they were 1214 lines (a line is the tenth of an inch) in diameter, and consequently, according to Decandolle's method of computation, were more than twelve centuries old. Those of the churchyard of Crowhurst in Surrey, on Evelyn's authority, were 1287 lines in diameter. There are two remarkable yews still in the same cemetery, and if they be the same which Evelyn refers to, they must be fourteen centuries and a half old. The yew-tree at Fortingal in Perthshire, mentioned by Pennant, in 1770, had a diameter of 2588 lines, and consequently we must reckon it at from twenty-five to twenty-six centuries old. The yew of Brabourn churchyard in Kent has attained the age of 3000 years; but that at Hedsor in Bucks surpasses all others in magnitude and antiquity. It is in full health, and measures above twenty-seven feet in diameter; thus indicating the enormous age of 3240 years! In all likelihood this is the most ancient specimen of European vegetation.

Hard-wooded Trees.

In this class are included a large number of trees with which every one is familiar. The list embraces—the oak, ash, elm, beech, chestnut, walnut, common sycamore, mountain ash, whitebeam, acacia, birch, wild cherry, Scotch laburnum, holly, hazel, box, elder, and hawthorn. The following are the principal:—

The *Oak* (*Quercus*) is the most valuable of all the timber-trees grown in Britain, not only because it is a hardy native, but for the many important purposes to which its durable timber, its astringent bark, and even its nutritious fruit, are applicable; and, moreover, for the delight which it gives to the eye in sylvan landscapes, the oak being the most picturesque tree of the forest when it has arrived at its mature age and form, and is still clad with foliage.

There are two species in our woods, whether natural or planted—namely, the *Q. robur*, whose acorns grow singly and with long stalks; and the *Q. sessiflora*, whose fruit grows in clusters, with short acorn stalks. The former is said to be the old Druidical British or naval oak, though the latter is more frequently met with, especially in woods which have been planted by the hand of man. The stalked-fruited is also of quicker growth, and is altogether what may be called a more elegant tree when full grown. The quality of the timber of both, when any difference is observable, is more owing to the difference of soil they have grown on perhaps than to any specific difference of the trees. Besides these two common sorts, which are natives, there are thirteen other species, which are exotics—namely, the willow-leaved, the evergreen, ash-leaved, cile-cupped; ilex, of which there are six shrubby varieties; chestnut-leaved, scarlet, velanida, white, Italian, durmast, Lucombe, and the Turkey, of which there are four varieties. This last is a fine free-growing tree, and deserves a place in every plantation. The other exotics are chiefly planted for ornamental purposes, not being yet considered as forest-trees.

All the species are readily raised from their acorns (oak-corns) when they can be procured; and in default of these, most of the foreign sorts may be grafted on the common. The young plants are transplanted twice or thrice in the nursery; and when four or five years from the acorn, may go to their final stations. Any kind of clayey loam is suitable for the oak; but a good gravelly loam, upon a subsoil of blue ferruginous clay, produces the finest timber in the shortest time. 'The largest oaks I have ever seen,' says J. Brown, 'grew upon a dry sandy loam, with a free exposure to air: however, although the oak may attain its greatest dimensions under such circumstances as these, we find it growing to the size of useful timber wherever it has the advantage of a soil with a dry bottom, and not too much exposed to storms—as, for instance, upon the top of a bare hill. The oak will not thrive nor live long in a damp mossy soil.'

England, as well as Scotland, at one period possessed many noble and remarkable oak-trees, the remains of which are in some instances still to be seen, while in others they are only remembered in tradition. Thus every reader has heard of the Fairlop, the Worksop, Damory's, the Great Oxford, the Skeleton, and other oaks. The first, for example, stands in a glade in Hainhault Forest, in Essex, about a mile from Barkingside, and has been known through many centuries by the name of Fairlop. The tradition of the country traces it half way up the Christian era. It is still a noble tree, though it has now suffered greatly from the depredations of time. About a yard from the ground, where its rough fluted stem is thirty-six feet in circumference, it divides into eleven vast arms, yet not in the horizontal manner of an oak, but rather in that of a beech. Beneath its shade, which overspreads an area of 300 feet in circuit, an annual fair was long held on the 2d of July, and no booth was suffered to be erected beyond the extent of its boughs.

The *Ash* (*Fraxinus excelsior*) is also a very valuable hard-wood tree, its timber being useful for many rural purposes, and particularly for implements and machines. The common ash, being prolific in ripening seed, is dispersed pretty generally over the face of the British isles; it is nevertheless much better managed when planted for timber or for underwood, unmixed with any other sort of tree. It should never be allowed a place in a hedgerow, nor on pasture-land, as its numerous surface-spreading roots engross to themselves every particle of nutritive moisture, to the destruction of all other surface-plants. According to the authority just quoted, the circumstances which are found favourable to the healthy development of the ash are, as regards soil, a good strong loam, rather rich than otherwise, and rather moist than dry—that is, the ash does not disagree with a little moisture, provided that this moisture have free and ready access away from the roots, and is not liable to remain in the least degree stagnated. The ash is also rather fond of shelter, and therefore, to grow it well, it is an advantage to plant it in a hollow or glen, or in the interior of a large plantation.

An ash-tree is in its prime when, by free and vigorous growth, it has attained a diameter of about twenty inches; for though on rich gravelly loam it will continue to increase until it is four or five feet in diameter, it has probably begun to rot at the core long before it has arrived at that vast bulk. Therefore, in order to raise ash-timber of the most valuable description, it is necessary to sow or plant a piece of land of the above character thickly, placing the trees about two feet apart. These will rise rapidly; and as soon as they appear to be choking each other, one-half of the poles may be drawn, and the rest allowed to stand till they arrive at a marketable size, which is when they are from eight to twelve inches diameter, and from forty to sixty feet high. When *ground-ash* is of these dimensions, it is suitable for every mechanical purpose where flexibility and extreme toughness are required. From its upright habit of growth, the ash forms one of our best forest-trees; and what is especially deserving of notice, its timber is better—that is, more tough, elastic, and durable—the more rapidly it is grown.

Seed should be gathered in the autumn, and immediately sown in nursery-beds; or the sowing may be deferred till spring. Some of the seeds may not rise till the second or third year; but as soon as the seedlings are five or six inches high, they should be rowed out to gain strength till finally transplanted. There are several varieties of the common ash, one of which is the creeping-branched, but which, by grafting it high on the tall stem of the common one, is made a rather ornamental weeping-tree. Other species are the yellow-barked, curled-leaved, various-leaved, and a great many other exotic species.

The *Elm* (*Ulmus*) is a lofty tree, valuable both for its use in the arts and its ornamental appearance. The small-leaved or English elm is generally preferred for planting, particularly in hedgerows, avenues, and the like. This tree is not a forester, never being seen but about dwellings, or where dwelling-houses have formerly stood. It is probably an exotic, as its seeds never ripen in this country, and is therefore propagated by suckers, which rise abundantly from the old roots, which circumstance makes the tree so eligible for hedgerows; for where once planted, fell the principals as often as wanted, a succession of young stems constantly appears. They are also propagated by layers, and often by grafting on the common wych-elm, especially when wanted for dressed ground, or for avenues where it is desired that no suckers should be seen.

Besides the common wych-elm (*U. campestris*), found wild everywhere in the hedges of Britain, and which grows, where allowed, to a large size, yielding large butts of coarse-grained but useful timber, there are several other sorts raised in nurseries—namely, the cork-barked, smooth, declining-branched (a truly picturesque tree), spreading-flowered, the white, and several others. All the elms delight in a gravelly loam, or in any soil which is not too wet, and they are well worth the planter's attention. No tree bears lopping or shredding better than the elm, it being hardly possible to hurt it by dismemberment. It is raised from seed when produced. In the forest, it requires considerable space, as its natural habit is to throw out on every side broad spreading branches. When confined, it grows up with a slender weakly trunk, the timber of which is of little use to the carpenter.

The elm attains a very large size, and has a very rapid growth, both in Europe and America; but the elm of the latter country has a much more majestic appearance than that of Europe. Michaux characterises it as 'the most magnificent vegetable of the temperate zone.' A specimen mentioned by Decandolle, which grew near the town of Morges in Switzerland, measured 17 feet 7 inches in diameter, and was estimated at 335 years of age.

The *Beech* (*Fagus sylvatica*) is a native forest-tree, occurring most commonly on the chalky districts of the kingdom. When full grown it is a beautiful and stately tree, and its timber is convertible into many kinds of domestic articles, very durable when polished by the cabinetmaker, and equally so if kept constantly under water. The beech is a very fruitful tree; and its mast or nuts, together with acorns, used formerly to fatten vast droves of swine and herds of deer, the then common food of the feudal lord and his vassals.

Young plants are readily raised from the seed sown on beds, and covered with loose soil about an inch thick. Like other seedlings, they are, when five or six inches high, rowed out on fresh ground, till large enough to be transferred to their final stations. The beech is not at all fastidious as to soil, so as there is some portion of calcareous matter present; but a subsoil of chalk or limestone is most congenial. According to Mr Brown, few trees suffer less from mismanagement than the beech; and upon thin, poor soils, and even in high and exposed situations, no hard-wooded tree is so worthy of a place. He has seen the beech grow well upon a soil and situation where almost no other tree could have existed, not even the Scots fir. There are several species: the white-American, the dark-purple, and the iron-coloured-leaved, are ornamental, and are propagated by grafting on the common. As a forest-tree, none of the species are now extensively planted, in consequence of the comparatively little value set upon beech timber.

At Newbottle Abbey, the seat of the Marquis of Lothian, a few miles south from Edinburgh, there are some remarkably fine large trees, most probably planted by the monks prior to the Reformation. 'Professor Walker measured a beech at this place in 1789; its trunk, where thickest, was 17 feet in girth, and the span of the branches was 89 feet. He thinks that it must have been planted between 1540 and 1560. It was blown down a short time before the year 1809. It contained upwards of 1000 measurable feet of timber (twenty loads, or twenty-five tons), and it is with reason reckoned among the largest beeches that have ever grown in Scotland. Another at Taymouth, of a like size, and seemingly coeval with this, was blown down when it had reached above 16 feet in girth. The large beech at Ormiston Hall, in Haddingtonshire, the bole of which we remember to have seen scooped artificially out into a shelter-house, was measured on the 10th of May 1762, and found to be 18 feet 10 inches. We believe it was quite entire when it was destroyed by a high wind. A large beech near Oxenford Castle, in Edinburghshire, was measured on the 6th of June 1763. At the height of three feet from the ground it was 19 feet 6 inches. This fine tree was then decaying. From the state of the Ormiston Hall and Newbottle trees, it may be concluded that the beech, if it meets with no accident, will grow with sound timber for at least two hundred and fifty years.

The *Chestnut*, or sweet chestnut, sometimes also called the Spanish chestnut (*Castanea vesca*), is a splendid forest-tree, exceeding all other British plants in its huge mass of foliage; it is also valuable for its timber, which is but little inferior to the oak. In the south of Europe it is chiefly regarded as a fruit-tree; but here, even in the south of England, in the finest summers, the fruit ripens but imperfectly. As a timber-tree, however, the Spanish chestnut deserves to be more generally planted than it has been of late years; and for a coppice or underwood plant it has no superior. For the number, the straightness, and durability of its poles, it excels all others, when a little trouble is taken to keep the growth perfectly regulated with respect to the purpose for which the crop is wanted. When timber or ornament is the object, the trees must constantly be divested of the shoots, which are apt to rise from the collet of the stem. A strong loamy gravel seems to suit this tree best; and young plants are easily raised from the nuts, dibbled in rows in the spring, and, while in the nursery, kept free from bottom shoots. The sweet chestnut requires considerable shelter, in order to permit of its full development; and should always be cut down before arriving at maturity, as the heart-wood is very liable to decay.

The *Common Walnut* (*Juglans regia*) is chiefly regarded as a fruit-tree, but it is no less valuable for its excellent timber, which, from its lightness and durability, is well adapted for gun-stocks. Where its fruit is of no great value, and especially where it does not ripen, if planted among other forest-trees, it would be drawn up into a shapeable single stem, as valuable as many others. Young trees are readily raised from the nuts, like the chestnut, and are similarly managed.

The *Sycamore*, *Great Maple* or *Plane-tree* (*Acer pseudo-platanus*), is a hardy native tree, which attains a large size, and has the property of growing more quickly than most other hard woods. It is employed to form household utensils and objects in turnery. It not only grows to a large size, but lives to a great age. 'There are many sycamores in Scotland at the present time,' says the 'Forester,' 'which I have myself measured, and found nearly twenty feet in circumference and sixty feet high. It is not a tree that carries height along with its girth; but it is, notwithstanding, a magnificent tree, and few, if any other, can vie with it upon the lawn or park. The circumstances which are found most favourable for the healthy development of the sycamore are—a dry sandy loam with a free exposure, as in the open parks about gentlemen's home grounds; however, it may be profitably planted in almost every situation, except in a damp or mossy soil.' The Oriental plane is one of those trees which attain the largest size, but the rate of its increase is not ascertained. In the valley of Bujükdére, about three leagues from Constantinople, there is a plane which recalls to mind one which Pliny has celebrated. According to the Roman naturalist, there was a plane-tree in Lycia which had a hollow trunk capacious enough to accommodate the consul Licinius Mutianus and eighteen followers, who found within its ample cavity a retreat for the night. This living vegetable grotto was 75 feet in circumference, and the summit of the tree resembled a small forest. The plane at Constantinople is 150 feet round, and within it there is a cavity of 80 feet in circumference. This transcends the tree of Pliny. There are other very large Oriental planes mentioned by Clark and others; and one of vast size was lately noticed by Mr Quin in his voyage down the Danube.

The *Mountain Ash*, familiarly known in Scotland as the *rowan-tree*, from its beautiful clusters of red rowans or berries, is a tree of small dimensions, but elegant form, and is grown principally for ornament in shrubberies. It is hardy and of easy growth in dry soils, and makes an excellent skirter or outside tree in ornamental clumps and plantations; its finely-formed foliage and white blossom yielding variety in summer, and its deep red berries as striking a variety in autumn and early winter.

The *Acacia* is not only a highly ornamental, but also a highly valued timber-tree, when allowed to attain a proper size. Though a native of Virginia, and there called the *locust-tree*, it has been recommended as a coppice plant for this country, because of the very quick growth of its young shoots, which rise from roots after the stem is cut over; and for the excellent and durable quality of the poles for fencing, and particularly as props for hops and other trees. But whether planted thickly for underwood, or in more open order for timber, the acacia requires much attention from the pruner during the first five or six years of its growth. It produces large luxuriant lateral shoots, which are but slightly attached to the stem, and which, if not stopped—that is, their points pinched off when they are about one foot long—are very likely to be blown off by the wind. This care may cease after the tree or pole is ten or twelve feet high, for after that height the growth becomes moderate. Young plants are raised from seeds or from layers, and thrive on any light sandy soil. The timber is highly prized by millwrights for cogs and other friction purposes.

The *Wild Cherry* or *Gean-tree* (*Cerasus avium*) is a hardy native, but is seldom cultivated as a timber-tree; nor has it that care bestowed upon it which it really deserves. The best specimens to be met with are those which have risen by accident in woods; but when such are felled, they are readily purchased by the cabinet-makers. As mentioned under FRUIT TREES, the wood is very suitable for boring and forming musical instruments. It is therefore a tree not to be neglected by the general planter, and should have place among others. Young plants are raised from the stones, sown thickly on a bed of good soil, either in autumn or in spring, and afterwards rowed out to receive the ordinary nursery treatment, until fit to be finally planted.

The *Hornbeam* is a forest-tree, but it ranks as an inferior one; its timber, however, is remarkably tough and durable, and consequently invaluable to the plough and cart-wright. It is a scrubbed, tortuous-growing tree, unless it has some pruning bestowed upon it when young. It is also a pretty good hedge-plant, and useful for forming screens or boundaries in gardens. Plants are raised from the keys, or seed, of which plenty are produced every year by old trees.

The *Birch* (*Betula alba*) is another inferior timber-tree, but useful as a coppice plant for many rural purposes. It has a beautiful and elegant contour, on which account it is introduced into ornamental scenery, especially if water be in the composition. Of the common birch there are several varieties, not to speak of the poplar-leaved, the tall, and the black American. Young plants are most conveniently raised from seeds, and the exotic species are raised from layers, or by grafting on the common one. Wherever there are poor thin-soiled stony heights, the birch may be planted as a useful cover; and its timber, if properly taken, is readily bought up for gunpowder charcoal.

The *Holly* (*Ilex aquifolium*) is a remarkably hardy evergreen, with smooth shining leaves furnished with prickly points. It is a native of Britain, and attains a great age, but seldom reaches a large size. Its timber is white and hard, which renders it suitable for veneering, and for making mathematical instruments. Different varieties are grown as ornamental shrubs.

The *Box* (*Buxus sempervirens*) is generally grown as an evergreen shrub, but when planted out with a proper soil and climate, it attains a height of from twenty to thirty feet. It grows to perfection in Turkey, whence its timber is imported for use in all cases in which exceedingly fine cross grain is required. Sawn across and planed, its surface is as smooth and fine as polished metal. Box blocks are on this account employed for wood-engraving.

Soft-wooded Trees.

In this section may be included the horse-chestnut, lime, alder, poplar, and willow.

The *Horse-Chestnut* (*Æsculus hippocastanum*) is only valued for the beauty of its flowers and the majestic port of the full-grown tree in park scenery. The timber is very inferior, and the nuts are only useful for deer. There are several species of this tree—namely, the smooth, Ohio, ruddy, and the pale-flowered. All these have prickly fruit, and are easily raised from their large nuts. They require shelter and good rich soil; grow rapidly under these conditions; and soon form highly ornamental objects. A section of this genus is called *Pavia*, or bucks'-eye, their fruit being round and smooth. (See BOTANY, p. 55.) The flowers of some of these last are magnificent, being of a glowing red, and are most conspicuous in the spring or beginning of summer. Avenues of these trees, as seen in the neighbourhood of Geneva, are of the most splendid description when in flower. The pavias are often propagated by being grafted upon the common horse-chestnut, and some of them are only shrubs.

The *Lime* (*Tilia*), of which there are several varieties, is a beautiful leafy tree, grown chiefly for ornament, and very suitable for avenues. Those which have most effect are the red-twigged and broad-leaved American, the latter possessing elegant pendulous flowers. As all the varieties require a heavy soil and sheltered situation, and their timber being not of corresponding value, they are seldom or never introduced into the forest. The lime is the European tree which, in a given time, appears capable of acquiring the largest diameter. Decandolle has some observations on the rate of growth of this tree, which may prove useful. He says—'That which was planted at Friburg in 1476, on occasion of the battle of Morat, has now a diameter of 13 feet 9 inches, which would give about two lines of annual diametric growth. This is about the rate of the increase of the growth of an oak, and therefore I suppose the tree had not found a favourable soil, and it would be nearer the truth to calculate the annual growth of the lime at four lines. There are in Europe a great number of limes of large size, and it would be interesting to have the circumference of those whose date is known. I shall mention for their size that of the Château of Chaillé, near Melles, in the department of the Deux Sèvres, which in 1804 measured 15 metres round (about fifty feet), and which I suppose was then 530 years old; that of Trons in the Grisons, already celebrated in 1424, which in 1798 measured 51 feet in circumference, and which I calculate to be 583 years old; that of Depeham, near Norwich, which in 1664 was 48 feet in circumference; and that of Heustadt in Wurtemberg, which in 1550 was so large as to have need of props, and which in 1664 was 37 feet 4 inches in circumference.' The largest now known in England grows in Moor Park, Herts.

The *Alder* (*Alnus glutinosa*) requires a peculiar locality—that is, a damp, bog-earthy soil; is but seldom ranked among forest-trees; and, except to occupy a spot where nothing much better will grow, is seldom noticed. It is most profitable kept as underwood; large poles, suitable for the turner, or for piles or planking for bridges, fetching a good price. Of common species there are four varieties, together with the hoary-leaved, oblong-leaved, waved-leaved, glaucous, with several varieties of these, and some shrubby species, the most of which are propagated by cuttings, or by grafting on the common one. (See Systematic Botany, p. 103.)

The *Poplar*.—There are several species of this tree—as the common black poplar (*Populus nigra*), the trembling poplar, the Lombardy poplar, and black Indian poplar. They grow rapidly, and rise to a great height, but narrow in mass, so as to be very conspicuous in hedgerows and landscapes. The timber is soft, but a good deal sought after; and where undrainable spots are wished to be decorated with stately trees, no better kind can be chosen.

The *Willow* (*Salix*), usually called the *Saugh* in Scotland, is an extensive genus, comprehending those shrubby species, the osiers, used for basketwork. A few species of the willow attain to the height and character of trees, the best of which, as yielding very good timber, is the white or Huntingdon (*S. alba*); and the crack-willow make excellent pollards, furnishing every five or six years a large crop of poles indispensable to the farmer. Another of the tree willows is that elegant plant the Babylonian or weeping-branched one, which forms so suitable an accompaniment to pieces of water, whether artificial or natural. The common osier is the sort mostly cultivated for the basket-maker, and the annual crop of rods from established stools pay the owner as well as any other crop on the farm. All the varieties are easily propagated by cuttings.

REARING OF TREES.

Trees grow spontaneously in all countries in which soil and climate will permit, and, as is well known, form forests of many hundreds of miles in extent on the North American continent. Whatever be the peculiar nature of any species of tree, it appears that the dimensions and form of all are more or less affected by their relative situation. If crowded, they have a tendency to grow tall and slender; if left abundance of space, they extend in breadth. The comparative absence or presence of air and light causes those distinctions. In a forest, each tree struggles upward, for its leaves to get a sufficiency of pure atmosphere and sun's rays, and therefore becomes all stem and top; whereas the tree in an open ground shoots out branches nearly from the bottom of the trunk, and attains a grandeur in its mass of foliage. Trees which are freely exposed are also much thicker and harder in the trunk than those in forests. This arises not only from having plenty of air and light, but from being exercised by winds. The well-understood principle in the animal economy, of exercise strengthening a limb—as, for example, the legs of a dancing-master or the arm of a blacksmith—is extended to the vegetable kingdom, in which those plants that are gently moved to and fro by winds, arrive at greater perfection of ligneous fibre than those kept altogether still.

In connection with this remarkable effect in the economy of plants, it is to be observed that all exposed trees have the largest roots; because, being liable to be blown over, they require to take a much firmer hold of the ground than if they were sheltered on all sides; in other words, the action of the tree, and the free air and light, cause numerous branches and a large breathing apparatus of leaves, and the tree must have a corresponding mass of roots for the supply of sap. So exact is this correspondence between the exposed and underground portions of the tree, that the extent of roots may always be judged of by the extent of branches, the one being of the same breadth as the other. The practical lesson acquired from these facts is, that to have trees with large bushy heads, they must be planted widely; and if wanted to be tall and slender, they should be more closely planted.

The generally thin soil and comparatively ungenial climate of Britain render this country unsuitable for the growth of the more delicate and fine kinds of foreign timber; but all the forest-trees already noticed, when planted and attended to with some degree of care, attain great perfection. The business of planting is seldom performed by the unprofessional culturist, being more advantageously left in the hands of nurserymen, who rear the trees from seeds, layers, or cuttings, in grounds set apart for the purpose, and at the proper time transfer them to the locality where they are to remain. For the sake of general information, we offer the following observations on different departments of this interesting subject.

Ornamental Plantations.

Even on the smallest possessions, a sprinkling of forest-trees in the hedges or corners of the enclosures gives a dignity to the spot which otherwise it would not possess. There cannot be a more cheerless object in a landscape than a house—however substantially built and furnished—standing naked and alone, without a sheltering tree or bush to indicate either the taste or competence of the occupiers within. The lowliest hut, environed by two or three aged oaks or hawthorns, is an interesting spectacle, and far more delightful to the eye than the proudest palace standing bare, and unaccompanied by trees.

To secure these embellishments, planting on an ornamental scale is necessary, and much good taste must be brought to bear on the subject. It is now allowed by all who have studied landscape gardening, that in the part surrounding the mansion trees should not be dotted about at equal distances, nor in lines; they should not be placed as blinds to the principal windows, but so arranged as to form irregular glades, diverging in as many directions from the house as can be done with effect and propriety. These glades should always be laid out with reference to some distant interesting object, or some striking feature of the surrounding country. The offices, which are generally in the rear, or at one end of the house, should be hidden by a screen of trees and shrubs; and all eye-sores, visible from the windows or elsewhere, should also be screened by plantation, which has a double advantage—namely, hiding a deformity by a profitable screen.

When it is intended to increase both the beauty and the value of an estate by planting, and whether for the personal interest of the proprietor, or with a view to that of posterity, ordinary prudence will direct him to fix on those parts which are the least valuable for agricultural purposes. The precipitous slopes of an undulating surface, where cultivation is difficult or impracticable—moist swampy hollows—or the ridges of bleak hills lying to the northward or eastward of the superior portions of the park or parks, whether arable or pasture land—will all be found the most eligible for conversion into woodland. And while such plantations yield the finest shelter and covers for game, they keep rapidly adding to the real value of the estate.

Whenever a project of planting is entertained, if only to occupy waste or worthless ground, it is not easy to separate the idea of ornament from the utility of the design, if it be no more than establishing an acre or two of coppice; for even such a feature, especially in a naked country, requires a little attention in the execution. Coppice, when properly stocked with the right sorts of plants, only appears in all seasons as a thicket of shoots of nearly equal height. Consequently the eye of taste would condemn the plantation as too lumpish, and wanting in variety of outline. But this, though but a trifling defect, may be easily obviated by planting tufts or groups of trees, variously disposed, to remain for timber; or the same thing may be effected by leaving at the first fall a few groups of the most promising saplings, here and there irregularly over the area. These permanent groups will not injure much of the underwood, while they will give as much variety to the whole as may be necessary. This point, however, will be again adverted to when describing the manner of laying down underwoods.

As the beauty of many places constitutes their chief value, and as that beauty is mostly if not entirely owing to the tasteful disposition of the plantations, it behoves every improving proprietor to study well the genius and character of his property before he begins planting on a large scale. The safest plan, in order to avoid taking any step which may afterwards be regretted, or to be done over again, is to sketch an idea, or upon the map, a comprehensive design, embracing everything that may be done with propriety. This being well digested and settled in the first place, may be called the general plan, and of which *as much only* as is most obviously called for, and practicably expedient, may be first of all executed, leaving the more distant and less necessary operations to be done as time and opportunity may allow. Such a general plan of planting an estate, whatever its extent may be, requires a considerable acquaintance with the principles of what is termed landscape gardening, and can only be designed and executed properly by the owner himself (who can do nothing wrong in this way, so as he pleases himself) or by a professional adviser.

It has already been observed that some proprietors may think it advisable to plant only the inferior portions of their acres, while others, who are determined to have a tastefully-planted park or a highly-embellished estate, place their groves, or groups, or single trees on any eligible spot, without regard to the quality of the soil, whether the worst or the very best. In this case everything is sacrificed to obtain such a disposition of the trees as will produce the most striking scenic effect; and such kinds only are selected as blend harmoniously with each other.

The character of the general surface surrounding a mansion fixes the style of planting and the kinds of trees. If the surface be moderately undulating, having easy swelling knolls and gently falling hollows, without asperities of any kind, such a surface is said to be beautiful, and consequently the plantations should be beautiful also; that is, composed of trees of the finest foliage and most elegant forms. But if, on the contrary, the surrounding country be wild in character, and marked with bold and rugged features, as naked rocks or cliffs, deep ravines or glens, &c. then a different style of decoration must be pursued—as planting in irregular masses all the most grotesque, ragged, and sombre-tinted trees that can be selected, in order to harmonise with the natural features of the country. Scenery of this kind is said to be picturesque; and where such tracts of country are chosen for a manorial residence, and the grounds are laid out and planted by a skilful gardener, the scenery is much more interesting to the eye of taste than any other, especially if water chance to be in the composition.

Great changes occurred in the style of planting during the eighteenth century. Up to the beginning of the reign of George I. all transplanted trees were arranged in right lines, as single, double, or quadruple avenues or vistas, or as boundaries to the enclosed grounds belonging to royal or other palaces, colleges, and other public buildings. But about this time it was discovered that very *few* ranks of trees were to be seen in the works of the great masters in the schools of painting; a new idea was entertained that, in all real scenery about to be created in the parks of the nobility and gentry of the British isles, ranks of trees were inadmissible, as being too stiff, formal, and not agreeable to nature. Thus a sentence of condemnation was passed upon every private avenue in the country, and they quickly disappeared before the axe of the woodman. A few only were saved, but they were curtailed in length; and now very few new avenues are planted. Along with the avenues, all the old regularly laid-out terraces and flower gardens were swept away, to make room for a new style, distinguished by the prevalence *of irregularity* and *curved outlines*.

Soon after this revolution in landscape gardening, a great many ridiculous pranks were played in obtaining *extreme* irregularity and *tortuous* lines; and some of the performers got severely handled by the satirists of the day. Kent, who began the revolution, died without having gained much reputation; but his successor, the famous 'Capability' Brown, became highly eminent, and was universally employed. He did more in altering the gardens and grounds of the country-seats of these kingdoms than any other professor before or since his time. His aim was to produce unmixed beauty by neatness and general smoothness, especially near the house; for which purpose he cleared away every obstruction, whether built or planted, in order to set the mansion fairly out upon a naked grass plot or lawn. Even the kitchen gardens were removed as far off as possible; and every bush, or other appearance of inequality was shaven off, to produce the wished-for smoothness. In this proceeding he and his copyists fell into the opposite extreme; instead of beauty, *baldness* was the result; instead of intricacy, *tameness*; and instead of the embosoming shelter of surrounding groves, complete nakedness and exposure to every wind that blows. This exposure detracted from the consequence of the building, whatever might be its size or style of architecture; because a partial display is always more interesting than a view of the whole at once. Nevertheless, Brown had the honour of laying out many beautiful parks and gardens, which remain to this day as monuments of his good taste and judgment; but many of his immediate followers brought discredit upon his style by their very awkward and unmeaning imitations.

The severe animadversions published against the Brownian style tended to correct some of Mr Brown's most ostensible errors; and the works of Messrs Repton, father and sons, Loudon, and others, have improved the style of English gardening, and brought it much nearer to the principles of real taste. The *clump* and the *belt* have been greatly modified; the first is now expanded into a less formal group, and while the latter has lost its continuity, it has been increased in depth, and its lengthened form as a boundary judiciously broken. Undergrowths, which were swept away by Brown, are again introduced; and the banks of lakes and rivers, formerly smoothed down to the water level, are now left more abrupt, broken, and irregularly fringed with overhanging trees, and aquatic shrubs and herbs.

Forest Planting.

The different methods pursued in establishing or laying down woodland, seem to have been determined by the number of acres or nature of the ground intended to be planted. Nevertheless there are certain points which in every case are worthy of the planter's attention, such as the best form for any given extent, the style of boundary, and the mode of enclosure. On these heads we transcribe the advice of a practical forester of long experience. 'As the future welfare of a plantation is considerably affected by the manner in which it is laid out, no man ought to attempt the laying out of ground for one, who is not naturally possessed of good taste for that sort of landscape scenery which is based upon the laws of nature, which will enable him to lay out the proposed plantation in such a manner as to give the greatest possible effect in ornamenting the neighbouring country. It is also necessary that the person who would lay out ground for a new plantation, should be possessed of a knowledge of the nature of the growth of each sort of tree when planted upon any given soil or situation; which knowledge will enable him to judge rightly as to the effects that certain trees will have when planted in any given spot; and he will also be enabled from such knowledge to say truly whether or not trees will grow well in the situation chosen for a new plantation. And it is further necessary that the party, in the laying out of a new plantation, should be acquainted with, or at least have in view, any local peculiarities of the district relative to cold and destructive winds from certain points. From such knowledge he will be able to lay out the proposed plantation in such a manner that it shall have the greatest possible effect in giving shelter to the surrounding fields, which is the principal end a proprietor aims at in having woods upon his estate.

The larger that any piece of plantation is, the sooner will the trees therein come to useful size, and answer the desired end; and the smaller it is, the more likely are the hopes of the planter to be disappointed. And the reason of this is obvious: for the young trees growing in an extensive plantation, as soon as they rise a little above the surface of the grass or heath, begin to shelter one another; whereas if the plantation be narrow, the young trees can hardly be said ever to come the length of sheltering one another—for every breeze of wind blowing through the whole breadth, acts upon every single tree almost as powerfully as if each tree stood singly and alone. Therefore it is most profitable for proprietors always to plant in large masses. Trees planted in a mass of one hundred acres extent will be more healthy, and come sooner to profitable size, both as affording timber and shelter, than they would if planted in a mass of ten acres. From this it follows, that if a proprietor wishes to plant one hundred acres upon his estate, he will raise more healthy timber by planting in *one* mass, than he would do by planting the same extent in four masses of twenty-five acres each. No young plantation, upon an exposed situation, should be less than one hundred yards broad at any given point; and where the soil is of a light, thin, mossy nature, and not apt to raise trees to good size, one hundred yards may even be too little for breadth.'

Again, 'the method of laying out plantations in the form of strips, so often to be met with in Scotland, gives a poor and mean appearance to a gentleman's estate, particularly when found about the home grounds. The form in which they have generally been made is in straight lines, from twenty to thirty yards broad. In such narrow belts of wood the trees are very seldom found in good health; and, upon a little consideration of the matter, this is not to be wondered at—because, from the narrowness of such strips, the proprietors were always afraid to thin them, wishing to keep them in a thick state, in order to give as much shelter as possible; and the natural consequence is, from being left too thick, the one tree soon kills the other. And even where such strips have been well managed, it cannot be expected that they could produce either good healthy timber or make a good shelter; for, being so narrow, the trees never come to shelter one another. But it is a happy circumstance in the history of arboriculture that few such strips are now planted: gentlemen are now beginning to see the impropriety of such a method of raising plantations; and now, almost in all cases of good management, we see the old-fashioned narrow strip giving place to the well-defined, extensive plantation, which is, indeed, the only profitable way of rearing trees for any economical purpose.'

Further, 'it is absolutely necessary that every piece of ground laid out for a plantation should be fenced in some way or other, previous to its being planted. A fence not only prevents the inroads of sheep and cattle, but it at the same time tends very much to shelter the young trees, and to bring them on rapidly. It is, indeed, surprising to observe the difference that a very low fence makes upon the growth of young trees, as compared with those which are not protected by one. Any proprietor or forester, upon looking through his several plantations, will observe that, in all young plantations, the most rapid growing, and at the same time the most healthy trees in it, are to be found immediately behind the outer fence; and upon the other hand, in all older plantations, the best grown, and at the same time the most healthy trees, are to be found in the centre of the same, or at least a considerable distance back from the fence. Now, it may be asked, what is the reason that the best wood is found in the inner parts of old plantations, while the most rapid growing trees are to be found, when young, behind the boundary fence? The reason, as proved from experience, is this:—During the first eight or ten years of the age of any young plantation, the boundary fence is the only shelter that the young trees have; and it is evident that those trees which grow immediately behind the fence will receive most of the benefit of its shelter; consequently, from the circumstance of their receiving more shelter than their neighbours further off, they must grow more rapidly, until such time as their tops begin to rise above the level of the fence, when they are considerably checked by the cold winds. At this stage they begin to grow thick and bushy, rather than advance in height; and immediately upon their becoming so, they begin to shelter all their neighbours inside, which, again, begin to have double the advantage of their neighbours outside; for the trees upon the outside had shelter only so long as they were below the level of the top of the fence, whereas those inside have now a shelter which every year increases upon them for their advantage, in height as well as in thickness. All this comes in to prove that a fence is a great means of furthering the healthy development of a young plantation, independent of its protecting from the inroads of cattle at the same time. I always calculate that a plantation with a good fence is ten years in advance of one without such protection.'—*Brown's Forester*.

Seedlings—Modes of Planting.

To secure a full supply of the plants required, and these of the proper sort and age, it is requisite that they be previously raised from seed on the premises, or be easily procured from a nurseryman in the near neighbourhood. Where a great extent of planting is intended to be done, the former plan is most economical; but the latter, in general, is the most convenient. To raise forest-trees from seed is an easy affair: it is only choosing a piece of good mellow soil within some enclosure; this must be trenched or double-digged, laid level, and freed from stones, &c. by the rake, divided into beds four feet wide, with one foot alleys between. In the month of March, sooner or later, according to the forwardness of the season, the seeds may be sown either in drills lengthwise of the bed, and deeper or shallower according to the size of the seed; that is, nearly an inch for small, and an inch and a half for large seeds, such as acorns and chestnuts; or small seeds may be sown broadcast, by withdrawing with the rake towards the alleys about an inch of the surface each way. On the fresh soil, the seeds are thrown as regularly as possible, and covered by having the removed soil again drawn over regularly and smoothly. The seed-beds must be guarded from birds and mice; and if the weather be warm, and parching winds prevail, they should be covered occasionally with mats, and also watered, if necessary. Seedling trees are usually transplanted into rows in nursing beds, some in the second, others in the third year; and there to stand till planted out for good, which should be done when they have arrived at a proper size—the nature and condition of the ground intended for them, as already observed, determining this point.

The surface to be planted may either be in a state of nature, and covered with heath, or with a turf of some kind or other; or it may have received some kind of preparation, as paring and burning; or ploughed, digged, or deeply trenched. It is almost unnecessary to add that the first is in the worst, and the last in the best condition for the reception of young trees. There are many cases, however, where there is no choice but the first; and yet the success which has attended such undertakings as planting a naked hill or a barren common is a direct encouragement, and proves that such naked portions of the country may be in a few years covered with useful trees.

When a large extent of such description of land is intended to be planted, it must necessarily be executed in the most economical manner. If the enclosed surface be acclivous, and covered with short herbage and thin staple, two or three year old plants of larch, Scotch fir, birch, intermixed with a few oak, beech, and ash, may be inserted by a one-handed tool, somewhat like a cooper's adze. One or two blows of the tool raises a triangular piece of the surface, under which the root of the plant is properly placed, and the raised sod turned back and trodden down with the foot. In this simple and expeditious way of planting, many hundred acres of hilly land have been stocked with trees; and though many of the plants are liable to suffer, if a dry summer follows the planting, a majority are sure to succeed, which well repays the cost. When such ground is level, an opening is made by first cutting the turf in the shape of a cross, and turning back the four corners from the centre, breaking up and making a hollow for the root; when the tree is placed upright, the turf is returned and trodden firmly down.

There is yet another method of planting rough unprepared ground, called *pitting*. The surface covering is first cleared off, the pit broken up with a mattock, and the loose earth thrown out with a spade; the tree is then placed, and planted with the removed soil. This method of planting is expeditiously performed when the ground works kindly; but if wet or clayey, the business is more difficult, the pits requiring to be opened, and the land drained, long before the trees can be planted.

The above methods of planting forest-trees are only had recourse to when the ground cannot be prepared in a superior manner. And notwithstanding the risk of being defeated in such attempts, it is quite certain that in numberless cases they have succeeded admirably; and very valuable woods now ornamenting both England and Scotland have been raised under these simple modes of planting.

When it is intended to plant a field which has been or may be ploughed, it is got in order by receiving a thorough fallow, to clear it of every kind of weed. The ploughings (with a strong team and plough) should be made as deeply as possible. Supposing the land to be got in perfect order by the middle of October, if intended for timber only, the trees may be immediately planted; but if intended for underwood as well as timber, the last ploughing may be deferred till January; and if the ground be then pretty dry and mellow, the whole may be immediately sown broadcast with a mixture of seeds, and harrowed in, after which trees may be planted at the distance of four or five feet. The mixture may consist of the seeds of oak, ash, beech, Scotch fir, and birch; and if a sprinkling of common furze be added, it will be no detriment. If Spanish chestnuts are intended to be a part of the underwood (for which they should always be preferred), the seeds should be dibbled in, as they are too large to be covered by the harrows.

This method of laying down woodland, if carefully performed, is always successful, as there is not only a full number and choice of trees for timber established, but the field answers the purpose of a nursery for many years, from which may be drawn unlimited numbers of young seedlings for planting elsewhere. Some of the finest and most profitable woods we happen to be acquainted with were laid down in this way about the year 1775.

The next successful method of planting forest-trees is placing them on deeply dug ground; for if digging be practicable, it is a proof that the land is in a good condition for their growth. The action of the spade forms a bed sufficiently deep for the generality of the best sorts of timber, and the loosened state of the soil renders the planting easy.

But by far the best preparation of the ground is trenching it eighteen or twenty inches deep. The surface, which is usually covered with vegetation of some kind, or the remains of vegetation, being turned to the bottom of the trenches, forms a fine nutritious stratum for the roots to luxuriate in; besides, the staple being opened and intermixed so thoroughly, admits all atmospheric influences, without which no plant can thrive.

When trees are planted upon either a dug or a trenched surface, seeds may also be sown and pointed in, for undergrowths are always valuable for some purpose or other. This is particularly necessary when the plantations are required as covers for game; and in park scenery, hawthorn, holly, and juniper berries, should always be sown when the trees are planted.

When ornamental plantations are made in a park, and especially if they are in view from the principal windows, they are wished to rise as quickly as possible, for the sake of immediate effect. The trees, therefore, receive extraordinary treatment. The ground is not only carefully and deeply trenched, but a most liberal dressing of good rotten dung and vegetable mould—the first trenched down, and the latter dug into the surface—is bestowed, and which of course excites the trees into much stronger and more rapid growth than if only the ordinary expedients were employed. But this superior and expensive practice is seldom necessary, and much seldomer executed. Indeed, in the rearing of extensive forests for valuable timber, it would be decidedly injurious; for though the young trees might rise rapidly for a few years, as soon as the exciting influence of the manure was over, they would, as all experience teaches, soon fall into a diseased condition, and never attain that hardy robustness which natural forest timber always presents.

Planting on Bad Land.—The preceding directions are sufficient in all cases in which the land is tolerably dry, or which may be rendered suitable by a little preparatory culture; but when the ground is moist, and barren of all useful produce, the following methods of preparation will require to be pursued.

The first thing to be done with a piece of wet land is to drain it, and then enclose it with fences. The draining operations will consist in making wide and deep ditches around the land to receive and carry off the water, and into these smaller cross drains are to be led. (For a minute account of the best methods of draining, see CULTURE OF WASTE LANDS, p. 500.) If the drains be finished in October, so as to allow the water to run off for three months, planting may begin about the middle of February, provided the weather be dry. 'I would recommend,' says a writer on this subject, 'strong plants, three years old; for I have seen many small things stuck in among rank grass, but I have rarely seen any of them grow. The ordinary way of planting does well enough for the firs; it is done in this way:—A cut is made at right angles to the line of the labourers' feet, another is made at right angles to that, and the soil raised; the root of the plant is inserted; and the spade being withdrawn, the soil is, or ought to be, firmly trodden down around it. I say ought to be, for very often it is not. The labourers ought to have the importance of this reiterated upon them; and I would, if possible, always have a big man in preference to a little one to wield the spade. There is an emphasis in the tramp of his foot, which, for the success of the young tree, is invaluable. The other mode of planting is more tedious; but where the proposed plantation is small, I think it is worth while to give all the additional trouble. This method consists in making pits for the reception of the plants. A square piece is dug out, the plant is placed in the middle, the soil is broken and put round the roots, the turf is cut in two, and being turned upside down, the halves are placed one on each side of the stem of the plant, and firmly trodden down all round. This, it will be seen, is tedious. Three plants may be planted by the first method for every *one* by the second; yet, where the plants are large, it is worth while to bestow the additional labour: especially in planting trees of the deciduous kind, this method ought always to be adopted. I have always found it advantageous to plant pretty close; but care must be taken to begin early to thin, otherwise the young trees fall into consumption. Ground treated in the manner now described, be it never so wet, will grow fine trees; that is to say, if there is anything like a soil at all.

Let us next suppose the ground to be planted to consist of a thin, poor soil on a hard close bottom. To plant such ground just as it lies, is a piece of the most consummate folly. Far better burn your young plants at once: they never will grow to anything. The plan which I have now to propose has a most formidable objection against it—it is very expensive. But let the proprietor arrange the matter in this way: instead of planting, say ten acres in one year, let him plant only four. It is far better to have a few trees thriving, than a great many pining out a miserable existence, to the disfigurement of the face of nature and the bitter regret of their owner. The first thing to do is to set about trenching the ground. To the ordinary mode of trenching there is a most decided objection. That part of the soil which is at all good, is mercilessly buried at great labour and expense; and the hard till, which has about as much nutrition for plants as freestone rock, is brought up to form the soil. This will never do. We must keep the soil which is at the top still at the top, and stir the till below. At first sight there is some difficulty here, but the difficulty must be overcome, and that may be done by a little calculation as to arrangements in the matter of digging and filling up the trenches. The cost will be only a little more than that of ordinary trenching, and it is vastly superior to it. It would also be an advantage, as each trench is cleaned out, to give it a rough course of picking along the bottom, which would make the soil, although never so wet before, dry and sweet as a garden. The best time for performing this operation is in the months of February and March, and then only when the weather is dry. It would be well if planting could be carried on simultaneously with trenching; in which case see that the plants be put in *deeper than usual*, and well trodden round the stem.

Ground thus treated will produce the finest trees. They will grow fast, keep free of moss, be healthy in the bark, and straight. It would be advisable, even with this trenching, to open drains throughout the whole that is planted, in order that the surface-water may be carried freely away. Land, when thus dried, becomes richer by every shower that falls. The water, in percolating through the soil, carries down with it a fresh supply of oxygen gas, which the roots of the trees, with their thousands of little mouths, are gaping to receive as their most nourishing food; and being thus fed, is it not natural that they should grow apace and be in good health? In this way you will have in six or eight years fine plantations, forming an ornament to your property and a shelter to the fields. By the other method you may plant thousands of trees; but where the soil is positively wet, you will never see any of them do more than make an ineffectual attempt to grow.

I have now a few observations to make regarding the after-treatment of trees planted in the manner now recommended. They must not be left to themselves; and if hedges be planted, they will require much care, for the first three years especially. They must be kept perfectly free from weeds, at whatever expense of labour. Thin, board-like hedges, cut close upon each side, are not the thing. I never saw any so treated do well. They must have breadth, and should be tapered on both sides to the top. But let us attend to the trees. Exactly a year after they are planted, where the ground has been trenched, it will be requisite to give a partial hoeing—that is, to cut down any tall weeds which may be overtopping any of the trees. Should any of the hard wood, in place of being green, become yellow, there is a plan which, if adopted, will completely restore them. Two years after they are planted, let them, in March or April, be cut over about three inches above the ground; in the month of July a careful person must go through and pinch off all the young buds except one, the healthiest, and the one which offers fairest to shoot into a main stem. This has a most magical effect. It insures a healthy tree, with a free bark, and perfectly straight. I have had oak, ash, and other timber thus treated, which have made beautiful shoots of upwards of two feet in one year. Trees which are on the whole thriving and sufficiently straight, but which are getting hard in the bark, I have generally improved very much by the following process:—You enter the point of a common gardening-knife as near the root as possible, and run it up to the first branches. In a year or two this cut will be covered with new bark, an inch or two in breadth, greatly contributing to a free circulation of the sap, and consequently promoting the health and growth of the tree. I have seen trees twenty and thirty years old materially benefited by this process. A handy labourer will do many hundreds in a day.

If the hints I have now given be followed, I am quite confident that they will save much disappointment to proprietors who are disposed to plant, and that many fine trees will be raised on situations in which, by the common management, they never would have attained to either beauty or value.' To this we need only add, that the young trees should be carefully distributed in the plantation according to the nature of the soils and the situations. In any large area of irregular surface there are generally patches of dry stony ground, of moss soil, of deep loam, or of light gravel; and not only so, but some portions will be more exposed to cold winds and rains than others, some portions will lie favourably to the south, others perhaps to the north or east; and while part of a forest may lie along the banks of a low sluggish river, others may be situated at many hundred feet above. Now as trees have different constitutions and habits, and are differently affected by soil and climate, it is evident that the forester who attends to these habits, and plants accordingly, is far more likely to succeed than he who plants hap-hazard, or with but little attention to these peculiarities. 'I have often regretted very much,' says another tree-cultivator, 'to see larch and Scots firs of thirty years' standing in an unhealthy and dying state, where, if beech or any other of the native sorts of hard-wood trees had been planted, they would undoubtedly have proved both useful and ornamental; and again, as often have I seen stunted-looking hard-wood trees striving for existence, where, if firs or pines had been planted instead, all would have been well.'

Pruning—Thinning—Felling.

When woods are planted as sources of profit, a very material part of their subsequent management is the labour of pruning and thinning the trees. It is not enough that trees grow and be annually increasing in bulk—they should also be assisted to take the finest and most valuable forms. A round straight butt, of moderate length, is far more useful and saleable than a crooked knotty one of twice the size. To have fine timber, it is absolutely necessary to bestow a little trouble to start them fairly off, during the first ten or fifteen years of their growth. The best method of raising a plantation is by using a mixture of different sorts, which may be deemed *principals* and *secondaries*. The first are those for which the land is judged most suitable, the second are nurses or supernumeraries, intended to be drawn out as soon as they press injuriously upon the principals, or when they have attained to a useful or marketable size.

To have tall and straight stems, the trees must be planted thickly at first; that is, only about four feet apart, or even less. In this order they shelter and prompt each other to ascend; and if in the spring the woodman pays his annual visit, armed with a light keen bill and a narrow *turning-saw*, he may direct the growth with the best effect. Every lateral branch which appears to be attracting too much of the powers of the plant, and especially if, as already observed, it be contending for supremacy with the leader, should be sawn off *close* to the bole as soon as it has attained a diameter of one inch. Such a wound will be soon healed up, and present no flaw when the tree is cut up at the saw-pit. All branches of smaller size need not be removed, for they serve to enlarge the trunk, and have no effect in distorting the grain until they attain the size when they should be pruned off. If branches are allowed to remain until they have acquired a diameter of from two to four or more inches, and then cut off either close, or, what is much worse, at some distance from the bole, the timber is sure to be deteriorated. Such wounds, it is true, will be healed over in time, but the timber will be wanting in its best property—namely, soundness and freeness from knots. All branches originate at the pith of the main stem; and whether they are alive or dead when the tree is felled, they are equally objectionable in the estimation of the builder or mechanic. The knots in fir timber are less objectionable, because they are preserved sound by the resinous quality of the sap; but neither are they desirable, if trees can be grown with a clear uninterrupted grain. The most valuable part of a tree is the bole, and the longer and freer from knots this is, the more saleable; and if any or every tree may be made to grow into fine sound boles of fifteen or twenty feet in length by such attention as is recommended above, it is surely worth the trouble and expense.

Trees grown for ornament in lawns require no other pruning than what may be necessary for the removal of rotten or decaying branches; and in general it will be found advisable to leave each kind of tree to assume its own natural form. Ornamental trees are always most beautiful in their proportions when the branches and spray reach towards the ground; but this will not be the case if cattle are allowed to browse beneath and around them. These animals nibble away all the foliage and spray within reach, so as to form in park scenery what is called the *browsing line*—an even bottom of foliage, anything but agreeable to the eye. The only plan of avoiding this inelegance is to exclude browsing animals altogether from ornamental grounds; but this is attended with opposite evils, and takes away that pleasing assemblage of forms which is the great charm of woodland scenery. Where cattle or sheep are permitted to browse, all young trees at least must be protected by circular palings, otherwise they would be disbarked, and generally destroyed.

All species of the hardy pine and fir tribe intended for profit should be planted pretty thickly; the supernumeraries thinned when young, but leaving a full number of principals to grow up to a marketable bulk, or until they cease to thrive, when they will all be ready for the axe together; for such woods cannot bear to be thinned gradually like other trees, being particularly liable to die if they lose the protection of their neighbours. When planted as nurses among deciduous trees, they are easily kept within bounds, and from damaging the other trees, by pinching off, from time to time, the *leading buds* of their branches. This induces a spray-covered, rather than a naked stem, and thus maintaining their character as nurses. By the same means, fir-trees may be formed into impervious screens, or sheltering hedge-like boundaries, very useful in many cases of rural improvement. Respecting the pruning of fir-trees planted for profit, and which are intended to grow up with clear-grained butts, a rule has been laid down by planters which is easily followed: it is this—prune off the lower branches every second or third year, always leaving *five tiers* of branches to form the head. This regular method of keeping the butt divested of its lower branches, and continued up to the highest convenient height, will certainly insure fine butts of clear-grained timber, as all the knots will be small, and all near the centre of the axis. The fine clear-grained butts imported from America and the North of Europe are trees which were never pruned; but having grown up in very close order, the lower spray was consecutively killed by the want of air and light, shut out by the close canopy of branches above. This is gaining sound timber by accident, and which may be done in any country, but by no means in such a short time as may be done by hand pruning.

According to James Brown, 'the distance at which trees in a plantation ought to stand one from another, must in all cases be determined by the nature of the soil and situation upon which the trees grow, and also upon the ultimate object the proprietor may have in view as regards any particular plantation; but as a sort of guiding rule for thinning, I may here state, that if in any particular plantation it should be intended to rear up trees for park or lawn scenery, then in such a case the distance between each individual tree ought at least to be equal to the height of the same; and this rule ought to be kept in view at all stages of the growth of the trees, in order that they may have free room and air to form spreading tops as well as massive trunks, which is the true and natural form of every tree, and which constitutes the great beauty of lawn trees. If it should be intended to rear up a plantation of hard-wood trees principally for the sake of value in timber, and of giving shelter at the same time, then in such a case the distance between each individual ought to be equal to about one-half the height of the same; and this ought to be kept in view at all stages of the growth of the trees, in order that they may not have so much free air and room as to allow the spread of their branches horizontally, nor yet to be so much confined as to be drawn up weakly from the want of air. If it should be intended to rear up a plantation of firs or pines, for the sake of shelter and timber, then the distance between each tree ought to be little more than the third of the height, which is the distance found most favourable to the useful development of the fir and pine tribes, as timber-trees.'

In very many instances trees are suffered to remain in the ground considerably beyond the time they should be felled and put to the proper object of their growth. They are seen to get rotten at the core, or the branches are seen to die; still, from an unwillingness to remove what may be viewed as old friends, they are allowed to remain till accidentally destroyed. Instead of following this practice, we recommend the proprietor of forest timber to have his woods periodically examined by a person skilled in timber, who should mark all the trees that seem ready for removal, and let them be removed accordingly. Unless for particular reasons, every tree should be felled on arriving at maturity, and a new one planted instead.

To insure dryness of timber, it has been found a profitable practice to disbark the oak and larch a year or two before felling. On this point Monteath, in his 'Forester's Guide,' says he is decidedly of opinion that larches treated in this way at thirty years of age will be found equally durable with those cut down at the age of fifty years, and treated in the ordinary way.

Transplanting.

Trees may be lifted from one place to another, or transplanted. The art of accomplishing this exceedingly delicate operation in tree culture was some years ago brought to perfection by the late Sir Henry Steuart of Allanton, whose treatise is the best authority on the subject. The transplanting of a full-grown tree has, in all ages, been deemed next to impossible; and when it was attempted, the operator thought it necessary to cut off a great number of the branches (and consequently the leaves), from an idea that, if suffered to remain, they would require more sap than the roots could supply in their new situation. Of course, just in as far as they deprived the tree of its branches, or, we may rather say, of its leaves, they deprived it of the principal organ of its existence, and it invariably decayed to a corresponding degree. The lopping was like a cutting off of the lungs in a human being; and it would be as absurd to expect a man in that state to be healthy and strong, as it was to hope for vigour in the stripped member of the forest.

Sir Henry Steuart having studied the internal structure of trees, began, a good many years ago, to practise the art of transplanting on what he justly calls the preservative principle—that is, without mutilating either roots or branches, as was universally practised till his time. His seat, Allanton House, is situated on an irregular slope, on the right bank of the river Calder, which is a tributary of the Clyde. The neighbouring ground, though diversified, has no very picturesque natural points; but he contrived, by the removal of large trees, and forming an artificial lake and river, to realise in some measure the miracle of bringing new and picturesque scenery into actual existence, in an almost endless variety of combination.

The following are the rules to be attended to in the transplanting of trees. The best season for transplanting is certainly during the months of October and November; for though trees may be transplanted in any of the winter months when the weather is mild and moist, they never do so well as when removed in the first-mentioned months. Taking up a tree requires as much care as replanting it; the spade and the pick-mattock are both necessary to raise the roots from their seat; and as the most tender fibres are the most active and useful, the greatest care should be taken to preserve them entire. Neither should these delicate fibres be exposed to a dry or frosty air; they should be kept moist and shaded till again put into the ground. The root should be placed no deeper in the new place than it was in the old; and all the ramifications laid as nearly as possible in their natural positions, and imbedded in the breast of the earth.

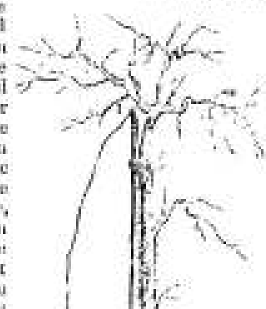
Trees may be transplanted from the age of one up to ten, or even twenty or more years; but when they are from four to six years from the seed, they are, both from age and bulk, in the best condition to be removed successfully. In planting with the one-handed tool, the smallest-sized plants must be used; for pitting, plants from two to three feet high may be chosen; and on digged, ploughed, or trenched ground, the young trees may be from two to six feet high, in which case the tallest may need propping against the south-west winds.

When single trees are to be planted on a lawn, a space of from four to six feet must be stripped off the turf, and rolled back; the soil within should be deeply broken up and excavated, to receive the full spread of the roots. A heap of richer loam or compost is laid in the centre, on which the tree is placed, and the roots are covered with the same, and watered, to consolidate the earth about the fibres. The other soil is then thrown on, and the turf returned to its place and beaten down firmly. Single trees should be staked; and if on a pasture, a cradle will be requisite to defend them from the browsing or rubbing of cattle.

Much has been written on the subject of transplanting large trees, and many successful exploits of this kind have been performed both in past and present times. Shady groves have been formed in the short space of a few months; proving that, with care, skill, and physical force properly directed, any tree of moderate size, say from twenty to forty feet high, may be transplanted with safety and success. One precaution very much facilitates the execution: it is that of digging a circular trench at a proper distance, say six feet, round the trunk, and deep enough to be below, and to cut through all the roots except three or four of the largest, which are left at equal distances to act as spurs for the better security of the tree when placed in its new situation. The trench, after the stumps of the roots are cut smoothly off, is filled with prepared compost for a new fringe of roots to strike into, and after one or two years the tree is in a condition for removal. In doing this, a deeper trench is made on the outside of the last, into which the mould from among the roots is drawn, until the whole is loosened from the soil; the spur roots are also followed out and laid bare. The method of raising the tree by a machine is mentioned beneath. In replanting, much depends on laying out the roots, and firmly imbedding them in moistened earth, and also adding a pretty heavy covering of soil round the stem, to keep the tree steady against wind.

Every tree about to be planted requires a little pruning; broken roots should be removed, and the head may require thinning. The branches should be equally balanced; and if any one appears to be a rival to the stem, it should be cut off close; so those rising with two stems should be deprived of the weakest. These remarks only apply to deciduous kinds; the pines and firs need no thinning when transplanted, unless some of the lower spray is dead.

A machine for transplanting has been formed on the principle of the common timber-truck—being a strong lever attached to the axletree of a pair of wheels. The latter are strongly constructed, at least five feet in diameter, and with a six or nine inch tire. The axletree is correspondingly substantial, and to its middle the pole or lever is securely fixed. The pole should be made of the best ash, seven inches square, with the edges planed off, and somewhat reduced in thickness towards the end. The length should be at least ten feet, for the longer it is, the greater the purchase in raising a tree. The pole is strengthened by side braces let into the axle, and mounted with an iron eye and ring at the point. When used, it is lashed against the tree, and the pole is raised and made fast thereto, as here represented. The wheels rest in the hollow made by baring and loosening the roots, though not upon any of them; and when all is ready, the strength of men, or that of a horse, is applied to the pole chain, which is, together with the tree, pulled to the ground, the root being lifted out of the soil; and, when thus borne on the machine, it is drawn away, root foremost, to its new place, previously prepared for its reception. The wheels are drawn into the new opening, the pole and tree are set at liberty, and if the root be heavy, the tree will resume its former position with but very little assistance. The machine is then loosened from the tree, and removed out of the way; the roots are then laid out carefully, and imbedded in loose soil, well consolidated and watered.



When a machine is made on purpose for removing large trees, the axletree may be made to fit a pair of cart-wheels for a temporary purpose; but the axle should be formed with *straight*, not *drooping*, ends, as they are usually made, because this renders raising the pole much easier. Upon the upper side of the axle there should be a thick block of wood bolted, to give more elevation to the root when drawn along; and on this an old sack, or a thick band of straw, is bound, to prevent chafing the bark of the tree.

Renovation of Decayed Trees.

In favourable circumstances, as respects soil and climate, trees seem to be immortal; but in our own country, these favouring circumstances are afforded on a limited scale, and consequently we can show no trees which are beyond the reach of decay. A time invariably arrives when they begin to show symptoms of decay, and the means to be adopted to prevent, as far as possible, the occurrence of this evil, require now to be noticed. On this delicate and important department of arboriculture we have pleasure in laying before our readers the detail of a process discovered by the late Sir Henry Steuart, communicated in a letter to Admiral Sir T. Livingston, Bart. 'Agreeably to my promise, I shall now give you an idea of my method of reviving or resuscitating old trees, which has often succeeded with myself, and which I have recommended to others; but there is no account given of it in the notes on any treatise on the application of the science of physiology to practical tree-culture, and particularly in removing large trees, for ornament.

The decay of old trees, both in England and Scotland, has been a subject of general complaint during at least a century; and it is observed, with regret, that their place does not promise to be very speedily supplied by existing woods and plantations. The general causes of the decay of trees are twofold: the first proceeds from diseases to which all woody plants are subject; the second from extreme old age, but more frequently from their having exhausted the pabulum within their reach. The pathology of the vegetable tribe, in this respect, differs materially from that of the human species. Among the sons of the forest there are no vicious efforts made by individuals, as among us, by means of disease, to shorten life. There are no gourmands nor sensualists, by fatal indulgences and artificial luxuries, to bring on a premature old age. The laws of nature in trees are allowed fairly to operate, and their existence, therefore, may be reckoned on, and even prolonged by art, to an indefinite period. It has been said that the roots of trees, in a favourable soil, will go abroad in search of their food to a distance from the stem equal to the entire height of the tree, taken from the ground; and wherever this is found to hold good, trees will live to a very great age, especially in a deep and calcareous soil.

Of your two fine old trees at Westquarter, in Stirlingshire, which I lately examined—a holly and a double-flowering thorn—I must say that they appear to me to have declined chiefly from the *latter* of the two causes above-mentioned—namely, their having exhausted the food or pabulum in their immediate neighbourhood; and, in the case of the thorn, in some measure from the ground being overstocked with other plants, that greatly crowd upon it, even to the exclusion of light and air, without which no plant can flourish. As to the holly, it seems stunted and hide-bound, and sends out no free shoots at top, such as a tree in health, in so fine a soil and climate, ought to do. The terminal growths of the thorn, also, have begun to decay; and if some salutary remedy be not speedily adopted to *excite the roots to fresh action*, it is plain that the evil will ere long extend to the greater branches, and, as a necessary consequence, to the trunk itself.

The first thing that I should recommend to be done with this noble thorn is to cut away the ivy that now strongly adheres to it. That parasitical plant has covered nearly the whole external surface of the stem. It already intercepts the kindly influence of the sun and air from the bark of the tree, under which the finer vessels of the descending sap lie, so that it may be said to prey upon the very vitals of the plant. The next object should be to clear the ground, for a considerable space, of overshadowing shrubs and bushes. So venerable a tree standing single would be the most graceful ornament of the verdant turf that surrounded it.

'The second thing that I would do would be to dig a trench round the tree, not exceeding three and a half or four feet out from the stem; which trench should be five feet broad at least, and as deep as to penetrate through both the soil and subsoil, however deep either may be, until you reach the rock, gravel, pure sand, or obdurate clay (*Scotticé*, till) that may lie below. In doing this the workmen may fearlessly cut through all the roots they meet with, leaving only three or four great ones, on the south and south-west sides, to act as *cables* in resisting the severe winds that usually blow from those quarters in every part of the island.

Next, let whatever parts of the trench that consist of good earth, or of earth capable of being easily made so, be thrown aside, and the sand or gravel, if any, be wheeled away; so that you may obtain a depth in the trench of two feet or more, if the soil permit, of well-mixed mould. For this purpose, let good compost or rich garden mould (of which I saw abundance near the spot) be intimately mixed, by two or three times turning, with the better parts of the contents of the trench, adding about a third part of good well-rotted dung, so as that a proper chemical action may be excited throughout the mass, and the whole rendered fit for the food of plants. This done, let the trench be filled up with such compound somewhat higher than the original soil; and let the space which has been left untouched, of four feet out from the stem to the edge of the trench, be covered, eight or nine inches deep, with the same prepared and friable compound, pointing it in with the spade only about three inches deep, so as not materially to injure the roots. In order to complete the process, let all the dead wood be carefully pruned from the branches with a saw—dressing the extremities afterwards with a sharp hedge-bill.

In the following spring, all moss or other impurity should be scraped off the bark, and the entire stem well washed, two or three times during the summer season, with soap and water and a soft brush.

By following the above method, which, however elaborate it may appear in the description, will be very easily reduced to practice, I feel confident that many fine old trees in gentlemen's parks, that are now allowed to decay, might have *another century* added to their existence; because the extension of fresh pabulum at pleasure to greater limits would be a labour well repaid, and attended with little expense, and as little difficulty. There are few persons who would not bestow more labour than this on a favourite tree; and there are perhaps fewer who will not admit that it might easily be applied to purposes of general utility as well as local ornament. The principles on which this process has been instituted are in accordance with the laws of animal as well as vegetable physiology, and will be confirmed by practice, if they be allowed to govern the process. I have uniformly found that the roots, where cut through in the opening of the trench, will send forth an immense body of vigorous ramifications, of from a foot to fifteen inches in length, during the first and second months after the operation, with thousands of capillary rootlets emanating from them; all which will go abroad in search of sap for renovating the vigour of the tree. In a tree of considerable age, such as the two above alluded to at your beautiful place, it is to be observed that much figure cannot be expected to be made during the first year in the elongation of its terminal shoot; and for this plain reason, that effects must necessarily be preceded by their causes, whether they lie on the surface or otherwise; but the leaves will speedily become larger, and of a deeper green colour, than for some years past; and by the autumn of the second year, it will be admitted that the tree is in some sort about *to renew its youth*.

During the early part of the first season, the new mould should be allowed to remain quite undisturbed; but towards the end of the year, the gardener or forester may cautiously look in, and he will observe the wonderful efforts towards the increase of leaves, and, by consequence, towards a fresh supply of sap, that the plant will even then have made. After the second year, the effects of this renovating process will appear still more striking.

Those directions apply equally to both the thorn and the holly at Westquarter, with this difference, that, in consideration of the far greater exposure in which the latter is placed, I should not advise that the trench be opened nearer than within five feet of the stem; also, a greater number of large roots (to act as cables in supporting the tree), say five or six, should be left entire, running across the trench.

The month of February, or beginning of March, according to the season, before the ascending sap begins to stir, would of course be the best time to carry into effect the methods of resuscitation above detailed.'

Coppice.—Live-fences.

Coppice or underwood is either natural or planted. Natural underwoods appear to be the remains of ancient forests, which are kept enclosed, and are felled periodically at long or short intervals, according to the purpose for which the stuff is to be applied. Planted underwoods are either willow holts for the basketmaker, hoops for coopers, hop poles, poles for fencing and hurdle-making, stakes and headers for hedging, broom, hay-rake, and mop handles, spray for birch besoms, fagots for brickmakers and bakers, kindlers, and other firewood, and withes for binding fagots, &c.

Thriving and well-fenced and well-managed underwoods are considered more profitable than timber-woods. The first are very soon a source of income, and as such are subject to tithe, which has caused many acres of them in England to be allowed to grow up into woods, which are free from tithe. But timber and coppice may be united; the standard trees to stand thinly, and if kept pruned up, the undergrowth is not much hurt by their shade. Mixed underwoods are cut every five, seven, or ten years, unless they are entirely of oak, when they are allowed to stand longer, for the sake of having larger poles, together with the bark, which last is a principal part of the value of the fall. When such a fall is made, every superior-looking well-placed pole is left as a standard, if standards be wanting; these at last become fine trees, and are felled in their turn. On the subject of oak coppice, Mr Brown remarks, that the value of the bark has fallen so much of late years, as to render the exclusive growth of this kind of underwood no longer a source of real profit. 'About twenty-five years ago, the price of oak bark was £16 per ton; while this year (1847) the highest price that has been given in Edinburgh is £5, 10s.—making its value at the present time only about one-third of what it was twenty-five years ago, and consequently reducing the value of oak coppice plantations in the same ratio; and upon this consideration, I do think that proprietors should not, at the present time, rear up oak plantations with the intention of converting them into coppice, as has in many instances been done of late. I have seen plantations of healthy oak-trees, about thirty-five years of age, cut down for the sake of the bark they produced, and with the view of converting them into coppice-wood, so as to have a crop of bark every twenty-five years afterwards. Now had those trees which were cut down at thirty-five years of age been allowed to grow for other forty or fifty years, they would of course have attained their full magnitude, and been worth to the proprietor, at the end of that period, more than three times the money that he could get as the produce of the same plants if cut down and disposed of in the form of coppice-wood at periods of twenty-five or thirty years. No doubt where old plantations are cut down, it is right and proper that the stocks of them should be converted into coppice-wood, for this is taking advantage of growths which can be converted into use, and which would otherwise be lost; but to raise up trees to a certain age, and then cut them down prematurely for the sake of their bark, is at best an enormous loss to the proprietor as well as to the country in general.'

The most profitable underwood is that which has been planted, and each sort of tree kept by itself, having regard to the quality of the soil most suitable for each, if there be any difference. For instance, ash and Spanish chestnut should have the driest spots; oak and birch those which are more moist; alder and willow the moistest. All the sorts should be planted very closely together, because this not only increases the length and number, but improves the form of the poles, circumstances which very much add to their value.

The ground should be prepared for underwood in the same manner as for timber-trees, either by the plough or spade. Wet land is usually laid into beds with narrow ditches between, the soil out of which serves to raise the beds, and give the roots more scope. Several wild shrubs introduce themselves among underwood, particularly hazel and hawthorn, neither of which are much objected to, as the first is a useful coppice plant, and the last is always in request about a farm.

Some of our ornamental shrubs arrive at the height of trees, and some of them produce excellent and beautiful timber; such are the cypress, holly, laburnum, and guelder-rose. Large scantlings of the second and third are much prized for veneering.

For live-fences, except in peculiarly bleak and barren situations, hawthorn is the best adapted: care, however, is required both in the planting and trimming. There is a general complaint that thorn hedges do not thrive well; but in most cases the want of success will be found to arise from improper treatment. The preparation of the land for planting hedges requires the greatest care, for if this be not cleared of weeds before the thorns are planted, it will be almost impossible to do it afterwards. Foul land should be well fallowed before the hedge is planted; and it is recommended to plant in the natural soil if it is good; but if poor, it will require to be manured. Old pasture-land should be pared and burned, and the ground otherwise well prepared for the reception of the hedge. If possible, the ground should be trenched to about eighteen inches deep, and four feet in breadth, the surface soil being placed in the bottom of the trench; and this will be found an excellent way of getting rid of weeds. The subsoil, if poor, will not do so much injury on the surface as it would do if left in its natural position; and if opposed to the growth of the thorn, it can be removed. The expense attending a thorough preparation of the soil will be amply repaid by having a clean and well-growing hedge, which is a great ornament to any estate. Indeed so convinced are most landed proprietors of the advantages of a thorough preparation, that the soil is now not only cleaned and trenched, but supplied with a compost of lime and ditch-clearings—a treatment which immensely facilitates the growth of the thorns at the most critical period of their existence. It is in the after-management, however, that the great error generally lies; and were proprietors to impose more stringent obligations upon tenants, or to take the keeping of the live-fences into their own hands, we would have fewer complaints as to the success of the thorn, and a greater degree of rural amenity thrown over the face of the country.

The season for planting depends in some measure on the nature of the ground; for if this be very dry, the planting should take place in the autumn, or early in spring, in order that the plants may have made some root before the heat of summer sets in. The autumn is recommended by some as the best season for planting on all soils, and the month of February by others; but perhaps it is immaterial which period be chosen. If spring is the time fixed upon, it should be as early as possible, so that the plants may not have made any progress in vegetation before transplanting. There are various modes of planting hedges, some preferring the even ground, others forming a mound, with a ditch at one side, and planting either at the top or on a shelf in the side of the mound; others, again, making a ditch on each side of the mound. If the land be good and dry, the hawthorn will grow quite well upon the level ground; but if the soil be of a wet nature, either one or two ditches will be required. In the former case, the land taken up with the fence will not be more than two and a half or three feet; while in the latter not less than eight will be entirely lost to the plough. The most common mode throughout the country, however, is ditch and hedge; the earth taken from the ditch forming the mound upon which the thorns are planted. Some prefer planting on the top of the mound, others on the slope; and when the last method is adopted, care should be taken not to put the plants too far down the ditch, which may prevent them from getting the necessary light and air. The hawthorn does not naturally sink deep into the ground, its roots rather spreading to a distance near the surface. A stunted hedge will generally be found to be overloaded with earth at the roots, while a free-growing and vigorous hedge has been allowed in some measure to follow its own natural habit. The thorns should be planted at the distance of about three or four inches apart, and about the same depth as they stood in the seed-bed. Some cut the plants before they are put in, others cut them after they are planted, to insure regularity; but this is an immaterial point, as the after-cutting will make the hedge uniform. The plants should then be covered with the finest mould, the points little more than projecting from the front of the mound. If the land is in tillage when the thorns are planted, and to remain so for some time, it will not be necessary to raise a fence for their protection; but if cattle are to graze upon it, this precaution must be taken, to prevent them from eating the buds.

After being planted, the ground should be carefully gone over two or three times a year, to cut up weeds. This operation must be performed until the plants have reached some height, and the weeds are completely eradicated, after which the usual cleaning at the roots once a year will be quite sufficient. The plants should never be cut till after three years old, for if cut when younger than this, the hedge is stunted, and never so healthy. The operation of pruning or cutting is frequently intrusted by landlords to their tenants, who seldom perform it in that efficient way in which it ought to be done. Hawthorn hedges, when well planted in good soils, will grow, even if they should be improperly pruned; but in poor soils and exposed situations they cannot thrive under the negligent treatment they are frequently subjected to. When a sufficient number of branches can once be made to rise from the bottom of the main stem, either in the first or second year, the main stem should never be cut until it has attained a considerable strength, which will generally be in the third or fourth year.

When hedges get bare and thin at the bottom, they ought either to be cut over by the root, or to have their sides dressed up close to the principal stems. In cutting off the side branches, it is advisable to make one or more notches in the main stem, by the hatchet, one stroke up, and the other down, so as to take out a piece of wood about half the thickness of the stem. By this method young shoots come out in great abundance immediately below the notch, which may be made at any height; and a complete and impervious hedge is formed much sooner than by cutting the stem over by the roots. There is another method of repairing thorn hedges, which is called *plashing*. It consists in cutting half through the stems adjoining the gap to be repaired, and then bending the upper portion over the vacancy, fastening them down by stakes, or by warping them into each other. By this means a live hedge is formed more speedily than by planting young shoots, and more effectually than by inserting dead branches. The bent stems soon send out shoots; and if the plashing has been done with care, and that on moderately young and pliant branches, it will be found to be a cheap, and, on the whole, a very efficient system.

When thorn hedges are cut too close by the ground, the decayed stocks should not only be taken out, but the earth where the stocks stood should be removed also, and replaced with good fresh soil, in which thorns have never previously grown. The thorn plants intended for filling up blanks should be carefully selected from such as have been transplanted two or three years, have stood thin in the nursery bed, are well rooted, and free growers. It is likewise advisable in all cases to set the young plants into the vacancies, with their tops entire, as they stood in the nursery ground, and not to be cut, as is too frequently the practice. Particular attention should also be paid to keeping their roots moist before planting; and when planted, the earth should be kept low round the stems, so that moisture may be drawn towards them, until the roots are firmly established in the soil. When either crab or beech plants are used for filling gaps in thorn hedges, it is not necessary to remove the earth as for thorn plants, but it should be well loosened and pulverised; and when the plants are set, a hollow space should be left round the bottom of the stems, as recommended for thorn transplants.

In high exposed situations, having thin moorish soils, or on hilly land composed of decomposed granite, thorn hedges are seldom if ever found to thrive. In such situations, the beech has proved itself superior to every other plant, either as an assistant or a substitute for thorns. It retains possession of the soil, and continues to thrive when thorns decay or die out; and when regularly and judiciously cropped, it forms a compact fence, which few animals will attempt to break through. Indeed experience has proved that, as a hedge plant, the beech will thrive in any climate or soil; and what is of essential importance, it retains its leaves during winter, giving a genial warmth and shelter, besides being highly ornamental.

A very durable hedge for high situations with a light soil, may be formed by an admixture of thorn and beech plants in the proportion of two of the former to one of the latter. Such a fence not only looks well, but lasts well, if trimmed with due care and regularity. Latterly, furze or whins have been employed with much advantage as fences; but this hardy native shrub will grow only where there is great freedom of air, and succeeds best in northern climates.

Many other shrubs and trees are used in live-fencing; but more for garden and ornamental than for field purposes. Among the most common of these are the holly, the privet, the sweetbrier, the yew, and the *Pyrus japonica*, all of which bear pruning and training almost to any degree. The thorn has also been occasionally trusted after the Dutch fashion — that is, training it along stakes, and keeping the hedge at a thickness of six or eight inches; but as shelter is as much the object of the British landholder as enclosure, this mode is not likely ever to be extensively followed.

In training any sort of hedge, attention should be paid to the form and manner of cutting. Main stems or trunks should always be cut upwards, and never by a descending blow of the hedge-bill, as the latter produces a jagged and splintery wound, which causes the wood to die much farther down than the up cut. Young shoots will spring from the very verge of an up cut; they never spring within several inches of, nor so readily from, a cut in the opposite direction. In cutting hedges for field use, all fantastic forms should be avoided, and the easiest and most effective shape preserved. Straight or slightly-inclining sides, with a tapering or pointed top, is the easiest form, and the one best adapted to the growth of the shrub. Rounded or pyramidal forms are not economical, as they require longer time for their execution; straight sides with square tops should never be allowed, as snow lodges on the top, and splits up the hedge when the load accumulates. Fantastic forms require not only more time from the hedger, but are injurious to the plant, and nothing looks so ill when badly executed. Hinds and common labourers ought never to be permitted to wield a hedge-bill; a thorough-trained hedger or forester should alone be employed.

THE HORSE.

The horse is universally acknowledged to be one of the noblest members of the Animal Kingdom. Possessing the finest symmetry, and unencumbered by those external appendages which characterise many of the larger quadrupeds, his frame is a perfect model of elegance and concentrated energy. Highly sensitive, yet exceedingly tractable, proud, yet persevering, naturally of a roaming disposition, yet readily accommodating himself to domestic conditions, he has been one of the most valuable aids to human civilisation—associating with man in all phases of his progress, from the temporary tent to the permanent city.

In ordinary systems of zoology the horse is classed with the *Pachyderms*, or thick-skinned animals—as the elephant, tapir, hog, hippopotamus, and rhinoceros. Differing from the rest of the class in many respects, he has been taken as the representative of a distinct family, known by the name of *Equidæ* (*equus*, a horse), which embraces the horse, ass, zebra, quagga, onagga, and dzeggetai. All these animals have solid hoofs, are destitute of horns, have moderately-sized ears, are less or more furnished with manes, and have their tails either partially or entirely covered with long hair. The family may, with little impropriety, be divided into two sections—the one comprehending the horse and its varieties, and the other the ass, zebra, and remaining members. In the former, the tail is adorned with long flowing hair, the mane is also long and flowing, and the fetlocks are bushy; the latter have the tail only tipped with long hair, the mane erect, and the legs smooth and naked. The colours of the horse have a tendency to *dapple*—that is, to arrange themselves in rounded spots on a common ground; in the ass, zebra, and other genera, the colours are disposed in stripes or bands more or less parallel.

By his physical structure, the horse is fitted for dry open plains that yield a short sweet herbage. His hoof is not adapted to the swamp; and though he may occasionally be seen browsing on tender shoots, yet he could subsist neither in the jungle nor in the forest. His lips and teeth, however, are admirably formed for cropping the shortest grass, and thus he luxuriates where many other herbivorous animals would starve, provided he be supplied with water, of which he is at all times a liberal drinker. Delighting in the river-plain and open glade, the savannas of America, the steppes of Asia, and the plains of Europe, must be regarded as his head-quarters in a wild state. There is doubt expressed, however, as to the original locality of the horse. The wild herds of America are looked upon as the descendants of Spanish breeds imported by the first conquerors of that continent; those of the Ukraine, in Europe, are said to be the progeny of Russian horses abandoned after the siege of Azoph in 1696; and even those of Tartary are regarded as coming from a more southern stock. Naturalists, therefore, look to the countries bordering on Egypt as in all likelihood the primitive place of residence of this noble animal; and there is no doubt that the Arabian breed, when perfectly pure, presents the finest specimen of a horse in symmetry, docility, and courage. Regarding the horse as of Asiatic origin, we now find him associated with man in almost every region of the habitable globe. Like the dog, ox, sheep, and a few others of the brute creation, he seems capable of accommodating himself to very different conditions; and assumes a shaggy coat or a sleek skin, a size little inferior to that of the elephant, or not larger than that of an English mastiff, just as circumstances of climate and food require.

In a state of nature, the horse loves to herd with his fellows; and droves of from four to five hundred, or even double that number, are not unfrequently seen, if the range be wide and fertile. The members of these vast droves are inoffensive in their habits, and when not startled or hunted, are rather playful and frolicsome; now scouring the plain in groups for mere amusement, now suddenly stopping, pawing the soil, then snorting, and off straight as an arrow, or wheeling in circles, making the ground shake with their wild merriment. It is impossible to conceive a more animated picture than a group of wild horses at play. Their fine figures are thrown into a thousand attitudes; and as they rear, curvette, dilate the nostril, paw in quivering nervousness to begin the race, or speed away with erect mane and flowing tail, they present forms of life and energy which the painter may strive in vain to imitate. They seldom shift their stations, unless compelled by failure of pasture or water; and thus they acquire a boldness and confidence in their haunts which it is rather unsafe to disturb. They never attack other animals, however, but always act upon the defensive. Having pastured, they retire either to the confines of the forest, or to some elevated portion of the plain, and recline on the sward, or hang listlessly on their legs for hours together. One or more of their number are always awake, to keep watch while the rest are asleep, and to warn them of approaching danger, which is done by snorting loudly, or neighing. Upon this signal the whole troop start to their feet, and either reconnoitre the enemy, or fly off with the swiftness of the wind, followed by the sentinel and by the older stallions. They are seldom to be taken by surprise; but if attacked, the assailant seldom comes off victorious, for the whole troop unite in defence of their comrades, and either tear him to pieces with their teeth, or kick him to death.

There is a remarkable difference in the dispositions of the Asiatic and South American wild horses. Those of the former continent can never be properly tamed, unless trained very young, but frequently break out into violent fits of rage in after-life, exhibiting every mark of natural wildness; while those of America can be brought to perfect obedience, and even rendered somewhat docile, within a few weeks, nay, sometimes days. It is difficult to account for this difference in temper, unless we suppose that it is caused by climate, or rather by the transmission of domesticated peculiarities from the original Spanish stock.

SUBJUGATION AND DOMESTICATION.

As in South America we have the most numerous herds, and the most extensive plains for their pasture, so it is there that the catching and subduing of the wild horse presents one of the most daring and exciting engagements. If an additional horse is wanted, a wild one is either hunted down with the assistance of a trained animal and the *lasso*, or a herd are driven into a *corral* (a space enclosed with rough posts), and one selected from the number. The latter mode is spiritedly described by Miers, whose account we transcribe, premising that a *lasso* is a strong plaited thong, about forty feet in length, rendered supple by grease, and having a noose at the end:—' The corral was quite full of horses, most of which were young ones about two or three years old. The chief guacho (native inhabitants of the plains are called peons or guachos), mounted on a strong steady animal, rode into the enclosure, and threw his lasso over the neck of a young horse, and dragged him to the gate. For some time he was very unwilling to leave his comrades, but the moment he was out of the corral, his first idea was to gallop off; however, a timely jerk of the lasso checked him in the most effectual way. The peons now ran after him on foot, and threw a lasso over his fore-legs, just above the fetlock, and twitching it, they pulled his legs from under him so suddenly, that I really thought the fall he had got had killed him. In an instant a guacho was seated on his head, and with his long knife cut off the whole of the mane, while another cut the hair from the end of his tail. This they told me was a mark that the horse had once been mounted. They then put a piece of hide in his mouth, to serve for a bit, and a strong hide halter on his head. The guacho who was to mount arranged his spurs, which were unusually long and sharp; and while two men held the horse by the ears, he put on the saddle, which he girthed extremely tight. He then caught hold of the animal's ear, and in an instant vaulted into the saddle, upon which the men who held the halter threw the end to the rider, and from that moment no one seemed to take any further notice of him. The horse instantly began to jump in a manner which made it very difficult for the rider to keep his seat, and quite different from the kick or plunge of our English steed: however, the guacho's spurs soon set him agoing, and off he galjopped, doing everything in his power to throw his rider.

Another horse was immediately brought from the corral, and so quick was the operation, that twelve guachos were mounted in a space which I think hardly exceeded an hour. It was wonderful to see the different manner in which different horses behaved. Some would actually scream while the guachos were girthing the saddle upon their backs; some would instantly lie down and roll upon it; while some would stand without being held, their legs stiff, and in unnatural positions, their necks half bent towards their tails, and looking vicious and obstinate; and I could not help thinking that I would not have mounted one of those for any reward that could be offered me, for they were invariably the most difficult to subdue.

It was now curious to look around and see the guachos on the horizon in different directions, trying to bring their horses back to the corral, which is the most difficult part of their work; for the poor creatures had been so scared there, that they were unwilling to return to the place. It was amusing to see the antics of the horses; they were jumping and dancing in various ways, while the right arm of the guachos was seen flogging them. At last they brought the horses back, apparently subdued and broken in. The saddles and bridles were taken off, and the animals trotted towards the corral, neighing to one another.'

To hunt down the horse in the open plain requires still greater address, and greater strength of arm. According to Captain Hall, the guacho first mounts a steed which has been accustomed to the sport, and gallops him over the plain in the direction of the wild herd, and circling round, endeavours to get close to such a one as he thinks will answer his purpose. As soon as he has approached sufficiently near, the lasso is thrown round the two hind-legs, and as the guacho rides a little on one side, the jerk pulls the entangled horse's feet laterally, so as to throw him on his side, without endangering his knees or his face. Before the horse can recover the shock, the hunter dismounts, and snatching his *poncho*, or cloak, from his shoulders, wraps it round the prostrate animal's head. He then forces into his mouth one of the powerful bridles of the country, straps a saddle on his back, and bestriding him, removes the poncho, upon which the astonished horse springs on his legs, and endeavours, by a thousand vain efforts, to disencumber himself of his new master, who sits composedly on his back, and by a discipline which never fails, reduces the animal to such complete obedience, that he is soon trained to lend his whole speed and strength to the capture of his companions.

The subduing of wild specimens in America, the Ukraine, Tartary, and other regions, must be regarded as merely supplementary to that domestication which the horse has undergone from the remotest antiquity. A wild adult may be subjugated, but can never be thoroughly trained; even the foal of a wild mother, though taught with the greatest care from the day of its birth, is found to be inferior to domestic progeny in point of steadiness and intelligence. Parents, it would seem, transmit to their offspring mental susceptibility as well as corporeal symmetry; and thus, to form a just estimate of equine qualities, we must look to the domesticated breeds of civilised nations. At what period the horse was first subjected to the purposes of man we have no authentic record. Trimmed and decorated chargers appear on Egyptian monuments more than four thousand years old; and on sculptures equally, if not more ancient, along the banks of the Euphrates. One of the oldest books of Scripture contains the most powerful description of the war-horse; Joseph gave the Egyptians bread in exchange for horses; and the people of Israel are said to have gone out under Joshua against hosts armed with 'horses and chariots very many.' At a later date, Solomon is said to have obtained 'horses out of Egypt, and out of all lands,' and to have had 'four thousand stalls for horses and chariots, and twelve thousand horsemen.' Thus we find that in the plains of the Euphrates, Nile, and Jordan, the horse was early the associate of man, bearing him with rapidity from place to place, and aiding in the carnage and tumult of battle. He does not appear, however, to have been employed in the useful arts of agriculture and commerce; these supposed drudgeries being imposed on the more patient ox, ass, and camel. Even in refined Greece and Rome, he was merely yoked to the war-chariot, placed under the saddle of the soldier, or trained for the race-course.

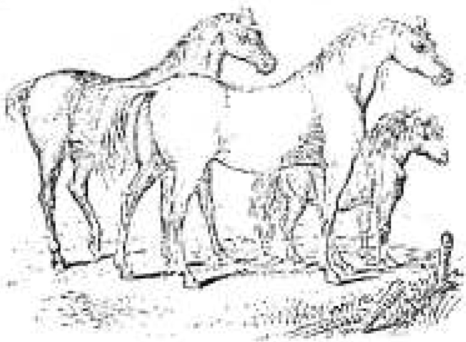
As civilisation spread westward over Europe, the demands upon the strength and endurance of the horse were multiplied, and in time he was called upon to lend his shoulder indiscriminately to the carriage and wagon, to the mill, plough, and other implements of husbandry. It is in this servant-of-all-work capacity that we must now regard him; and certainly a more docile, steady, and willing assistant it would be impossible to find. But it is evident that the ponderous shoulder and firm step necessary for the wagon would not be exactly the thing for the mail-coach; nor would the slow and steady draught, so valuable in the plough, be any recommendation to the hunter or roadster. For these varied purposes men have selected different stocks, which either exist naturally, or have been produced by a long-continued and careful system of breeding. In a state of nature, the horse assumes various qualities in point of symmetry, size, strength, and fleetness, according to the conditions of soil, food, and climate which he enjoys. It is thus that we have the Arabian, Tartar, Ukraine, Shetland, and other stocks, each differing so widely from the others, that the merest novice could not possibly confound them. Besides these primitive stocks, a thousand *breeds*, as they are called, have been produced by domestication, so that at the present time it would require volumes even for their enumeration. In our own country, for example, we have such breeds as the Flanders, Norman, Cleveland, Suffolk, Galloway, Clydesdale, and Shetland; and of these numerous varieties, as may be required for the turf, the road, the cart, or the carriage. All this exhibits the wonderful ductility of the horse, and proves how admirably he is adapted to be the companion and assistant of man, as the latter spreads himself over the tenantable regions of the globe. It is to the character, training, and management of the horse thus domesticated that we devote the following pages.

DOMESTICATED VARIETIES.

Horses exist, as we have said, in numerous varieties, distinguishable by size, strength, colour, and other qualifications, the result most likely of peculiarities of climate, food, and artificial treatment. The following is a brief notice of the leading varieties or breeds now common in Britain:—

The Arabian.

The Arabian horse is considered to occupy the highest rank among the numerous cultivated varieties, and embodies that qualification in its purest condition known by the term *thorough-bred*. The pure Arabians are somewhat smaller than our race-horses, seldom exceeding fourteen hands two inches in height. Their heads are very beautiful, clean, and wide between the jaws; the forehead is broad and square; the face flat; the muzzle short and fine; the eyes prominent and brilliant; the ears small and handsome; the nostrils large and open; the skin of the head thin, through which may be distinctly traced the whole veins of the head. The body may, as a whole, be considered too light, and the breast rather narrow; but behind the arms, the chest generally swells out greatly, leaving ample room for the lungs to play. The shoulder is superior to that of any other breed; the scapulæ, or shoulder-blades, incline backwards, nearly in an angle of 45 degrees; the withers are high and arched; the neck beautifully curved, and the mane and tail long, thin, and flowing; the legs are fine, thin, and wiry, with the pasterns placed somewhat oblique, which has led some to suppose that the strength was thereby lessened, which is by no means the case; the bone is of uncommon density, and the prominent muscles of the fore-arm and thigh prove that the Arabian is fully equal to all that has been said of his physical powers.



English Hunter—Arabian—Shetland Pony.

The Arabs of the Desert have made the breeding of horses their sole occupation for ages bygone; and from their strict attention to certain rules, they may be justly regarded as the first breeders in the world. They take infinite trouble in grooming their steeds, and are extremely regular in their hours of feeding them morning and evening. They get but little drink, and that is supplied to them two or three times a day; they conceive that much water not only destroys their shape, but also affects their breathing. In spring, they are pastured on dry aromatic herbage; and during the rest of the year they are fed on barley, with a small quantity of straw; and they are the hardiest horses in the world. The Arab trains his horse by kindness, and never on any occasion strikes it; the consequence is, that the animal shows a degree of affection and tractability in which most British horses are quite deficient. The pure Arab horse is employed only for riding, and possesses great fleetness.

The following interesting account of the hardihood of the Arabian is given by M. Chateaubriand, in his travels in Greece:—'They are never put under shelter, but left exposed to the most intense heat of the sun, tied by all four legs to stakes driven in the ground, so that they cannot stir. The saddle is now taken from their backs. They frequently drink but once, and have only one feed of barley in twenty-four hours. This rigid treatment, so far from wearing them out, gives them sobriety and speed. I have often admired an Arabian steed thus tied down to the burning sands, his hair loosely flowing, his head bowed between his legs, to find a little shade, and stealing with his wild eye an oblique glance of his master. Release his legs from the shackles, spring upon his back, and he will "paw in the valley, he will rejoice in his strength, he will swallow the ground in the fierceness of his rage;" and you recognise the original picture as drawn by Job.'

The Arabs are exceedingly particular regarding the pedigree of their horses; and they have amongst them a breed which they declare has descended from a horse of King Solomon. It must not, however, be supposed that all the horses of that country are of the finer kinds; for the Arabs have three distinct breeds: the two inferior kinds, they allege, were introduced from India and Greece. The superior kinds they call nobles; and they are never sold without a pedigree, which is most scrupulously attended to.

The British Racer.

The British race-horse is a cultivated breed, originally sprung from the Arabian, and to which is traced the quality of being *thorough-bred*. The skins of race-horses are delicate, with short hair, usually tending to the bright brown or bay generally characteristic of the horses of the East, and sometimes to the gray, prevalent likewise amongst the Arabs and Barbs. They are frequently chestnut, which may be looked upon as a mixture of the dun or tan colour of some of the races of Northern Europe with the finer brown or bay; and sometimes, though very rarely, they are of the bright black common to the great horses of the plains of Germany. They are of medium height, rarely exceeding fifteen hands. Their form is that which an almost exclusive attention to the property of speed has tended to produce. They have the broad forehead, the brilliant eyes, the delicate muzzle, the expanded nostrils, and the wide throat, characteristic of their Eastern progenitors. Their light body is comparatively long, and suited to the extended stride. Their chest is deep, so as to give due space to the lungs, but comparatively narrow, preventing the fore extremities from being overloaded, and the limbs from being thrown too far asunder in the gallop. Their shoulder is oblique, to give freedom of motion to the humerus; and their haunch is long and deep, beyond that of any other known race of horses, indicating the length of those bones of the hinder extremities on which the power of progression essentially depends. Their limbs are long and muscular to the knee and hock, and below tendinous and delicate; and their pasterns being long and oblique, give elasticity to the limbs.

The pedigree of race-horses is always a matter of consequence to the breeder and purchaser of these animals, and is preserved with the same degree of care as the genealogy of many a noble family. By jockeys and others, therefore, a list or stud-book is kept of the sires and dams of their horses, which can be exhibited if required. The pedigree of many fine racers of the present day is traced through stud-books to the Darley Arabian, a horse purchased by a Mr Darley at Aleppo, from which it was imported to England. One of its immediate descendants was the celebrated Flying Childers, bred by Mr Childers of Carr-House. This beautiful racer is reputed to have been the fleetest runner ever known in England, or perhaps in the world. On one occasion he ran (carrying nine stones two pounds) round the course at Newmarket—which measures 3 miles, 6 furlongs, and 93 yards—in six minutes and forty seconds.

Horse-racing—which, in the opinion of competent judges, is unnecessary, as far as keeping up serviceable breeds of horses is concerned—is usually spoken of as the *turf*, from its being performed on stretches of turf-ground at Newmarket, Epsom, and various other places. Among an idle, and in many instances a profligate class of persons, this *sport*, as it is termed, affords scope for a most extensive system of fraud, betting, gambling, and general dissoluteness of behaviour; in a word, this cruel pastime may be described as a great canker lying at the root of society in England; and, countenanced by the high in rank, is at the present moment not the least effective of the many drags on social advancement.

Hunters—Saddle-Horses.

The hunter is a combination of the thorough-bred race-horse and half-bred horses of greater strength and bone; but changes are continually taking place in its character. The older race of hunters has been giving place to one of lighter form and higher breeding, and even the thorough-bred horse is now employed by numerous sportsmen. In his improved state, the hunter may rank as a saddle-horse of the first class, combining strength with fleetness. The prime qualities of a hunter may be briefly summed up—head small, neck thin, crest firm and arched, a light mouth, broad chest, body short and compact, the hocks well bent, power behind to push him over difficulties, and broad well-made feet turned outward. He is prepared for his duties by physic, air, and exercise. To do him justice, the hunter should not work above three days a week; and after a hard day's run, he ought certainly to have two or three days of rest. We cordially coincide in the following remarks of Mr Youatt on the cruelty of abusing this noble animal:—'It is very conceivable, and does sometimes happen, that, entering as fully as his master into the sports of the day, the horse disdains to yield to fatigue, and voluntarily presses on until nature is exhausted, and he falls and dies; but much oftener the poor animal has intelligibly enough hinted his distress: unwilling to give in, yet painfully and falteringly holding on. The merciless rider, rather than give up one hour's enjoyment, tortures him with whip and spur until he drops and expires. Although the hunter may be unwilling to relinquish the chase, he who "is merciful to his beast" will soon recognise the symptoms of excessive and dangerous distress. To the drooping pace, and staggering gait, and heaving flank, and heavy bearing on hand, will be added a very peculiar noise. The inexperienced person will fancy it to be the beating of the heart; but that has almost ceased to beat, and the lungs are becoming gorged with blood. It is the convulsive motion of the muscles of the belly, called into violent action to assist in the laborious office of breathing. The man who proceeds a single mile after this, ought to suffer the punishment he is inflicting.' The charger or cavalry-horse partakes of the qualities of the hunter—great strength and spirit, without which he would be unable to endure the toil of warfare in a rough country.

The proper kind of saddle-horse is only a variety of the hunter, possessing less or more *blood*, according to the nature of the work required of him, and the taste of the breeder. Of the great varieties of saddle-horses, there may be said to be a chain of connection, as respects spirit and form, from the racer to the cart-horse; and therefore the station which any individual occupies is almost undefinable. The saddle-horses of England are celebrated for their beauty and action; and nowhere are seen so many of elegant forms as in London. Latterly, the breeds have been tending to greater lightness, the state of the roads not now requiring the strength of limb which was at one time necessary.

Coach-Horses—Hackneys.

The better kind of coach-horses owe their origin to the Cleveland bay, and are principally bred in Yorkshire, Durham, and the southern districts of Northumberland, and some few have been produced in Lincolnshire. The coach-horse is produced by a cross of the Cleveland mare with a three-fourth or thorough-bred horse, which is possessed of sufficient substance and height. The produce of these is the coach-horse of the highest repute, and most likely to possess good action. His points are advantageously placed, with a deep and well-proportioned body, strong and clean bone under the knee, and his feet open, sound, and tough. He possesses a fine knee action, lifts his feet high, which gives an elegance to his paces and action: he carries his head well, and has a fine elevated crest. The full-sized coach-horse is, in fact, only an overgrown hunter, too large for that sport. The carriage-horse, reduced to drawing stage-coaches, is generally used in a very disgraceful manner. Urged with a heavy draught to the height of his speed, almost incessantly wrought, whipped unmercifully, and poorly groomed, his fate is often melancholy in the extreme. It ought to be recollected, that in proportion as the load or draught is increased, so is the animal's power of speed lessened; and therefore to make him both draw a heavy weight and run also, is to put him beyond his natural powers, and his muscular energy suffers accordingly. We shall afterwards advert to the principles which ought to regulate both draught and speed.

The term *Hackney*, in common use, is employed to denote a kind of horse fitted for general services, and is therefore understood to exclude the horses of the highest breeding, as the thorough-bred horse and hunter; and there is further associated with the idea of a hackney, an animal of moderate size, not exceeding fifteen hands, and possessing action, strength, and temper. Our present breed of hackneys have a considerable portion of racing blood in them, varying from a half to seven-eighths. The latter are too highly bred for the general purpose of a roadster, as their legs and feet are rather tender; and their long paces and straight-kneed action are ill adapted for the road, being more fitted for cantering and running than the trot, which is the distinguishing characteristic of a good hackney. Indeed they should never be permitted to go at any other pace than a trot, which is undoubtedly much better adapted for the road than for cantering.

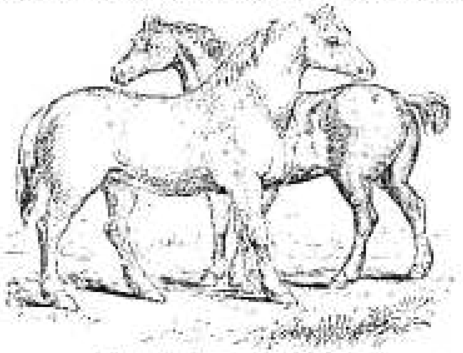
Nothing is more essential in a hackney than sound strong fore-legs, and also well-formed hind ones; his feet must be quite sound, and free from corns, to which hard-ridden horses are very liable; and he ought only to lift his fore-legs moderately high. Some are of opinion that he cannot lift them too high, and conceive, while he is possessed of this quality, he never will come down. There is a medium, however, in this, as a horse that raises his fore-legs too high in trotting is always disagreeable in his action, which greatly shakes and fatigues the rider; besides, he batters his hoofs to pieces in a few years. The principal thing to be attended to is the manner in which the hackney puts his feet to the ground; for if his toes first touch the road, he is sure to be a stumbler. The foot should come flat down on the whole sole at once, otherwise the horse is not to be depended upon in his trotting. A hackney should be particularly even-tempered, and not given to starting. The thorough-bred hackney ought to possess two qualities, indispensable to the safety of the rider—he should never shy at anything on the road, and his motion at a trot should be much more smooth than that of a half-bred horse.

The Cart or Draught-Horse.

The cart-horses of Great Britain are extremely variable in point of size as well as in shape, differing in almost every county. One principal character, however, is weight, to give more physical force in the draught. They should not be above sixteen hands high, with a light well-shaped head and neck, short pointed ears, with brisk sparkling eyes: their chests should be full and deep, with large and strong shoulders, but rather low in front than otherwise. The back should be straight, and rather long, but not too much so, as this always impairs his general strength; the animal should stand wide on all his four legs, and considerably wider behind than before; he ought to have great pliability in the knee-joints, and be able to bend them well, which assist in producing a brisk and active step in walking, a quality of much consequence in a cart or wagon-horse. The height to be desired in a draught-horse, however, will depend upon the purpose for which he is to be employed.

In the midland counties of England—Warwickshire, Derbyshire, Leicestershire, Lincolnshire, and Nottinghamshire—there is a very large breed, called the great cart-horse. It was bred in the lowland rich alluvial pastures of the plains of these counties, from the Flemish and Dutch horses, with the larger English breed. Mr Bakewell introduced horses, and also mares, from the Netherlands, and thus produced those fine animals with Belgic blood both on the side of the sire and dam. The very large horses of seventeen hands and upwards are only useful for the purposes of brewers' drays, wagons, and the slop-carts of London. It is, however, doubted if they answer the better for their gigantic size; and all who have written on the subject, consider that they are inferior in point of strength, on account of their bulk; for by the feeding which is required to increase their dimensions, little of muscular fibre is produced, the growth being principally in the cellular tissue and fat; and the additional quantity of food required to keep up their system must more than counterbalance any advantage to be reaped from their size.

Latterly, considerable pains have been taken to improve the qualities of ordinary cart-horses, among which we include those required in agriculture. A breed called the Clydesdale is highly valued for either cart



Clydesdale Horse—Suffolk Punch.

or plough. Animals of the Clydesdale breed reach to a large size, and are not unfrequently to be met with sixteen and a half hands high. These animals are strong and hardy, but their heads are somewhat coarse, and they are rather flat on the sides and hinder quarters. The usual colour of these horses is gray or brown. This breed is supposed to have originated about one hundred and thirty years ago, between the common Scotch mare and the Flanders horse. As a breed, the Clydesdale is rapidly rising in estimation, and is now undergoing considerable modifications and improvements chiefly for farm purposes.

Ponies.

A horse beneath thirteen hands is called a pony, but this definition is not very strictly attended to, and the same thing may be said of the *galloway*. The old Scottish galloways, which took their name from the district of Galloway, in the south-western extremity of the country, are now nearly extinct. They were stout, compact animals, sure-footed, and of great endurance, and on these accounts invaluable in travelling over rugged and mountainous districts. The beauty and speed of the galloway were supposed to have arisen from the breed having been the produce of the Spanish jennets that escaped from the wreck of the Spanish armada; and these, crossed with our Scottish horses, gave rise to this esteemed breed. But we apprehend they were famous at a date long prior to that event, as this district is known to have supplied Edward I. with great numbers of horses. This breed seldom exceeded fourteen hands in height: their colour was generally bright bay or brown, with black legs, small head and neck, and their legs peculiarly deep and clean. A compact stout-built pony, of from thirteen to fourteen hands high, and possessing some of the qualifications of the galloway, is called *a cob*, which is valuable as a steady pacer, at an easy rate.

The small ponies of the Highlands of Scotland and Shetland (usually called *shelties*) may almost be termed wild animals; for they go at large in herds on the hills and wastes, and are not shod till caught and put into training. They are docile and tractable, and being very sure-footed, are the best adapted for boys' riding. The Welsh pony is more handsomely formed than that of Shetland; has a small head, high withers, deep round body, and excellent feet. The Exmoor and Dartmoor ponies are also a hardy sure-footed race, well adapted for riding in wild districts. The ponies of Norway and Sweden, which are of a dingy cream colour, and of which there are now occasional importations to Britain, are considerably larger than the Shetland or Welsh breeds, but also hardy and very docile.

REARING OF HORSES.

The breeding and rearing of horses are carried on professionally in England; chiefly in Yorkshire; but many private gentlemen and farmers also address themselves to it as a means of pecuniary profit and the improvement of their animal stock. We do not pretend here to offer any specific directions on this branch of our subject, it being one in which the public at large are not particularly interested; and a few observations seem all that is necessary.

The circumstance which the breeder of horses requires to keep most in mind is, that the qualities, good or bad, of the animal are hereditary. Finely-made horses produce finely-made descendants, and *vice versâ*: heavy cart-horses never produce animals possessing the qualities of racers. Thus the bone, blood, and general make are directly transmissible; and, in the case of crossing, the produce is found to possess a proportional share of both sire and dam. Cross-breeding between extremely different horses is not found advantageous: it is a generally recognised principle that the nearer the resemblance between the parents, so will the produce be more satisfactory. Mr Smith, in his 'Observations on Breeding for the Turf,' remarks, that 'the stock of some mares will frequently partake most of the dam, and that of others most of the sire; and sometimes one foal will partake most of the mare, and the next perhaps most of the horse, &c. It also occasionally happens that the produce bears some resemblance to its grandsire, grandam, or other distant kindred; and although this does not perhaps often occur, so as to be very perceptible, yet as their qualities must, in a lesser or greater degree, descend to their progeny, it has always had its due weight; hence the value and partiality to blood, or ancestral excellences, transmitted through many generations.' He further observes, however, 'that he is disposed to attribute more in general to the dam than to the sire, inasmuch as he is decidedly of opinion that a good mare put to the worst thorough-bred horse would be much more likely to produce a runner, than a bad mare put to the most fashionable stallion in England; and therefore a person possessing good mares may bring any stallion into repute.' The grand aim of the breeder must be the propagating of excellences, and avoiding defects; but this is not to be accomplished, as respects important alterations, all at once; improvements in this, as in everything else, being the work of time and a judicious experience. Breeding *in-and-in*, as it is called, or between close relationships, is decidedly pernicious, and should by all means be avoided.

The season for mares is about February and March, but in some cases it continues later; and the term of gestation is generally over eleven months. The foal remains with the mother till weaned, which takes place earlier or later, according to the quantity of milk, the strength of the animals, and the season of the year. On removal, it requires to be carefully attended to, and provided with soft nourishing diet. Few things contribute more to the health and perfection of young horses than a sweet, sound, and hard-bottomed pasture range.

The operation of cutting is seldom performed on thorough-bred colts, but with all others it is common. It is an operation which ought by all means to be left to the veterinary surgeon or skilful farrier. The best authorities recommend it to take place with young cart-horses when four or five months old, but if for carriage or light work, it may very properly be postponed till the animal is twelve months old. The use of the operation is to render the horse more submissive than if left in an entire state, and to devote him altogether to the work he is required to perform. The advantages, whatever they are, are in some measure lessened by the lowering of spirit. The practice, however, is universally recognised in Britain, as one indispensable where numbers of horses are congregated, and required to be kept in good condition.

Breaking, or reducing the young animal to obedience, is a most important point in the education of the horse. If previously accustomed to handling, the difficulty of breaking will be much lessened. Racing colts are now begun to be broken at one year old, and saddle colts at two years, and are finally and fully broken and trained, some at three, and few later than four years old. Breaking horses is a regular business, and is best left to the person who is well accustomed to it, provided he follow a judicious course of treatment. As in the training of children, gentleness, yet firmness, ought to be a prevailing principle of management. The chief apparatus of breaking is a powerful bridle or head-tackle, with boots or pads strapped on the legs, to prevent them knocking against each other. The young horse is to a certain extent trained before his back is mounted; all the preliminary part of the process of subduing being accomplished while he is led by the bitted tackle. His back is not to be mounted till he is evidently able to endure the load without injury to his figure; too early mounting is apt to make him hollow-backed for life. In putting on a saddle for the first time, great caution should be taken; let the girths be drawn loosely, the crupper smooth, and keep the stirrups from dangling. In short, the animal requires on this trying occasion to be treated with as much kindness as it is possible to employ.

Having, by the various means which are adopted, brought the animal into subjection, and in effect taught him that he must in future act the part of a dutiful servant to an indulgent but firm master, the next step is to teach him his paces. These are partly artificial. Commence with slow and regular walking; whenever he is inclined to bolt, bringing him back to the steady pace you desire. After he has been accustomed to slow paces on a methodic plan, go on to the slow trot, then the quick trot, and lastly the canter and gallop. By no means allow him to mix these paces—that is, half-canter and half-trot—which would be an ungainly hobble; but let him know that he must, for the time being, keep to one kind of pace. The skill of the breaker consists in enforcing these lessons, and teaching the animal to change readily and neatly from one pace to another by little more intimation than a twitch of the rein. Lawrence recommends that 'a graceful canter should be encouraged, commencing with the proper or off-leg foremost, and the nag accustomed to be pulled up from the canter to the trot without unseemly and unpleasant blundering. The lessons should not be too long or fatiguing, but the young animal kept in as cheerful and easy a state as possible.' The first shoeing ought to be performed with great care, so as to alarm the animal as little as possible.

In connection with the breeding of horses we may say a few words respecting *mules*, or the hybrid offspring of the horse and ass. The mule proper is the produce of a male ass and mare; when the parents are the horse and she ass, the produce is called a *hinny*. The mule is the superior animal, partaking to a larger degree in the qualities of the horse; it is more robust, plump, and hardy, and better adapted for all the ordinary purposes of riding and draught. The hinny is more thinly made, has a longer head, and is altogether more like the ass than the horse. Mules of both kinds live to a very old age, and when properly trained, they are tractable, and very serviceable animals. There are comparatively few mules in Britain; but in Spain, and some other countries of southern Europe, also in Spanish America, they are numerous, and are used in carriages of people of the highest rank. According to a well-known principle in natural economy, by which intermixture of kindred species is not allowed to go beyond a single step, and only for one generation, mules do not breed; and the stock requires to be kept up by a recurrence to the common parentage.

The Teeth—Age.

The horse attains maturity at five years old, and he is in his prime till eight or nine. If no unfair play be used, his age may be judged of from his teeth, or, as it is called, *mark of mouth*. At five years old, when the teeth have been fully developed, the horse possesses six teeth in the front of each jaw, called the incisors or *nippers*; it is with these teeth that he bites. At a short distance from each end of the row of incisors, and in each jaw, there is a solitary canine tooth; these canine teeth are technically named *tushes*. At a greater distance inward in each jaw, and on each side, there are six grinders—the whole apparatus being designed to bite or crop the herbage, to tear, and to chew. At five and a half years old, the nippers are marked by a natural cavity formed in the substance between the outer and inner walls, and it is the presence or absence of these darkish marks that certifies the age of the animal. When the horse reaches six years, the marks in the two front nippers in the nether jaw are filled up, and the tushes are blunted. At seven years, the two nippers next the middle ones are also filled up; at eight, the two outer ones are filled up also, and the tushes are round and shortened. The lower nipper teeth are now all smooth; the marks are gone; but in the teeth of the upper jaw marks remain a year or two longer. At eight years, the disgraceful practice of *bishoping*—a term given from the name of the inventor—is often resorted to, for the purpose of imitating the obliterated marks. An engraving tool is employed to cut the surface, and a hot iron is then applied to give a permanent dark stain. This infamous trick may impose on the ignorant; but a person skilled in horses can easily detect the imposition, from the stains being diffused around the marks, and other appearances.

As a horse, if well treated, remains in excellent working condition till twelve, and even later, the disappearance of the marks on the teeth is often of little consequence. Some horses are as valuable to their owners at fifteen years as they are at eight; and for ordinary saddle-work, ten to twelve may be considered an age sufficiently young. It is important, however, that the teeth are capable of mastication; for if the animal is unable to chew his food properly, he cannot be kept in good condition, or fit for the performance of his duties. In consequence of the very general abuse of horses, few live till twenty-five years old; and the instances of any living till above thirty are rare.

Technical Terms.

Horsemen employ terms to horses which are not strictly adhered to in ordinary language. A male horse left uncut is said to be an *entire horse*, to distinguish it from the *gelding*, or cut animal. A female horse is always spoken of as a *mare*. A young male horse is called a *colt*, and a young female a *filly*. *Thorough-bred*, as already noticed, is applied only to animals whose pedigree can be traced to an Arabian origin, without stain or any common intermixture. When the pedigree of the racer is to a certain degree stained, the animal is called a *cocktail*. The term *blood* is of more loose signification; but what is generally understood by it is a horse which is thorough-bred, or of the blood of the Arabian, and consequently shows a fine spirit and action. A horse may be half-bred, three parts bred, and so on, according to his pedigree. The half-bred is produced from a racer and a common mare. Some of the best riding-horses are of this stamp. The term *welter horse* is applied to racers who are able to carry the highest weight.

Horses are measured by *hands*, four inches being reckoned to the hand; the measure is taken at the fore-leg and shoulder. To all the more prominent parts of the body and members certain technical names are applied; for example, to take the four extremities first:—the *muzzle* includes the lips, mouth, and nostrils; the *withers* are the sharp protuberance over the shoulders between the back and neck; the breast is the *counter;* the *arm* is the upper part of the fore-leg, but enveloped in the muscle of the shoulder; beneath it is the *fore-arm*, which is the higher part of the visible leg, and extends downward to the *knee;* below the knee we have another stretch called the *shank*, which extends to the *pastern*, or, as we might call it, the ankle; the *fetlock* is behind the pastern; beneath are the feet. A few of the hinder extremities are named as follow: the *croup*, which extends from the loins to the root of the tail or rump; the *flank*, extending from the ribs to the haunches; and the *leg* or thigh, which reaches down to the *hock* or middle joint of the hind-leg, corresponding to the knee in the fore-leg. The left side of a horse is called his *near* side; and his right the *off* side.

The greater number of British horses are of a dark colour, inclining to black or brown, but of innumerable shades. One kind of brown is called bay, and another the chestnut; a yellowish chestnut is termed the sorrel. The roan is a blending of red and whitish tones. The gray is a mixture of white and black hairs, and in old age, becomes altogether white. The dark colours are the most esteemed for their physical qualities, and patches of white on the legs are considered defects or foul markings.

STABLE MANAGEMENT.

The horse, as has been already mentioned, possesses very delicate senses, and is nice in his habits, in which respect he differs very materially from black cattle. In a state of nature, the animal seems to be best adapted for a mild and genial climate, and to rejoice in freedom and space. When reduced to domestication, care should be taken to violate as little as possible his natural tastes and habits. His delicacy of constitution, augmented in no small degree by an artificial mode of life, should warrant the best attentions of his keepers; and whatever be the nature of his work, he should be treated with kindness, regularly fed and supplied with pure water, allowed a cleanly and well-ventilated habitation, and his body and limbs preserved free from dirt and all offensive matter that may cling to them. The leading features of management may be defined as follows:—

The Stable.

The stable varies in size, according to the number of horses kept. Of whatever dimensions, the situation should be dry and airy; if in any respect damp or fœtid, the animals will assuredly contract disease. When the stable is calculated to contain many horses, it is seldom regular in temperature, from the fluctuation of numbers in it at any one time. To avoid this defect, the best size, in ordinary circumstances, is that which will accommodate six or eight horses, leaving plenty of room to each.

A stable with a row of stalls only on one side is better than one with double rows; if double, the space between should not be less than eight or ten feet wide. Sixteen feet is a proper width for a stable with a single row, six of the feet being allowed for the depth of the stalls; each stall should also be six feet wide, but commonly only five and a half are given. The floor of the stalls should be neatly paved, either with stones or with the new caoutchouc pavement; slope very little from head to feet; and be bounded by a gutter, with gratings to carry off all liquid refuse. The gangway, or space beyond the stalls, should be also paved in a neat manner; and care ought to be taken that rats are effectually excluded from the walls or any part of the flooring. The stalls should be lined with smooth wood. The stable should have only one door, and that not opposite a stall; it ought to be at least four and a half or five feet wide, and eight feet high. A pinchedness in any of these details is far from economical.

The inner walls of stables are often kept shamefully dirty. They ought by all means to be well white-washed, at regular intervals, in order to extinguish vermin and wipe off impurities. The interior ought to be well lighted with windows, which should be kept clean, and never permitted to remain in a broken condition. A little carelessness in this respect may occasion the loss of a horse; for broken windows in stables are about as dangerous to the health of the inmates as broken windows in a dwelling-house.

When we say that the stable should be well lighted, we certainly oppose one of the most vulgar prejudices respecting horse management. In most instances stables are kept as dark as dungeons, greatly to the injury and discomfort of the inmates. It is impossible to understand what can be rationally designed by keeping horses standing during their waking hours in the dark. Nature never intended anything of the kind; and we say the practice should be abolished. Mr Stewart pleads as warmly as we do on this point. 'A horse was never known to thrive better from being kept in a dark stable. The dealer may hide his horse in darkness; and perhaps he may believe that they fatten sooner there than in the light of day. But he might as well tell the truth at once, and say that he wants to keep them out of sight till they are ready for the market. When a horse is brought from a dark stable to the open air, he sees very indistinctly; he stares about him, and carries his head high, and he steps high. Dark stables may thus suit the purposes of dealers, but they are certainly not the most suitable for horses. They are said to injure the eyes. There is not perhaps an animal so liable to blindness as the horse. It cannot be said that darkness is the cause; but it is well known that the eyes suffer most frequently where there is no light. Whether a dark stable be pernicious to the eyes or not, it is always a bad stable. It has too many invisible holes and corners about it ever to be thoroughly cleaned. All these things considered, it is evident that the stable ought to be well lighted.' The preferable plan of lighting is by skylights, made to open when required, for the sake of improving the ventilation.

Hay-loft—Racks—Mangers.

The hay-loft, or place of deposit for hay, ought not, as is usually the case, to be over the stable, but adjacent; and a chamber level with the floor of the stable is preferable. The reason for this is, that the hay may be preserved free from the breath of the animals and effluvia which rise from the stalls. Lawrence strongly opposes the use of hay-lofts over stables:—' According to the good old and present custom, it is the receptacle of all kinds of impurities as well as hay—the excrements of cats and mice, and exuviæ of spiders, and the accumulated and sacred dust of perhaps half a century. Add to these trifles the perpetually-ascending clouds of steam from the stabling below, contaminating, drying, and exhausting the hay of its fragrance, and of every pure and beneficial quality. Hay should remain in the stack, in order to have it in its utmost fragrance and moisture of quality, to be cut often, and taken fresh to the horses, there being a clean and cool hay-room near the stable, to contain small quantities. The gangway and walls of the stable should be perfectly clear of all encumbrance of chests, pails, brooms, shelves, saddles, or lumber of any kind, for which extra rooms are the proper place.' In cases where hay-lofts are used, let them be kept as clean as possible, and allow no opening to the racks. The hay must be brought down in small quantities, and placed in the racks.

Hay-racks of the best material and form are made of iron, the bars rounded, and two inches from each other. The rack need not traverse the whole breadth of the stall, because in such a plan rubbish collects in the corners. A size to hold from a half to a whole stone of hay will be sufficient in most instances; and the form should be that of a convex or bulged grating from the wall, placed a little above the head of the horse. A rack of this or any other shape cannot be kept too clean; the bars should be daily rubbed, and all refuse of hay removed.

The manger, from which the corn and other kinds of food are eaten, is also best made of cast-iron, and need not be larger than a foot in length and breadth, and about nine inches deep. The old-fashioned wooden mangers, traversing the extremity of the stall, are absurdly large, and as they sometimes are splintered, they injure the animal when feeding or at rest. The form and dimensions of the manger, however, are of much less importance than being kept in a high state of cleanliness. All horses are nice feeders, but some are more fastidious than others, and will not partake of food from a foul manger, or one even which has been blown upon. Let the groom, therefore, keep his horse's manger as clean as he would do his own dish, and at all events do not allow it to get dusty or out of order. The manger is commonly used for dry food only; but some attentive stable-keepers also provide a manger for water, and this seems to be highly judicious. Drinking from pails is a slovenly practice, independently of its being inefficacious. It is now allowed that horses, when stalled, should have a little fresh water beside them to drink, if they feel the desire to do so; and it may be doubted if any horse will drink when nature does not need this refreshment. Be this as it may, a good plan is to have, in one corner at the head of the stall, an iron manger shaped like that for corn, and into which pure water can be made to flow from a pipe when the groom thinks proper. A waste pipe beneath should be provided, to run off the water which is left, or which has been rendered impure by the droppings from the animal's mouth.

Bedding—Ventilation—Cleaning.

The good horse sleeps in a lying posture, his legs being partly drawn under him, and his head remaining up. A horse that habitually sleeps standing, or will not lie down at night, is usually reckoned to be of little value; for it is indispensable to doing his duty during the day that he rests well at night. The preparation of a bed for the animal ought to be one of the most pleasing parts of a stable-keeper's duty, and he should perform it well. The best bed is made of wheat-straw, but when that is dear, or cannot be got, the straw of oats may suit the purpose. The more even and less rumpled the litter, the better. The bed should be made level, or sloping slightly from the sides and head towards the centre, and be completely free of hard lumps. All ought to be smooth, clean, soft, and the depth of litter perhaps seven or eight inches. Every morning the soiled litter is to be taken away to the dung-yard, and the clean portion separated and placed at the head of the stall, or in some other convenient situation, ready to be employed again at night.

Ventilation, or a means for the provision of fresh air, is of the first importance in the economy of the stable. Small apertures at different places should be made in the walls, to allow the entrance of pure air, and the escape of such as has been vitiated. A better plan for the removal of the foul air, especially from stables in which a number of horses are kept, would consist in leading it away in a tube from the roof to the flue of a fire. (See VENTILATION.) Architects generally do not make any provision of this nature in stables, and as few stable-keepers think of instituting such an effectual process of ventilation, we can only here state, as a general principle, that means of some kind should be adopted to keep the atmosphere of the stable in an equable temperature, and as pure as possible, both night and day. We invite attention to Mr Youatt's observations on this important point:—'If the stable is close, the air will not only be hot, but foul. The breathing of every animal contaminates it; and when, in the course of the night, with every aperture, even the keyhole, stopped, it passes again and again through the lungs, the blood cannot undergo its proper and healthy change; digestion cannot be so perfectly performed, and all the functions of life are injured. Let the owner of the valuable horse think of his passing twenty or twenty-two out of the twenty-four hours in this debilitating atmosphere. Nature does wonders in enabling every animal to accommodate itself to the situation in which it is placed, and the horse that lives in the stable-oven suffers less from it than would scarcely be conceived possible; but he does not, and cannot, possess the power and the hardihood which he would acquire under other circumstances. The air of the improperly-closed stable is still farther contaminated by the urine and dung, which rapidly ferment in the heat, and give out stimulating and unwholesome vapours. When a person first enters an ill-managed stable, and especially early in the morning, he is annoyed not only by the heat of the confined air, but by a pungent smell, resembling hartshorn; and can he wonder at the inflammation of the eyes, and the chronic cough, and the inflammation of the lungs, with which the animal, which has been shut up in this vitiated atmosphere all night, is often attacked, or if glanders and farcy should occasionally break out in such stables! It has been ascertained by chemical experiment that the urine of the horse contains in it an exceedingly large quantity of hartshorn; and not only so, but that, influenced by the heat of a crowded stable, and possibly by other decompositions that are going forward at the same time, this ammoniacal vapour begins to be rapidly given out almost immediately after the urine is voided. When disease begins to appear among the inhabitants of these ill-ventilated places, is it wonderful that it should rapidly spread among them, and that the plague-spot should be, as it were, placed on the door of such a stable? When distemper appears in spring or in autumn, it is in very many cases to be traced first of all to such a pest-house. The horses belonging to a small establishment, and rationally treated, have it comparatively seldom, or have it lightly; but among the inmates of a crowded stable, it is sure to display itself, and there it is most of all fatal. The experience of every veterinary surgeon, and of every large proprietor of horses, will corroborate this statement.'

The more cleanly the stable is kept, the more easily will it be ventilated. Stables are often kept in a most offensively foul condition. In the first place, they are often ill-paved, and the refuse of the animals, getting imbedded in the interstices of the stones of the stall and gutter, keeps up a constant exhalation. Then there is no proper provision for disposing of the foul litter and urine. It is customary to rake out the used litter and other impurities to a dung-heap immediately outside the door, and there it steams and loses its value, besides being a nuisance to passengers. Instead of this bad economy, let all be raked or shovelled out to a dung-pit covered in from the outer atmosphere, so that every particle of the ammoniacal gases may be preserved. Into this pit let a smooth channel from the stalls convey rapidly and effectually all liquid refuse. Any man who willingly allows the liquid manures of his stable to run to waste, may with great justice be said to be daily picking his own pocket. Should the gaseous odour be intense, and the quantity of litter in the heap incapable of absorbing it, add now and then a spadeful of earth; or, what will be more effectual, a sprinkling of gypsum or dilute sulphuric acid. Any of the disinfectants and deodorisers, now attracting attention, may be used in stables with obvious advantage.

The stable should be clean swept, brushed, and thoroughly ventilated every morning, leaving impurities neither on the ground nor in the atmosphere. Good feeding and regular exercise may partly neutralise the effects of uncleanliness; but in the event of epidemical influenza, glanders, and other diseases, these effects become sadly manifest; and then, as Mr Stewart humanely observes, 'the proprietor begins to look about him. It is time for him to know that God has not given him absolute and unconditional control over his fellow-tenants of the earth. Oppression has wide dominions, but there are limits which cannot be passed; and death reveals the operation of a wise and beneficent law.'

Stable Furniture—Stablemen.

Every stable is to be provided with proper receptacles for hay and straw. The oats, peas, beans, bran, &c. should be kept in one large chest with divisions, or separate chests, and, if possible, be placed in an apartment separate from the stable. For small stables, an adjoining room should be fitted up neatly for the accommodation of the corn chest, the saddles, and other apparatus; all saddles, bridles, and small articles being properly hung on hooks on the wall, or placed on other appropriate supports. A cupboard for combs, brushes, &c. will be an advantage. If the stable be not supplied with water in pipes, a well should be at hand.

Horses require to be under the charge of persons who understand the business of attending to them in all their varied wants. Some individuals seem to imagine that any boy or lad will do for taking care of a horse. This is both inhumane and bad policy. Where only one horse is kept, a steady lad, under the directions of his master, and instructed in the line of his duty, will often be found sufficient; but he requires constant looking after, for all young persons, and some old ones too, are disposed to play pranks with horses, and rob them of their food. The ordinary class of ostlers are not regularly instructed in the qualities and wants of the horse. All they know is empirical, and their prejudices are frequently absurd. Let all such persons, therefore, be estimated at their proper value; and on committing your horse to any of them at an inn, see that he does his duty to the animal both as respects cleaning and feeding.

In stables in which two or more horses are kept, a regular groom should be employed; and this person should reside close by the stable, so as to be always at hand. The qualifications of a groom ought to be steadiness of conduct, promptitude in a case of difficulty, openness to advice or instructions, experience in well-managed stables, taste for cleanliness; and he should be as desirous of making his charge comfortable as he would his own person.

In large establishments there are head and undergrooms, strappers, and stable-boys—the latter a kind of loose appendages to the concern, who act as drudges to the superior officers, and look forward to promotion. In establishments of moderate size, the groom and driver, or coachman, are the only functionaries. It is the duty of the groom to attend to the horses in every particular, when in or about the stable, and when taking exercise. The duty of the driver is more particularly to keep the chaise or other vehicle in order, and also to clean the harness.

If all horses were good-tempered, or rendered docile by kind treatment, they might be advantageously left at liberty in their stalls; circumstances, however, require that they should be restrained; but this should be done with as little pain to them as possible. The halter or rein from the head-gear should be led to a ring at the head of the stall, leaving the animal at liberty to lie down in an easy posture. The rein, whether of rope or chain, should not be tied to the ring. It should go through the ring, and drop down with a plummet at the extremity to keep it down, yet allowing the animal to pull it up or allow it to sink at pleasure. A shorter halter may be employed during the day than at night, so as to keep him from straggling backwards into the passage or gangway. Some horses are most restive in restraint, and commit tricks to loosen themselves; and others, by awkwardness of movement, get cast—that is, benumbed or cramped—when lying; and it is often necessary to employ skill and force to raise them to their feet. A soft level bed and abundance of room are the best preventives for this kind of accident.

Grooming—Dressing—Trimming.

The skins of horses are liable to become clogged with a scurf of dried perspiration, along with particles of dust and mud, which collect and lodge among the hairs. It is of great importance to remove these impurities by currying and brushing, for the sake of the health of the animal, independently of the value of the operation as respects the appearance of his coat. The degree to which this species of grooming is carried will of course very much depend on circumstances; but as a general rule, it should take place every morning before the horse is led forth to the labour of the day.

The grooming is commenced while the animal is in his stall, his wrapping-cloth, if he have one, being removed, and the restraining rein being lengthened, to allow his standing a little back into the gangway. If restive, his head must be tied up. All refuse having been previously removed, a little of his bedding may be drawn out for his hind-feet to stand upon. The first thing done is to curry him with a curry-comb—a flat iron instrument, with rows of short blunted teeth and a handle. By being drawn along the surface of the body and limbs, it rakes up the lumps of hair, and generally loosens and brings up all extraneous substances. The groom commences with the neck and shoulders; next he goes to the body, hinder quarters, belly, and legs, both sides being treated alike. The curry-comb must not in any case be used roughly, and with thin-skinned horses its application must be very gentle. If the horse be regularly groomed, and its work not dirty, a gentle scrubbing with the curry-comb will in most cases suffice. In performing the operation, a brush may be held in the other hand, with which to clear out the teeth when necessary. After the curry-comb has gone its rounds, apply the brush in turn, going over the whole surface with it, from head to heels, to remove all raised impurities, and to lay the coat smooth. Lately, a rough hair-glove has been introduced into use as an improvement upon the brush; and it certainly possesses the advantage of being more easily applied to the head, limbs, and flank, than the brush. Should the horse be changing his coat, which he does twice a year, the curry-comb must not be used at all; a rubbing with a straw-wisp being perhaps sufficient.

After the currying and brushing, the groom proceeds to comb the forelock, mane, and tail, so as to make all the hairs lie straight. This finishes the grooming; but if the legs or feet be white, they will perhaps require washing with warm water and soap—to prevent the growth of a yellow appearance—and then dried with a wisp. We have only to add, that if horses are not groomed regularly in this manner, they will inevitably lose their health, or be troubled with parasitical animals lodging beneath the hairs, and never have a glossy and cheerful appearance. Some horses have a great repugnance to being groomed, but this generally arises from harsh treatment while they were young: if treated considerately, they will feel pleased with the friction, and grateful for the attention bestowed on them.

The cleaning of a horse after work is as necessary as the morning grooming. When a horse is brought to the stable in a state of perspiration, it should not be taken in to be at rest all at once, but be walked gently about till it becomes moderately cool. This allows the excitement of the blood-vessels and muscles to be allayed gradually, and prevents any sudden stoppage of the pores of the skin. To assist in drying and cooling down the animal, he may be scraped or rubbed with wisps. Wisping is preferable. After the horse has been walked and wisped, his legs and feet should be washed with water and a brush or sponge, and also his belly, if it be dirty with sparks of mud; but after any such washing, every part should be thoroughly dried with a fresh wisp. Never leave a horse with wet legs or feet. In the country, it is not unusual to walk horses into a river to wash their legs—a practice most detrimental to their health, and which should not be allowed.

When the horse has been cleaned and dried, the cloth may be thrown over him, and tied to his stall. The cloth used in summer should be lighter than that used for winter. It is customary for grooms to exercise horses with the stable-cloths wrapped round them, and then perhaps the next hour they are taken out saddled, and without any cloth at all. This seems an inconsistency. The use of cloths is to protect the animal's loins from cold, and is unnecessary in fine weather. If the horse has to stand still out of doors, and the weather be ungenial, his loins ought by all means to be protected by an oiled cloth. The horse is very susceptible of injury by exposure of the loins; and it will be observed that, to shelter that part, cavalry soldiers wear a long riding-cloak, which falls loosely over the hinder part of the animal.

Nature gives the horse a beautiful flowing tail and mane, for the purpose of whisking off flies, and for other uses; but mankind, in taking the creature under their protection, have in many instances, and for no good reason, as far as we are aware, deprived it of these graceful personal appendages. The most contemptible piece of this rash interference has been the docking of the tail, and causing it to cock up, thus leaving the rear of the animal exposed. The tail should be left flowing to a point, and only trimmed to a limited extent; and the same thing may be said of the mane. Nature has likewise given the animal long hairs on the legs, independently of the fetlocks. These various appendages have likewise not been given unnecessarily; they answer as a kind of thatch to carry off the moisture which trickles down the legs, so as to keep the feet dry and the legs warm. These parts, therefore, should be trimmed sparingly; and the fouler the animal's work, the more should be left on. Any trimming should be executed tastefully with a comb and pair of scissors. It is customary to clip away the long hairs about the ears and muzzle, but this also must be performed with great discretion. These hairs have their uses, those about the ears in particular, and harm is not unfrequently done by their removal.

Management of the Feet.

When the horse has been stabled for the night, it will be the duty of the groom to see that the hoofs, above and below, have been cleaned, particles of sand removed from the crevices of the shoes, and the feet generally in a good condition. The feet have a tendency to harden and crack, and thus a good horse may become lame. The fore-feet are most liable to this serious evil. To prevent hardness and soreness of feet, it is customary to stop them at night with a soft moist material, most commonly pieces of horse-dung, which is crammed into the sole. No special directions on this point can be given; for some thin-soled horses do not require stopping, and the hind-feet are seldom in need of anything of the kind. When the frog is liable to thrush, the feet require to be kept dry, and cleaned and attended to with peculiar care. To prevent over-dryness of hoofs, as well as the undue action of moisture, it is advisable to anoint the horny part of the feet with an ointment made of tar, fish-oil, and bees-wax, melted together in equal proportions; but this should not be done unless it is absolutely required. If well washed, and kept clean, the feet will seldom require any of this kind of varnishing.

When at large in a wild state, horses, as may be supposed, go barefooted, like all the other lower animals. The hoofs grow with a slight curve up in front; but this does not seem to impair their speed. If domesticated horses were always to walk on turf, and not be obliged to carry or draw a weight, their feet might remain unshod; but the circumstances of their condition make it necessary to protect the hoofs from tear and wear by means of shoes. Horse-shoes have been used of many different shapes and materials; but it is needless here to speak of any others than the iron shoes in common use. The shoe must be of weight conformable to the powers and uses of the animal, but exactly to suit the curve of the hoof, flat, and of equal thickness, and be secured by nails to the hoof. The proper paring of the hoof before shoeing, and the shoeing itself, are matters to be left to the discretion of regular farriers. As a general principle, care must be taken not to drive the nails into any tender part, and the hoof should be as little broken as possible. A gentleman's horse should be shod at regular intervals, and a shoe never suffered to come off from too long usage.

Exercise.

Every horse ought to be exercised daily in the open air. The exercise should be in the early part of the day: when not exercised by work, he must be walked out and trotted on purpose. An authority already quoted (*Lib. Use. Know.*) observes:—' The horse that, with the usual stable-feeding, stands idle for three or four days, as is the case in many establishments, must suffer. He is disposed to fever, or to grease, or, most of all, to diseases of the foot; and if, after these three or four days of inactivity, he is ridden fast and far, is almost sure to have inflammation of the lungs or of the feet. A gentleman's or tradesman's horse suffers a great deal more from idleness than he does from work. A stable-fed horse should have two hours' exercise every day, if he is to be kept free from disease. Nothing of extraordinary, or even of ordinary labour can be effected on the road or in the field without sufficient and regular exercise. It is this alone which can give energy to the system, or develop the powers of any animal. In training the hunter and the race-horse, regular exercise is the most important of all considerations, however it may be forgotten in the usual management of the stable. The exercised horse will discharge his task, and sometimes a severe one, with ease and pleasure, while the idle and neglected one will be fatigued ere half his labour be accomplished; and if he be pushed a little too far, dangerous inflammation will ensue. How often, nevertheless, does it happen that the horse which has stood inactive in the stable three or four days, is ridden or driven thirty or forty miles in the course of a single day! This rest is often purposely given, to prepare for extra exertion—to lay in a stock of strength for the performance of the task required of him; and then the owner is surprised and dissatisfied if the animal is fairly knocked up, or, possibly, becomes seriously ill. Nothing is so common or so preposterous as for a person to buy a horse from a dealer's stable, where he has been idly fattening for sale for many a day, and immediately to give him a long run after the hounds, and complain bitterly, and think that he has been imposed upon, if the animal is exhausted before the end of the chase, or is compelled to be led home suffering from violent inflammation. Regular and gradually-increasing exercise would have made the same horse appear a treasure to his owner. Exercise should be somewhat proportioned to the age of the horse. A young horse requires more than an old one. Nature has given to young animals of every kind a disposition to activity; but the exercise must not be violent. A great deal depends upon the manner in which it is given. To preserve the temper, and to promote health, it should be moderate, at least at the beginning and the termination. The rapid trot, or even the gallop, may be resorted to in the middle of the exercise, but the horse must be brought in cool. If the owner would seldom intrust his horse to boys, and would insist on the exercise being taken within sight, or in the neighbourhood, of his residence, many an accident and irreparable injury would be avoided. It should be the owner's pleasure, and is his interest, personally to attend to all these things.'

Watering and Feeding.

A horse should be exercised a little after being watered. He should on no account be allowed to drink when heated, particularly if heated to the extent of perspiring. The only refreshment allowed in these circumstances is a rinsing of the mouth, and the muzzle may be washed and relieved of froth. When not permitted to take water of his own accord in the stall, let him be offered a pail three or four times a day; and after drinking copiously at either a pail or pond, he may be trotted or gently cantered, the motion being generative of heat, and at least prevents any chill.

Horses are fed on different materials in different countries; but principally on the various kinds of grasses and cereal grains. The Germans give them foods of brown bread while on a journey; in India, rice and spices are employed for their diet; in England, the chief articles of food are oats and hay, with inferior proportions of beans, peas, cut straw, and bran. The quantity, and also the nature of the food will depend on the habits of the animal, and the work to which he is put. If the work be hard, he must be fed to a considerable extent on oats, which are more nutritious than most other articles in use; but if the work be light, a lighter diet of hay, with perhaps only a small quantity of oats, will suffice. The stomach of the horse being small, he cannot eat much at a time; and it is always preferable to feed him often, and at regular intervals, than to offer him large feeds at irregular periods. There is another reason for offering small feeds: the horse nauseates food which he has blown upon, or previously touched, and will accordingly reject it if offered a second time, or allowed to stand beside him. For various reasons, therefore, it is better to give him only a little at a time, so as to leave none behind. If the animal be a poor feeder, or apt to waste his food, greater care must be taken in this respect.

Oats ought to be sound, old, and dry. If musty, reject them. In almost all cases it is preferable to have them bruised; for by this they are more easily digested and nourishing than if left whole. It is now customary to mix oats with chaff composed of the cuttings of clover or meadow hay, and the straw of wheat, oats, or barley. In some stables a machine is kept to cut these materials. The length of the cuttings should be about half an inch. Bruised oats have a tendency to scour the animal; but the admixture of chopped stuff counteracts this quality.

Of hay, clover, and meadow-hay, little need be said. They should be sound, and sweet-flavoured, without any mustiness. The hay should, if possible, be a year old, and well saved for use in an adjacent stack. Some horses are fond of peas; but they require to be given with caution, as they are apt to swell in the stomach. Almost all horses are inordinately fond of carrots, which, when administered in small quantities, do not purge the animal, and improve his coat. A respectable authority states, that 'for agricultural and cart-horses, eight pounds of oats and two of beans should be added to every twenty pounds of chaff; and thirty-four or thirty-six pounds of the mixture will be sufficient for any moderate-sized horse [daily] with fair or even hard work.' In this estimate no hay is supposed to be given. When the horse is fed on the two last articles, hay and oats, four feeds, or nine or ten pounds of oats per day, will be a fair allowance during winter, and in the case of moderate work; but in summer, half the quantity, along with a proportion of green herbage, will suffice. Many gentlemen follow a general rule of allowing twelve pounds of oats per day to each riding-horse, and this is given in three or four meals. A pony, having but moderate work, will be well fed on six pounds of oats per day, with a fair proportion of hay. Latterly, sago has come into use as an article of horse diet; and we believe it is highly nutritive, and may be employed to a certain extent to supersede oats, or to be mixed with them. It should be partially softened by preparation.

Several serious diseases arise from improper feeding, particularly at intervals during hard labour; and on this point we refer to our observations on

THE DISEASES OF HORSES.

In consequence of the general mismanagement and ill-treatment of horses, they are exposed to a number of formidable diseases. Those of most frequent occurrence are glanders, inflammation of the lungs, broken-wind, inflammation of the bowels, and certain illnesses of the feet and legs. Referring our readers to larger works on the horse for full information on these diseases, and recommending all unskilled persons at once to hand over their horse to a veterinary surgeon when unwell, we propose only to give a few hints as to the best means of prevention. The institution of schools of veterinary surgery, at which the anatomy, peculiar nature, and diseases of horses are explained by men skilled in this important department of science, has been a powerful auxiliary in improving the qualities of horses, preserving their lives, and saving them from much needless distress.

Glanders.

This is a disease of the nose, in some measure resembling the effects of a cold. It is believed to be occasioned by breathing vitiated air, and takes the form of an irritation of the delicate membranes of the nostrils, accompanied by an offensive discharge. Glanders is highly infectious, and may be communicated hereditarily. When not removed in time, it will perhaps terminate in farcy, a disease of the veins, which causes swellings called farcy-buds. The preventive of either of these dangerous maladies is cleanliness in the stable and pure ventilation.

Inflammation.

The more ordinary inflammation is that of the lungs, and is caused by sudden changes of temperature; it is, in reality, the grand disorder of the horse, and its effects are only paralleled by those of pulmonary consumption in the human species. Already we have spoken of the great impropriety of exposing horses, while heated, to cold draughts. Allowing them to stand any length of time in the open air, in cold or moist weather, is equally objectionable, and positively cruel. Inflammation of the lungs, however, will arise from various causes besides cold, and these have engaged the most serious attention of veterinarians. Some time ago, the Highland Society of Scotland offered a premium for the best essay on the *inflammatory complaints generally* of farm-horses, and the prize was awarded to Mr Matthew M. Milburn, Thorpfield, near Thirsk, Yorkshire, whose paper appeared in one of the numbers of the 'Quarterly Journal of Agriculture.' Some of the parts of the essay appear to us so worthy of being made known to persons who have the management of horses, that we take the liberty of giving them publicity in our pages.

After showing that there is not any particular predisposition to disease in the breeds of horses usually employed in heavy draught, nor in the particular conformation of the animals, Mr Milburn proceeds to say that 'the post-horse, and such as are required to perform fast work, are more liable to attacks of diseases of the brain, the nerves, and the lungs, simply because their work consists of rapid and powerful exertion; the farm-horse, the animal of long and steady exertion, to gripes, inflammation of the bowels, and stomach-staggers—results, as I shall presently show, of a management unsuited to the character of the labour we require from them. The stomach of the horse is remarkably small—smaller in proportion to his size, and the quantity of food he requires, than any other domestic animal. Nature intends for him a supply of nutritious food, and that *at short intervals*; wherein he materially differs from the ox, whose capacious stomach will contain food which will not be digested for hours. The post-horse, the hunter, and the carriage-horse, have food of the most nutritious description, and the time during which they are worked is necessarily short, owing to the extreme exertion required; they return to their food; and although their appetite may for a time be impaired, and their stomach and bowels affected by the general debility of the system, yet they recover their tone as soon as the rest of the frame admits of their taking food. The farmer's horse, on the contrary, has food of a less nourishing nature; his rack is filled with straw, or at best with clover; the ploughman rises early, gives him a feed of corn, and leads him to his work, where he continues for seven, eight, and even nine hours, and his whole day's work is completed before he is allowed to eat. We do not find the ox, worked under similar circumstances, so affected in the stomach and bowels, simply because his capacious stomach, when filled, requires many hours to empty; while, as we have seen, it is different with the horse. Debilitated and hungry, the horse returns, and his rack is plentifully supplied, and a good feed of corn given him, and he is left to himself: he eats voraciously, half masticates his food, loads his debilitated stomach, and his digestive organs are weakened, and permanently injured. This course is repeated—a habit of voracity is acquired; and at no very remote period the food lodges and obstructs the pyloric orifice (the passage from the stomach to the bowels), fermentation ensues, gas is evolved, the stomach is distended, he grows sluggish and sleepy, drops his head upon his manger; or he is delirious, and evinces that the sympathy which exists between the stomach and the brain has excited the latter organ; he rolls, paws, and is seized with convulsions; at length he expires, and he has died of stomach-staggers. The half-masticated food has irritated the bowels, extra exertion of the muscles has been required to propel the fæces to the rectum, and cholic or cramp (spasms) of the bowels has followed; or a course of continued irritation, or of continued cholic, or both, has ended in inflammation of the bowels. I remember a beautiful farm-horse, which, owing to the distance of part of the farm to which he belonged from the buildings, was worked the long hours described, and finished his day's work before his bait. He was constantly subject to attacks of the gripes, which were subdued; but he died of stomach-staggers. The same stable, then so often subject to diseases, is now, by a change in the system, completely free from them. Another case, however, occurred: a beautiful compact little mare was constantly afflicted by cholic; she eventually died of inflammation of the intestines.

There are other parts of the management to which horses employed in agriculture are subject, which induce diseases of the bowels. For instance, a boy returning from work, with heated and sweating horses, to save himself trouble, allows them to drink copiously at some pool or stream he passes. Suddenly one or more of the horses exhibit symptoms of gripes; they suddenly lie down, roll about, look at their sides, rise up, seem relieved, and again speedily relapse; the sudden application of the cold water has produced spasms in the bowels, through which it has passed. This is neglected, or perhaps gin or whisky, aided by pepper, is administered as a remedy, and severe and general inflammation of the bowels is the result: this is mistaken for another attack, and again the poison is administered, and the inflammation increased, and death follows. The horse of heavy work, too, is longer exposed to the inclemencies of the weather than the animal of light work. In the former, the rain is allowed to fall upon him for hours, and it is allowed *to dry upon his back;* the sympathy between the skin and the alimentary organs is known to every groom; obstructed perspiration, and consequent irritability, is conveyed from the one to the other, and disease is the consequence. It is true the latter is also partly exposed to the rain, but for shorter periods, and the wisp and brush are liberally applied when he enters the stable; a determination of blood takes place to the skin, perspiration is promoted, and disease thus prevented.

Of the best means of preventing these diseases in farm-horses we will now treat: we have attributed the peculiar liability to them in farm-horses to mismanagement, with the exception of certain instances of peculiar formation of the animals; and although the farmer must necessarily work his horses longer hours than the horse of rapid work is capable, there is no necessity for depriving the animal so long of food. No horse should work more than five or six hours without a bait. If we examine the history of the stables of large farmers, whose fields necessarily lie at a great distance from the buildings, and where they are worked long in consequence, and compare it with that of small farmers under the contrary circumstances, we shall find a striking difference as respects the health of the animals. The case referred to above strikingly illustrates the truth of this observation. But it may be asked—How is it possible to bait the animals so far from home? The difficulty seems to be in procuring food upon the spot; for if this is not done, the precaution will be neglected, and at anyrate the land will be occupied by it. This, however, may be remedied. In the case, for instance, of a field intended for turnips, which has to be worked during the spring, a part of it, half an acre, or in proportion to the size of the field, may be sown with winter-tares, a few of which may be mown off, and given to the animals green, without carrying them from the field, interfering with any crop, or wasting any time in carrying the horses to a distance. If the field be intended for summer-fallow, the spring tare will answer, and which may be used in the same manner, instead of allowing the poor animals greedily and indiscriminately to crop the leaves of the hedges at every turning, from the impulse of hunger. There is another easy way of baiting, which some carters adopt, and which might be applied to the farmer's horse, especially when carting. It consists in securing a bag containing corn over the animal's mouth and nose, by a string, which passes over the poll, and is locally denominated a "nose-bag," or "horse-poke," and which should be removed when he has finished his food. To prevent the effects of the wet upon the skin, an unexpensive glazed cloth may be thrown over the horse's back, and secured to the collar and traces. This may by some be considered very troublesome; but it will be found that when it is once begun, it will be considered no more trouble than carrying the rest of the harness; and if disease is prevented, the trouble amounts to nothing. To counteract as much as possible any habits of greedy feeding which the horse may have acquired, his corn should be mixed with chopped straw, or chopped clover, which will secure its proper mastication, and prevent many troublesome complaints, as well as render all the nutrition of the food available. These may be substituted by an admixture of clean chaff with corn—a plan which is pursued in a farm stable with which I am acquainted, and is found a useful practice. It would save the animals much time in eating if all their food was chopped, and perhaps steamed; but on this subject we have not sufficient data to determine with accuracy.'

The cure, it has been hinted, must generally be left to the veterinary practitioner, whose chief object should be to empty the stomach. In severe cases, an ounce of laudanum and a drachm of pounded ginger, in a quart of warm ale, may be used with probable success.

Broken-windedness.

When the breathing of a horse is rapid and laborious, it is said to be *thick-winded;* and when it breathes irregularly, the inspiration taking one effort, and the expiration two, it is called *broken-winded.* Inflammation of the lungs from cold is a cause of thick-windedness, the condition of these organs preventing the full action of the air-tubes. This complaint, if not removed, will most likely terminate in the broken-winded condition; but broken-windedness will take place without this premonitory symptom. The main cause of broken-windedness is sharp work after over-feeding—causing the animal to run while the stomach is full. The distended membrane presses upon the lungs, and causes a rupture in the air-cells, by which several cells are thrown into one. Thus the breathing is rendered irregular by imperfect muscular action in the parts.

This disease is almost invariably a result of sheer carelessness in the persons whose duty it is to superintend the feeding of the horse. The case, according to Mr Youatt, stands thus:—'Suppose a horse to be a gross feeder, and to have filled his stomach with straw and hay, or provender that occupies a great bulk, and contains little nourishment, the lungs are squeezed into less than the natural compass. Let the horse be now suddenly and smartly exercised; more blood must be purified, and in the violent effort to accomplish this, some of the cells give way. Therefore we do not find broken-winded horses on the race-course, for although every exertion of speed is required from them, their food lies in small compass, and the stomach is not distended, and the lungs have room to play, and care is taken that their exertion shall be required when the stomach is nearly empty. Carriage and coach-horses are seldom broken-winded, unless they bring the disease to their work, for they, too, live principally on corn, and their work is regular, and care is taken that they shall not be fed immediately before their work. The farmer's horse is the broken-winded horse, because the food on which he is fed is bulky, and too often selected on account of its cheapness; because there is little regularity in the management of most of the farmer's stables, or the work of his teams; and because, after many an hour's fasting, the horses are often suffered to gorge themselves with this bulky food; and then, with the stomach pressing upon the lungs, and almost impeding ordinary respiration, they are put again to work, and sometimes to that which requires considerable exertion.

This disease depends as much upon the cramped state of the lungs, from the pressure of an over-gorged stomach, in the ordinary state of the animal, as on the effects of over-exertion. The agriculturist knows that many a horse becomes broken-winded in the straw-yard. There is little nutriment in the provender which he there finds; and to obtain enough for the support of life, he is compelled to keep the stomach constantly full, and pressing upon the lungs. Some animals have come up from grass broken-winded that went out perfectly sound.

The cure of a broken-winded horse no one ever witnessed; yet much may be done in the way of palliation. The food of the animal should consist of much nutriment condensed into a small compass; the quantity of oats should be increased, and that of hay proportionably diminished; the bowels should be gently relaxed by the frequent use of mashes; the water should be given sparingly through the day, although at night the thirst of the animal should be fully satisfied; and exercise should never be taken when the stomach is full.'

Curb—Bog-Spavin—Bone-Spavin.

The hock-joint is particularly liable to derangement, so as to render the animal unsound. One of these affections is called *curb*, which arises from over-exertion of the ligaments, and takes the form of an enlargement a few inches beneath the joint of the hock. A more serious complaint of the hock is the *bog-spavin*, which takes place from over-exertion, and is an inflammation in the vesicles containing the lubricating material for the joint. This disease is almost incurable; and the poor animal is in general only fit for ordinary and moderate work all the rest of his life. The *bone-spavin* is a still more formidable disease. It is an affection of the bones of the hock-joint, caused by violent action, or any kind of shoeing which throws an undue strain on certain ligaments, and deranges the action of the bones. A bony deposit takes place, the joint is stiffened, and the consequence is a lameness or stiff motion in the hind-legs. Blistering, as a counter-irritant, and rest, are the principal remedies prescribed for this complaint; but the best thing of all is never to overload the horse, or put him to any violent exertion, so as to *prevent* not only this, but all other similar complaints.

Physicking.

Horses that are attended to with the greatest care occasionally get into a condition which requires physic—that is, purgative medicine; as, for example, when they have been too long on hard food, and require a laxative, when they get into a heated state of body from constant work, when their bowels get overloaded or disordered, or when they are getting too fat. The most simple laxative is a *bran-mash*. Bran is put into a pail, and softened with boiling water; when cooled sufficiently, it is given to the animal as the last food at night, instead of corn or hay. About half a pailful is a dose. Horses used by commercial travellers or others during the whole week, and fed on corn, are indulged in a mash on Saturday night; and this, with the rest on Sunday, keeps them in good condition. When a working-horse is lamed, or becomes sick, and must remain idle for a few days, he requires to be relieved by a dose of physic. Generally, this consists of from four to nine drachms of Barbadoes aloes, powdered, and formed into a round moistened mass, fit to be swallowed. It requires to be administered by a skilful groom, who will push it over the throat adroitly, without alarming the animal. Sometimes the powder is mixed with a little Castile soap. An hour or less after taking physic, a bran-mash should be given, and then the horse be gently exercised. On his return to the stable, he may be offered a drink of water from which the chill is taken, or as warm as he will take it.

We should consider it imprudent to offer any further explanations of the materia medica of horses; and again recommend all unskilled or but partially-instructed persons not to attempt doctoring their horses themselves, but to obtain at once the advice of a veterinary surgeon.

ADVICE IN PURCHASING A HORSE.

The purchasing of a horse is ordinarily a matter of very serious difficulty, in consequence of the proverbial trickiness of dealers, and the many defective points in the animal's constitution, which cannot be seen with all the care that may be bestowed. In offering any hints on this important particular, we must refer to the instructions of authorities whose testimony is worthy of confidence. Mr Stewart has written a valuable little manual, entitled 'Advice to the Purchasers of Horses,' which should be in the hands of all who have frequent occasion to make purchases. The following are a few of his admonitions:—

'In buying a horse, one of the chief requisites to be attended to is the degree of nervous energy which the animal possesses; and it is the union of this energy with good conformation that makes many horses invaluable. Its absence or presence, however, is not likely to be discovered by the purchaser without a trial; and to avoid disappointment in this respect, it is therefore advisable to obtain one prior to purchase. The horse should be set to the work he will be called on to perform; and if he is intended for the saddle or single harness, he should have no companion on his trial, for many animals work well in company that are downright sluggards when alone. Some horses have an unpleasant way of going, or are difficult to manage, or have some vice which is only displayed when at work. These are so many more reasons for having a trial prior to striking a bargain. But if that cannot be obtained, some sort of conclusion regarding the animal's spirit may be drawn from his general appearance. The way he carries his head, his attention to surrounding objects, his gait, and the lively motion of his ears, may all or each be looked to as indicative of "bottom," or willingness to work. It is only, however, in a private stable, or in that of a respectable dealer, that these *criteria* can be depended upon; for in a market-place, the animal is too much excited by the cracking of whips, and the too frequent application of them, to be judged off as regards his temper. Neither must the buyer be thrown off his guard by the animation which horses display at an auction, or on coming out of the stable of a petty dealer; for it is a fact, which cannot be too well made known, that there are many unprincipled dealers who make it their business, before showing a horse, "to put some life in him"—that is, they torture him with the lash, till, between pain and fear, the poor animal is so much excited, as to bound from side to side with his utmost agility at the least sound or movement of the bystanders.'

This writer continues, in relation to the head and other parts of the animal:—'The head, as being a part not at all contributing to progression, should in the saddle-horse be small, that it may be light—the nostrils expanded, to admit plenty of air, and the space between the branches of the lower jaw, called the channel, should be wide, that there may be plenty of room for the head of the windpipe. In the draught-horse, a heavy head is not, as far as utility is concerned, an objection, for it enables him to throw some weight into the collar; and hence, excepting its ugliness, it is rather an advantage, if he is used entirely for draught. But it makes the saddle-horse bear heavy on the hand of the rider, makes him liable to stumble, and, when placed at the end of a long neck, is apt to wear out the fore-feet and legs by its great weight. The neck of the saddle-horse should be thin, not too much arched, and rather short than long, for the same reason that the head should be light: and in the draught-horse it may be thick, stallion-like, and sufficiently long to afford plenty of room for the collar, and for the same reason that the head may be large in this animal. The windpipe should be large, and standing well out from the neck, that the air may have an easy passage to and from the lungs. A horse intended to be used for the miscellaneous purposes of carriage and draught should have a head and neck neither too light nor too heavy.

That the saddle-horse may be safe, and have extensive action, it is necessary that the withers be high. This advantage is indicated by the horse standing well up before; and it is usual, in showing a horse, to exaggerate the height of the forehand by making him stand with his fore-feet on a somewhat elevated spot. A horse with low withers appears thick and cloddy about the shoulder. In the ass and mule, the withers are very low, and the shoulders very flat, and this is the reason why they are so unpleasant to ride, and why it is next to impossible to keep the saddle in its proper place without the aid of a crupper. High withers, however, are not essential to the racer or the draught-horse. The former does all his work by leaps, and that is performed best when the horse stands somewhat higher behind than before: neither are high withers necessary to the draught-horse; but in the roadster, they are as important as the safety of the rider is, for a horse with a low forehand is easily thrown on his knees. In the draught-horse, this tendency towards the ground is obviated by the support the collar affords.

The chest should be deep and wide in all horses, but especially so in one intended for quick work, in order that there may be plenty of room for the play of those important organs—the lungs.

The back should not be too long nor too short; for though length is favourable to an extended stride and rapid motion, yet it makes the horse weak, and unable either to draw or carry any considerable weight. On the other hand, if the back be too short, the horse's action must be confined; and short-backed horses, in general, make an unpleasant noise when trotting, by striking the shoe of the hind-foot against the shoe of the fore one: and though they are in general very hardy, and capable of enduring much fatigue, and of living on but little food, yet a back of middling length is better by far than one immoderately short or long. The back should be nearly straight.

In the saddle-horse, and where safety is desirable, the position of the fore-leg is worthy of attention. It should be placed well forward, and descend perpendicularly to the ground, the toe being nearly in a line with the point of the shoulder. The pasterns should neither be turned in nor out. When they are turned inwards, the horse is in general very liable to cut the fetlock-joint by striking the opposite foot against it. The draught-horse may be excused though he leans a little over his fore-legs, but the saddle-horse will be apt to stumble if he does so.'

Minute attention should be bestowed on the examination of the fore-legs and feet: these, in fact, are the great trying points. If the feet be not round and full, so as to stand firmly and flatly on the ground, and if tender or thin in the hoofs, the animal is not to be trusted for saddle-work. Mr Lawrence on this subject remarks—'The feet of saddle-horses, be they ever so sound and good in nature, detract greatly from the value of the nag, unless they stand even on the ground; since, if they deviate inward or outward, the horse will either knock or cut in the speed—that is to say, will strike and wound the opposite pasterns either with his toe or his heel; and if he bend his knees much, and is a high goer, will cut the inside of the knee-joint. Nature has been very favourable in the hinder hoofs, with which we have seldom much trouble; but there is, now and then, a most perilous defect in them—namely, when the horse is so formed in his hinder quarters that he overreaches, and wounds his fore heels with the toes of his hind-feet.' The defect here spoken of will be observed to cause an unpleasant clattering noise in trotting. The fore-legs, from the knees downwards, should be clean made, sound, and flexible at the joints. Bad usage knocks up a horse, or founders him; and his legs, being in a kind of benumbed state, will either wholly or partially refuse to perform their office. By ease and physicking, the horse recovers; but his system has been shaken, and he is apt to come down. This is a fearful defect in a horse; for no one is for a moment safe on his back. Weakness in the fetlock-joint will also cause a horse to stumble and come down, and is therefore an equally serious defect. When the horse stumbles either through weakness or bad management so as to come down on his knees, the likelihood is, that the knees are broken; and it is well known that wounds of this nature never heal over to resemble the original. The horse with broken knees is, in short, damaged for life, at least in as far as he is a marketable commodity.

Horses are sold either with or without warranty. At sales at repositories, the terms of warranty are generally announced in a public manner; but when the sale is private, no warranty is binding which is not expressed in writing in the receipt. The principle that a price above ten pounds warrants a horse sound, is not now recognised as binding. The warranty, to be of any legal value, must be something different from a mere verbal understanding or illusory custom.

DUTY OF HORSES.

Draught.

The horse is equally willing to make himself useful as a beast of burden or draught; but his powers are best adapted for the latter, and particularly on a level road. The formation of his body does not suit him for climbing or going up-hill with a load; and his strength is always exerted to greatest advantage when he can throw his centre of gravity forward as a make-weight. The amount of load which he can draw in a wheeled vehicle depends on the arrangement of the load to the pull. The pulling point is across the shoulders, and the most advantageous method is, to make the line of traction proceed *direct* from the shoulders to the load—in no shape bent or distracted from its course. The load should be placed lower than the line of the shoulders, thus making the line of traction go by a straight slope to the seat of resistance. The load should not be at a greater distance than will allow freedom of motion to the hind-legs. If it be placed too low, a part of the power will be uselessly spent in upholding it. (See LAWS OF MOTION.)

According to the calculations of James Watt, the weight which a horse can draw, called a *horse-power*, is 1,980,000 pounds raised one foot high per hour, or 33,000 pounds raised one foot per minute. The weight is supposed to hang at the end of a rope passing over a freely-moving pulley. This calculation is based on considerations more favourable than those which usually attend horse-labour. There are, in reality, no rules to guide the imposing of loads on horses; for everything depends on the degree of friction on the wheels of the carriage, the nature of the road, and the strength of the animal in question. One thing is certain, that a horse always exerts his power better by himself than when yoked with others. The load which it requires four horses to draw unitedly, if divided, could be drawn with equal ease by three. The following observations referring to the operations of Sir C. Stuart Menteith deserve to be noticed:—

'From the experience this gentleman has had in the use of animal power upon common roads, he is of opinion that the most economical mode of employing horses in draught is to give every horse his own carriage, and that he should solely depend upon his own exertions in drawing the load, as otherwise it is well known that it is difficult to find either man or beast equally willing or capable to make the same exertion, or to have the same spirit or motion; and at the same time never to exceed six miles on one stage, and to be performed twice daily. In a stage of three and a half miles, Sir C. S. Menteith employs wagons weighing eighteen cwt., in which horses draw three tons. The road is in general upon a declivity of one foot of fall for every eight, sixteen, or eighteen feet, with several ascents of one foot in every thirty feet, up which a horse draws the load of three tons, and a wagon of eighteen cwt.; but in order to facilitate the ascent, a continuous line of sandstone railroad is first laid down, upon which a plate of iron, six inches wide by a quarter of an inch thick, is fixed down. In order to enable a horse to bring a load of three tons down any rate of descent, a friction-break has been employed, similar to the one in common use in Belgium, from which Sir C. Stuart Menteith derived this important application. The break is a strong plank, fixed to the back of a cart or wagon, which, by means of a screw, the carter presses against the two hind-wheels of the machine, so as to give a sufficiency of friction to retard the too rapid descent of the carriage. This plan has been employed with great success by Mr Croal, coach proprietor in Edinburgh, from the suggestion of Sir C. S. Menteith, who has now used it more than fourteen years upon his coal-wagons. The mode adopted by Mr Croal is to fix a lying axle to the plank pressing upon the hind-wheels of a coach, and which is turned by an upright shaft, with a bevel-wheel connecting the two shafts, and turned by a winch by the hand of the coach-guard, without moving from his seat. Were this break applied to every coach, the lives and limbs of thousands would be preserved, as the guard would be able to stop horses when running away with a carriage—as it is thought that treble, as it were, of the weight of a coach is to be drawn, if the two hind-wheels are prevented from revolving by the break. This kind of break enables a coachman to drive with perfect security down a descent of any length, and at any rate of speed. If the employment of horse wagons, weighing from twelve to thirteen cwt., were adopted in conveying coal through the streets of London, one horse would do the work of two: at present, four immense horses draw three chaldrons of coal, or four tons one cwt., in a wagon weighing perhaps two tons; so that the shaft-horse is obliged to draw a weight of six tons in turning out of one street into another.'

The larger the size of wheels in a vehicle, within a reasonable proportion, so is the friction in overcoming obstacles on the road less, and so is the draught more easy to the horses. The benefits of large wheels, however, have often been completely lost by not making them run fairly in an upright position. The custom has been to make them *dished* or bevelled outward from the axle, and to cause the axle to lean downward at each extremity to accommodate this peculiar shape. It is of importance to understand that a wheel always runs best when its tire is of equal diameter, when the spokes are at right angles to the axle, and when the axle projects straight out. This is exemplified in the trundling of a hoop: a hoop which is perfectly upright and even on the rim, requires less force to send it forward and keep it moving than if it were bevelled, and inclined to go round in a circle. For the sake of convenience, wheels may be a little dished, though now that the roads are good that is scarcely necessary.

The power of draught of a horse depends on the rate at which he is compelled to proceed. He exerts his power to most advantage at a fair pull, when moving at the rate of from two and a half to three miles per hour. If he go at a greater speed, he is less able to draw. As a general rule, if the speed be doubled, the load should be halved; and if the speed be twice doubled, the load should be quartered; yet this will only hold as correct for short distances. Much work may be procured from a horse if he be impelled only for short stages. A horse in a stage-coach, running only five miles at a time, and then resting for a few hours, will last at least four times longer than another horse of equal power which runs ten miles at a time. This is well understood by all stage-coach proprietors, and short stages have now almost everywhere superseded long ones. Such a fact should also be known to all private travellers. Whether employed in a gig, chaise, or for riding, the horse on a journey should take his day's work in two distinct stages: one in the morning, and another in the afternoon, when rested and refreshened. He should also, to remain in good condition, have a rest during the whole of Sunday. In journeying with light loads, a distance of from twenty to twenty-five miles is considered a sufficient day's task.

Riding.

The art of riding or equitation, forms a regular branch of instruction, and is seldom well performed by those who have not been regularly taught. It is not to be supposed that anything we can say can supersede the instructions of the riding-school; but it may be of use to offer a few hints on the subject from the most esteemed authorities.

Riding should be performed in that manner which is least calculated to oppress the horse and fatigue the rider, and which will be most secure for both parties. The first principle in horsemanship is, that the horse and his rider should act and react on each other, as if governed by one common feeling. To attain this end, the rider must acquire the knack of balancing himself properly on the animal, and establishing the means of making himself understood through certain movements of hand and body. A good horseman will act according to the following directions, given in Walker's 'Manly Exercises:'—'The place of the rider's seat is that part of the saddle into which the rider's body would naturally slide were he to ride without stirrups. This seat is to be preserved only by a proper balance of the body, and its adaptation to even the most violent counteractions of the horse. In relation to the thighs, the rider, sitting in the middle of the saddle, must rest chiefly upon their division, vulgarly called the fork, and very slightly upon the hips. The thighs, turned inward, must rest flat upon the sides of the saddle, without grasping; for the rider's weight gives sufficient hold, and the pressure of the thighs on the saddle would only lift him above it. The knees must be stretched down and kept back, so as to place the thighs several degrees short of a perpendicular; but no gripe must be made with them, unless there be danger of losing all other hold. If the thighs are upon their inner or flat side in the saddle, both the legs and the feet will be turned as they ought to be. Thus turned, they must be on a line parallel to that of the rider's body, and hang near the horse's sides, but must not touch; yet they may give an additional hold to the seat, when necessary, and the calves must act in support of the aids of the hands. The heels are to be sunk, and the toes to be raised, and as near the horse as the heels, which prevents the heel touching the horse. As to the body, the head must be firm, yet free; the shoulders thrown back and kept square, so that no pull of the bridle may bring them forward. The chest must be advanced, and the small of the back bent a little forward. The upper parts of the arms must hang perpendicularly from the shoulders, the lower parts at right angles with the upper, so as to form a horizontal line from the elbow to the little finger. The elbows must be lightly closed to the hips, and, without stiffness, kept steady, or they destroy the hand. The wrist must be rounded a little outwards. The hands should be about three inches from the body, and from the pommel of the saddle, and from four to six inches apart; the thumbs and knuckles pointing towards each other, and the finger-nails towards the body. When the rider is in the proper position on horseback without stirrups, his nose, breast, knee, and instep, are nearly in a line; and with stirrups, his nose, breast, knee, and toe, are in a line. The man and the horse throughout are to be of a piece. When the horse is at liberty, or disunited, as it is termed, the rider sits at his ease; and as he collects and unites his horse, so he collects and unites himself. There must, however, be no stiffness of manner more than in sitting on a chair; for it is ease and elegance which distinguish the gentleman.'

Riding, to one accustomed to it, is best performed with a curb and snaffle bridle; the curb, however, being only employed to bring the animal up by pressure on the mouth when occasion requires. As some horses have a much more delicate mouth than others, the nature of the bridle must depend on circumstances. In holding the reins, a union of firmness, gentleness, and lightness, is the essential requisite. The foregoing authority alludes to the manner in which the reins are to operate on the mouth of the animal:—'The hand being connected with the reins, the reins to the bit, the bit operating in the curb on the bars, and in the snaffle on the lips, the rider cannot move the hand, and scarcely even a finger, without the horse's mouth being more or less affected. This is called the *correspondence*. If, moreover, the hand be held steady, as the horse advances in the trot, the fingers will feel, by the contraction of the reins, a slight tug, occasioned by the cadence of every step; and this tug, by means of the correspondence, is reciprocally felt in the horse's mouth. This is called the *appuy*. While this relation is preserved between the hand and mouth, the horse is in perfect obedience to the rider, and the hand directs him, in any position or action, with such ease, that the horse seems to work by the will of the rider rather than by the power of his hand. This is called the *support*. Now, the correspondence or effective communication between the hand and mouth—the appuy, or strength of the operation in the mouth; the support, or aid, the hand gives in the position or action, are always maintained in the *manege* and all united paces. Without these, a horse is under no immediate control, as in the extended gallop, or at full speed, where it may require a hundred yards to pull before we can stop him. The degree of correspondence, appuy, and support, depends, in horses otherwise similar, on the relative situation of the hand. The act of raising the rider's hand increases his power; and this, raising the horse's head, diminishes his power. Depressing the rider's hand, on the contrary, diminishes his power; and this, depressing the horse's head, increases his power.'

Much may be done to animate a horse, either in riding or drawing, by addressing a cheerful word to him, instead of the lashing and scolding with which he is too frequently visited. If a horse requires correction or urging by the whip, he should only be touched lightly behind the girth and saddle, never on any account on the head, or on a fore part of the body. We have frequently seen riders so lost to humanity as to whip their horses when restive over the head and ears. Should a horse attempt to baffle his rider, he must be pressed by the legs, urged lightly with the spur, and kept in his proper track, but not drawn up with the curb, or terrified by abuse.

The most common pace in road-riding is the trot, which, in effect, is a rapid walk, and most difficult for a rider to perform with address and a small degree of fatigue to himself. In slow trotting, the body should adhere to the saddle, and when it becomes fast or rough, the body may be raised at the proper moments to ease the jolting. This rising of the body, however, is to be a result of the horse's action, not an effort of the rider. The proper method is to rise and fall with the leading foot, the body rising from the seat when the foot is elevated, and falling when it sinks.

In the course of either slow or fast riding, the horse may trouble his rider by plunging, shying, or restiveness. If he kick and plunge, sit upright, hold on by the legs, and do not vex him by any lashing; when let alone, he is not long in coming out of his freak. When he shies, or flies to one side, as if afraid of something, press him on the side to which he is flying, keep up his head, and bring him into his track. Pressing both legs against his sides will generally keep him from running backward. When he becomes restive—that is, turns round, and has a disinclination to go in the way he is required, the rider must keep him in his track by dint of pressure, a touch of the spur, and the hand. If he has been accustomed to spurs, and finds that your heels are not provided with these appendages, your case is very hopeless. We must allow Walker to point out the course to be pursued with a restive horse. If he persists in turning round, the rider must continue 'to attack his unguarded side, turn him two or three times, and let the heel and spur, if necessary, assist the hand, before he can arm or defend himself against it. If he still refuse to go the right way, the rider must take care that he go no other, and immediately change his attack, turning him about and reining him backward, which the horse is easily compelled to do when he sets himself against going forward. In these contests, the rider must be collected, and have an eye to the surrounding objects; for restive horses try their utmost to place their riders in awkward situations, by sidling to other horses, carriages, the foot-pavement, the houses, &c. In this case the rider, instead of pulling him from the wall, must bend his head to it, by which his side next the wall is rendered concave, and his utmost endeavours to do injury are prevented. The instant, therefore, that the rider perceives his horse sidling to any object, he must turn his head to that object, and back him from it. There are some horses who fix themselves like stocks, setting all endeavours to move them at defiance. There, happily, their defence can in no way endanger the rider. It must, however, be converted to punishment. Let them stand, make no attempt to move them, and in a short space—frequently less than a minute—they will move of themselves.' The same author recommends the rider to remain perfectly cool in all these awkward circumstances. 'When passion,' he observes, 'possesses the rider, it prevents that concord and unity taking place which ever should subsist between the rider and his horse. He should always be disposed to amity, and never suffer the most obstinate resistance of the horse to put him out of temper. If the contest does not demand his utmost exertion of strength, he should be able to hum a tune, or converse with the same composure and indifference as though his horse were all obedience. By these means the instant a horse finds himself foiled, he desists, having no provocation to contend farther, and is abashed at his own weakness. It is the absence of passion which, added to cool observation, makes the English the best riders and drivers in the world.'

Neither in the above section nor elsewhere have we said anything of the accoutrements of the horse, as every article of this kind must be left to the taste of the party concerned. The harness made by all saddlers is now both handsome, commodious, and durable, and so well calculated for the comfort of the wearers, that it would be superfluous to say anything respecting it, further than to recommend that it be always kept clean and glossy, and that it do not gall or press unduly on any part of the animal's body.

CATTLE—DAIRY HUSBANDRY.

NEXT to the horse, the cow is justly valued as the most useful animal which man has been able to domesticate and retain permanently in his service. The ox tribe, of which it is the female, belongs to the order *Ruminantia*, in the class *Mammalia*—these terms implying that the animals ruminate or chew their food a second time, and have mammæ or teats with which they suckle their young. In the ox tribe (*Bovidæ*) there are different species, all more or less varying from each other; and of the domesticated ox, the varieties from the effect of cultivation are now very numerous. The ox, in one or other of its varieties, for the sake of its labour as a beast of draught, for its flesh, or for the milk of its female, has been domesticated and carefully reared from the earliest times; in some countries having been raised to the rank of a divinity, or at least held as an object of extreme veneration.

The domesticated species of the family, common to Britain and adjacent parts of Europe, is, in all its varieties, materially altered from its wild parentage. Influenced by climate, peculiar feeding, and training in a state of subjection, its bony structure is diminished in bulk and power, its ferocity tamed, and its tractability greatly improved. Our observations in the present sheet will refer chiefly to the cow, on which very great changes have been effected by domestication; the most remarkable of these being her increased capacity for giving milk. In a wild state, the udder is small, and shrinks into an insignificant compass when the duty of suckling is over; but when domesticated for the sake of its milk, and that liquid is drawn copiously from it by artificial means, the lacteal or milk-secreting vessels enlarge, and the udder expands, so as to become a prominent feature in the animal. In this manner, by constant exercise, the economy of the cultivated species of cow has been permanently altered, and rendered suitable to the demands which are constantly made on it. Yet it is important to remark, that those milk-yielding powers are not equal in the different varieties or breeds of cows. Some breeds, from the influence of circumstances which it is here unnecessary to inquire into, give a large quantity of milk, but of a thin or poor quality, while others yield less milk, but of a good or rich quality. Whether, then, the cow-keeper wish *quantity* or *quality*, is the question for him to solve in making a selection of stock. In general, near large towns, where the demand for milk is considerable, the object of dairymen is to keep cows which will give a large quantity of milk, no matter of what sort. Private families in the country are usually more regardful of the quality of the article; they wish a little milk which is good, some fine cream, and perhaps also some well-flavoured butter and cheese, and on that account are more careful in the choice of their animals.

VARIETIES OR BREEDS.

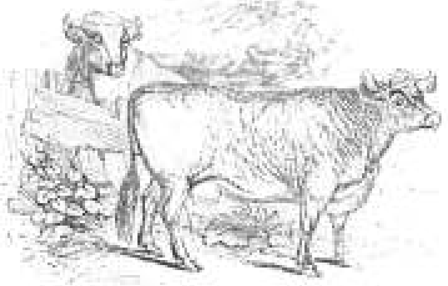
The breeds of cattle throughout the United Kingdom vary in different districts, from the small hardy varieties of the north Highlands to the bulky and handsome breeds of the southern parts of England. It has been customary to classify the whole according to the comparative length of the horns—as the long-horned, short-horned, middle-horned, crumpled-horned, and hornless or polled breeds. Besides these, there are many intermixed varieties or sub-breeds. The middle-horned cows, which are found in the north of Devon, the east of Sussex, Herefordshire, and Gloucestershire, and the breeds peculiar to Durham, Ayrshire, and Fifeshire, are among the most valuable and handsome of those now cultivated.

The intelligent author of the work on Cattle, published by the Society for the Diffusion of Useful Knowledge, thus describes what ought to be the proper form and shape of cattle:—'Whatever be the breed, there are certain conformations which are indispensable to the thriving valuable ox or cow. If there is one part of the frame the form of which, more than of any other, renders the animal valuable, it is the chest. There must be room enough for the heart to beat and the lungs to play, or sufficient blood for the purposes of nutriment and strength will not be circulated; nor will it thoroughly undergo that vital change which is essential to the proper discharge of every function. We look, therefore, first of all to the wide and deep girth about the heart and lungs. We must have both: the proportion in which the one or the other may preponderate, will depend on the service we require from the animal; we can excuse a slight degree of flatness of the sides, for he will be lighter in the forehand, and more active; but the grazier must have width as well as depth. And not only about the heart and lungs, but over the whole of the ribs, must we have both length and roundness; the *hooped* as well as the deep barrel is essential; there must be room for the capacious paunch, room for the materials from which the blood is to be provided. The beast should also be ribbed home; there should be little space between the ribs and the hips. This seems to be indispensable in the ox, as it regards a good healthy constitution and a propensity to fatten; but a largeness and drooping of the belly, notwithstanding that the symmetry of the animal is not improved, are considered advantageous in the cow, because room is thus left for the udder; and if these qualities are accompanied by swelling milk-veins, her value in the dairy is generally increased. This roundness and depth of the barrel, however, are most advantageous in proportion as found behind the point of the elbow more than between the shoulders and legs; or low down between the legs rather than upwards towards the withers: for the heaviness before, and the comparative bulk of the coarser parts of the animal, are thus diminished, which is always a very great consideration. The loins should be wide. Of this there can be no doubt, for they are the prime parts; they should seem to extend far along the back; and although the belly should not hang down, the flanks should be round and deep. Of the hips it is superfluous to say that, without being ragged, they should be large; round rather than wide, and presenting, when handled, plenty of muscle and fat. The thighs should be full and long, close together when viewed from behind, and the farther down they continue close the better. The legs may occasionally vary in length according to the destination of the animal; but shortness is a good general rule, for there is an almost inseparable connection between length of leg and lightness of carcass, and shortness of leg and propensity to fatten. The bones of the legs (and they are taken as a sample of the bony structure of the frame generally) should be small, but not too small—small enough for the well-known accompaniment, a propensity to fatten—small enough to please the consumer; but not so small as to indicate delicacy of constitution and liability to disease. Lastly, the hide—the most important thing of all—should be thin, but not so thin as to indicate that the animal can endure no hardship; movable, mellow, but not too loose, and particularly well covered with fine and soft hair.'

Of the various breeds and cross-breeds now common in Britain, there are a few which enjoy the best reputation. We may name, for example, the *Old Yorkshire Stock*—a cross between the *Teeswater* and *Holderness breed*—the *Long-horned* or *Lancashire breed*, the Short-

horned or *Dutch breed*, the *Middle-horned breeds of Devonshire, Sussex*, and *Hereford*, the *Ayrshire breed*, the *Fifeshire breed*, the *Alderney breed*, &c. Some of these merit particular attention:—

The *Short-horn* or *Teeswater* breed is considered of great value, both for milking and feeding. There are many varieties of it, known by the names of the counties where they have been raised. The best of these varieties are large in the carcass, well proportioned, broad across the loins, chine full, legs short, head small, but handsome, neck deep, but in keeping with the size of the body, colour generally red and white mixed, or what is called flecked, hide thin. The flesh of the true Short-horn is thick, close-grained, retaining the juices well; and from this circumstance is in request for victualling ships going on long voyages.



Short-Horn.

Regarding the milking qualities of this breed, Mr Dickson, an eminent cattle-dealer, who has had the most extensive experience throughout the whole country, says—'It has been frequently asserted that the short-horned cows are bad milkers: indeed, that no sort of cattle are so deficient in milk. But this deficiency of milk does not proceed from the circumstance of the cows being of the short-horned kind. Had the flesh been neglected as much as the milk by the eminent breeders, and the property of giving milk as much cherished as the development of flesh, the short-horned cows would have been deep milkers. Indeed, it is not to be doubted that, where the general secreting powers of the animal system have been increased, the power of secreting milk will be increased with the power of secreting fat; all that seems requisite is, to encourage the power of that secretion which is most wanted for the time. It would be to desire an impossibility to wish the full development of flesh, fat, and milk, at the same time; but there is no absurdity in desiring a large secretion of flesh and fat at one time, and a large secretion of milk at another, from the same cow. Accordingly, this is the very character which has been acquired by short-horned cows. They will yield from six to sixteen quarts a day throughout the season; and they are such constant milkers, that they seldom remain dry above six weeks or two months before the time of calving. I know a Scotch breeder who had a short-horned cow which gave fifteen quarts a day during the flush of the grass in summer, and never went dry for two seasons. A cross between a Galloway cow and a short-horned bull in Berwickshire yielded twenty pints a day during the best of the season, and she had to be milked five times a day to keep her easy.' We have thus considered it our duty to give the opinion of Mr Dickson regarding the value of the short-horned breed of cows as a dairy stock, seeing that the demand for short-horned bulls has of late years been great in many of the counties of both England and Scotland. It seems, however, a well-confirmed opinion, that the breed which of all others appears to be gaining ground throughout the United Kingdom for abundant produce on ordinary pasture, is the Ayrshire kyloe, which is described as without a parallel under a similar soil, climate, and relative circumstances, either for the dairy or feeding for the shambles. But the ever-variable circumstances in climate, soil, shelter, and the quality and quantity of the pasturage, as well as the nature of the winter feeding and general treatment, will always have an effect upon the stock.

The *Ayrshire* breed, which is considered the most valuable in Scotland, is of the small sized and middle-horned race; its origin is unknown, as it has been long settled in the county from which it derives its name. In modern times, the breed has been improved by judicious selection, coupling, and general treatment. The common characteristics of this excellent variety of cows are thus described by Mr Aiton in his 'Survey of Ayrshire:'—'Head small, rather long and narrow at the muzzle; eye small, smart, and lively; horns small, crooked, and set at considerable distances from each other; neck long, rather slender, tapering towards the head, with no loose skin below; shoulders thin; fore-quarters light; hind-quarters large; back straight, broad behind, the joints rather loose and open; carcass deep; legs small, short, with firm joints; udder capacious, stretching forward; the milk-veins large and prominent; teats short, all pointing outwards.' The Ayrshire cow is very docile, feeds well, is easily managed, and, as a dairy cow, is equal to any other. It is said to be inferior, however, for feeding, to the medium-horned Devon and Hereford breeds.

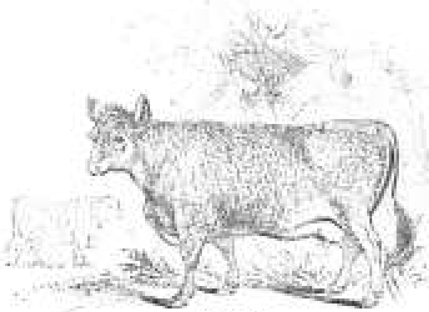
Ayrshire.

Many of the Ayrshire dairy cows, when properly fed, will yield from 6 to 8 gallons per day during a part of the summer. The quantity varies much during the year, from 1½ to 6 gallons, or more; and the highest average of the milk yielded by this breed is 1000 gallons per annum. It is only some of the finest cows that will yield such a quantity as this, and from 500 to 750 gallons may be calculated as the most general yearly produce. Every 2½ gallons of milk will afford 1 pound of butter, of 16 ounces to the pound, or 8 gallons will give 3 pounds. About 25 gallons of milk will give one stone of cheese, 14 pounds to the stone; and a good milch cow will thus produce 26 stones annually, which, at 10s. per stone, is £13 per annum for this article alone.

The *Devonshire* is a handsome breed of cattle, well set upon their legs, straight along the back, small muzzle, generally red in colour, and both as oxen and cows they feed well at an early age. The cow is much smaller than the bull, but roomy for breeding, and is distinguished for her clear round eye and general loveliness and neatness of features. Fed on the fine pastures of North Devon, the cow yields a rich quality of milk, and in reasonable abundance. The North Devon breed prevails in some parts of Somersetshire, and has been introduced into other districts of the country, but is not considered suitable in situations greatly differing in climate and herbage from its native county, which, on the whole, is mild, and rather moist.

The *Hereford* breed is larger than that of North Devon. It is broad across the hind-quarters, narrow at the sirloin, neck and head well proportioned, horns of a medium size, turned up at the points, colour deep red, but with face and some other parts generally white, and countenance cheerful and sagacious. This breed is reckoned among the best in England as respects the abundant production of milk, and when too old for that purpose, it fattens to a greater weight than the North Devons.

The *Galloway* breed of cattle is well known for various valuable qualities, and easily distinguished by the want of horns. It is broad across the back, with a very slight curve between the head and quarters, broad at the loins, the whole body having a fine round appearance. The head is of a moderate size, with large rough ears, chest deep, legs short, and clean in the neck. The prevailing colour is black, those of this colour being thought the most hardy, although this varies. This breed is highly esteemed, as there is no other kind which arrives at maturity so soon, and their flesh is of the finest quality. The milk is very fine, but is not obtained in very large quantities. Great numbers of this breed are sent annually to Smithfield market; and it is remarkable that they are generally in as good condition after the journey as before. The *Suffolk* dun,



Suffolk.

also a hornless breed, is supposed to be a variety of the Galloway, from their general resemblance. 'Some exaggerated accounts,' says Mr Youatt, 'have been given of the milking properties of the Suffolk cow; but nevertheless she is not inferior to any other breed in the quantity of milk that she yields. In the height of the season some of these cows will give as much as eight gallons of milk in the day, and six gallons is not an unusual quantity. The produce of butter, however, is not in proportion to the quantity of milk. The Rev. Mr Aspin of Cockfield had three cows, one of them a heifer with her first calf. They were kept on three acres only of grass, without any change of pasture, until after mowing time, and in the winter chiefly on straw, with very little hay. Both the old ones yielded eight gallons of milk per day during the height of their season, and the quantity of butter made from June to December was 613 pounds. The Rev. Arthur Young, the secretary to the Board of Agriculture, forty years ago, adds, that one Holderness cow would have consumed all the food of the three without returning half of the produce. There are few short-horn cows, although far superior in size to the Suffolks, and consuming nearly double the quantity of food, that will yield more milk than is usually obtained from the smaller polled breed. Fifty thousand firkins of butter are sent to London every year from Suffolk, of which each cow furnishes on an average three firkins, each firkin weighing half a hundredweight; and this independent of three-fourths of a wey of cheese.'

The *Improved Kerry* is an Irish breed, of rather diminutive size, hardy, and which can subsist on scanty pasture. This renders them exceedingly well adapted for hilly pastures, and for cottagers who may not have the best food to offer their stock. Their milk and butter are rich in quality, and for their size they are good milkers. They are quiet enough when let alone, but if the least irritated, no fence can contain them. The Irish cows have improved very much of late years, in consequence of crossing with English stock; and they are now in many respects thought equal to the breeds of either England or Scotland.

The *Long-horned* or Lancashire is distinguished by the length of its horns, the thickness of its hide, and the large size of its hoofs. It is far from being a handsome animal; nor is it held in very general estimation either for milking or for feeding.

The cattle of the *Highlands of Scotland* are of small bulk, and very hardy. The most esteemed are those belonging to the Western Highlands and Isles, called the Argyleshire breed, and frequently *kyloes*. It is thought that this breed might be much improved by judicious crossing, as was seen in the case of the Ayrshire kyloe, formerly mentioned. This breed is rather handsome in appearance; the horns are long and upright, head large, neck short and deep, legs of a good length, and the beef is in general estimation. The cattle of the Highlands and Isles are bred on an extensive scale of farming, for the purpose of sending to the southern markets. Small in size at first, they increase in bulk as they are transferred to a more genial climate and richer pasturage as they proceed southward, till, by annual stages, they reach the neighbourhood of London, when they are large and heavy. These breeds may therefore be considered an object of culture for the shambles rather than for the dairy.

The *Alderney* breed of cattle is awkwardly shaped, with short bent horns, and light-red, dun, or fawn-coloured skins. The appetite of the cow is voracious, and it yields little milk; but that is of an exceedingly rich quality, and the animal is on that account frequently preferred by country families, who do not regard the expense of keep.

We have thus briefly treated of some of the many breeds of cattle considered valuable as dairy stock in Britain; but we pretend not to give any decided opinion as to which is best. The merits of each have been vigorously contested by their respective advocates, and it would be extremely difficult to decide between them. Upon the form and qualifications of a perfect cow, it ought to be observed, that whatever breed is selected, there is a wide difference between the form of one meant for fattening and that intended for the dairy. The first should resemble the ox as nearly as possible; while the latter should be long and thin on the head, with a brisk, quiet eye, lank in the neck, narrow across the shoulders, but broad at the haunches; and there should be no tendency to become fat. The udder should be large and full-looking, but not protruding too far behind; the teats all pointing out and downwards, equal in size, and rather long and tapering. A cow with a high backbone, large head, small udder, and showing an inclination to become fat, will be found to be a bad milker. This description applies to all breeds; and of course the difference between a cow for fattening and one for yielding milk will be comparative.

Mr Aiton mentions the following as the most important qualities of the dairy cow:—'Tameness and docility of temper greatly enhance her value. One that is quiet and contented feeds at ease, does not break over fences, or hurt herself or other cattle, will always yield more milk than those who are of a turbulent disposition. To render them docile, they ought to be gently treated, frequently handled when young, and never struck or frightened. Some degree of hardiness, however, a sound constitution, and a moderate degree of life and spirits, are qualities to be wished for in a milch cow, and what those of Ayrshire generally possess. Some have thought that a cow living on a small quantity of food was a valuable quality, but that will depend on the quantity of milk given by the cow that eats little compared with those that eat much. If the cow that eats little gives as much milk as the one that eats more, it certainly is a valuable quality; but of this I entertain doubts, which forty years' experience and observation have served to confirm. Speculative writers affirm that some cows will fatten as well, and yield as much milk, when fed on coarse, as others will do on rich food. Cows that have been reared and fed on coarse pasture will yield some milk of a good quality, and from which the best butter may be extracted; while a cow that has been reared and fed on much better pasture, would, if turned on that which is bad, give scarcely any milk. But if a cow that has been accustomed to feed on bad pasture be put on that which is better, she will greatly increase in milk, and fatten much faster. If two cows of the same age and condition, and which have been reared and fed on food of equal quality, are put, the one on bad food, and the other on that which is good, the latter will yield four times the milk, and fatten four times faster than the former. A cow need not always be fed on green clover, cabbages, and cauliflower; but she will neither fatten nor yield milk if she gets no better fare than rushes, bent, and sage grass.' A writer in the 'Farmer's Magazine,' some years ago presented the following doggrel lines, as combining what are popularly considered the good points of a cow, such as is common among the short-horned breed of Yorkshire and Durham :—

'She's long in her face, she's fine in her horn,
She'll quickly get fat without cake or corn;
She's clean in her jaws, and full in her chine,
She's heavy in flank, and wide in her loin.

She's broad in her ribs, and long in her rump,
A straight and flat back, without e'er a hump;
She's wide in her hips, and calm in her eyes,
She's fine in her shoulders, and thin in her thighs.

She's light in her neck, and small in her tail,
She's wide in her breast, and good at the pail,
She's fine in her bone, and silky of skin—
She's a grazier's without, and a butcher's within.'

To insure the perpetuation of valuable qualities in cows, it is necessary to breed from good bulls of a variety similar to the cows. The heifer or young cow, if properly pastured, should begin to breed at two years, or not beyond two and a half years old. The cow is at her prime at from four to six years, and declines into old age at ten or eleven years, when it is customary to fatten her for market. Dairymen, in selecting cows, prefer those which have had their third or fourth calf when they have attained their fifth or sixth year. The bull is in his prime at three years, and should not be used after eight or nine years old.

GENERAL MANAGEMENT OF THE COW.

The cow goes with young nine calendar months, or 270 days; but this length of time is liable to variation, from the effect of circumstances. A calf is most likely to survive and be healthy which has been carried exactly the nine months. Cows come into season at different periods of the year, in which state they remain for a few days, after which the affection ceases, but it afterwards returns in three or four weeks. The farmer watches these periods, and permits the company of the bull at such a time as will produce the young at a season of the year when grass is plentiful for the nourishment of the mother. This should generally be an advanced period of spring, for the cow will require nourishing diet some time before she drops her calf as well as afterwards.

A cow may be kept in milk up to the time of her calving, by daily taking a quantity from her; but this is most injurious to the fœtus, and the excitement of the new upon the old milk is apt to produce local inflammation. In towns, where dairymen care nothing for the calf, and must have milk at all risks, cows are often maltreated by being milked to the last; but no one who conducts a dairy on proper principles will be guilty of this inhumanity. The best plan is to allow the cow to go gradually dry, and not milk her at all for six or eight weeks before calving. This will keep her in a reasonably good condition, and save extra food, which it is not advantageous to give on a luxuriant scale, because high feeding at this period may induce inflammation and fever at calving.

Calving—Treatment of the Calf.

No animal is so liable to abortion as the cow: it takes place at uncertain periods during the pregnancy; sometimes it occurs from fright, teazing by other cattle in the field, or from over-high condition; but also not unfrequently from some bad habit acquired by the animal. It has been found that the habit is infectious; and when once it has got among a parcel of cows, it can be banished only with the greatest difficulty. In all cases the aborted fœtus should be buried deep and far from the cow pasture; the cow physicked, and its parts washed with chloride of lime; the cow-house thoroughly lime-washed and otherwise purified; and lastly, the cow fattened and sent to market.

If in a state of health, no difficulty will occur at the parturition; but should the case be otherwise, we prefer leaving the cow-keeper to ask assistance from a person of practical skill, or veterinary surgeon, than to offer any speculative advices on the subject. With respect to the treatment after calving, we beg to quote the following directions from the volume on Cattle, 'Library of Useful Knowledge:'—'Parturition having been accomplished, the cow should be left quietly with the calf; the licking and cleaning of which, and the eating of the placenta, if it is soon discharged, will employ and amuse her. It is a cruel thing to separate the mother from the young so soon; the cow will pine, and will be deprived of that medicine which nature designed for her in the moisture which hangs about the calf, and even in the placenta itself; and the calf will lose that gentle friction and motion which help to give it the immediate use of all its limbs, and which, in the language of Mr Berry, "increases the languid circulation of the blood, and produces a genial warmth in the half-exhausted and chilled little animal." A warm mash should be put before her, and warm gruel, or water from which some of the coldness has been taken off. Two or three hours afterwards, it will be prudent to give an aperient drink, consisting of a pound of Epsom salts and two drachms of ginger. This may tend to prevent milk fever and garget in the udder. Attention should likewise be paid to the state of the udder. If the teats are sore, and the bag generally hard and tender, she should be gently but carefully milked three or four times every day. The natural and the effectual preventive of this, however, is to let the calf suck her at least three times in the day if it is tied up in the cow-house, or to run with her in the pasture, and take the teat when it pleases. The tendency to inflammation of the udder is much diminished by the calf frequently sucking; or should the cow be feverish, nothing soothes or quiets her so much as the presence of the little one.' For instructions respecting the condition and diseases incidental to cows at and after the period of calving, we must refer to the valuable work now quoted.

If the calf be a male, and is to be pastured and fattened for market, or to be bred as a working ox, it should be cut between the first and third months; if deferred later, the operation is dangerous. Whether calves are kept for veal or for stock, they are begun to be fed in the same manner, by sucking milk from a dish. As they naturally seek for the teat when their nose is put to the dish, the fingers of the attendant may be put into their mouth when in the milk, and this will set them going in the art of artificial sucking. 'The milk,' says the author of Clerical Economics, 'should be given to them sparingly at first, to render their appetite more keen, and prevent them from loathing at their food. For the first two weeks they should be fed on the milk first drawn from the cow, locally termed the *forebroads*, which abounds with serum; and as they grow up, the quantity of milk is gradually increased to as much as the calves can be made to drink. After the first two or three weeks, by all means give them plenty of milk, warm from their mother; and let it be that which is last drawn from the cow, locally termed *afterings*, which are much richer. Keep abundance of dry litter under them. Have them in a place that is well aired, and of a uniform temperature, neither too hot nor too cold; let the apartment be quite dark, excepting when the door is opened to give them food. If they enjoy the light, they become too sportive, and will not fatten. Take care they are fastened to the wall, in such a way, by "swivels," that they cannot hang themselves. Never let them make their escape at the door, or, by their running and jumping, they will do more injury to themselves in three minutes than a week's feeding will make up. Don't keep them till they become too old, because, when they begin to grow to the bone, they require more milk than the manse can generally produce; and whenever they cease to advance in the fattening process, they begin to recede, and the milk for a week or two is lost. They should be kept from four to seven weeks, according as milk may be abundant and rich. If a calf be kept long, during the last two or three weeks it will require the richest part of the milk of at least two or three cows to bring it to the highest pitch of fatness. When the milk begins to fall short of the calf's appetite, some mix eggs, and others peas-meal, into their food; others try infusions of hay, oil-cake, and linseed; but none of these additions are approved of by those who feed calves to the greatest perfection. Meal is understood to darken the flesh, web, and lights of the animal; but sago has of late years been almost, from the first two or three weeks, boiled and mixed in its liquid state with the milk, and to great advantage. Begin with a saucerful of it or so, and gradually increase the quantity. Calves are very fond of chalk, and they also feel the want of salt. If a calf happens to be dropt about the middle of summer, when the processes of butter and cheese making wont admit of their being fattened to perfection, they are sometimes, even at the manse, brought sparingly forward for two or three months on whey and skimmed milk; and in November, when veal is very high priced, they are fattened at considerable cost, and sold so as to yield a great return, owing both to their weight and the high markets at that season of scarcity. A calf well managed in ordinary seasons and prices, should yield, when sold, six or seven shillings for every week it has been kept and fattened.'

Cow-house—Cleaning.

The cow-house should be airy and well ventilated, of moderate temperature, and kept very clean. The stalls for the cows should be paved with smooth stones, slope gently towards the foot, where there should be a clear run of a gutter to carry off the urine to a pit outside. (See No. 31.) The stalls must be daily scraped and swept, and all refuse carried out to the dung-heap. In general, far too little litter is allowed. The cow should have plenty of straw bedding, kept in a cleanly condition; and this, when soiled, is to be mixed with the dung for manure. The only fastening for the cow should be a chain to go round the neck, with the other end round an upright post, but easily movable up and down, and allowing room for the animal shifting its position. The feeding manger or stone trough is on the ground, and ought to be kept free of all impurities; for though the cow is not so nice as the horse, it has a disinclination for food not fresh and cleanly.

Except in dairies of a high order, it is customary to keep cows in a shamefully unclean condition. The floor of their habitation is filthy, the walls ragged and full of vermin, and the hides of the animals dusty or barkened with dirt. Persons who keep cows are not aware of the loss they incur from allowing them to live in this uncleanly state. Some people seem to think that they do quite enough for their cows if they give them food and shelter; but besides this, they require to be kept very cleanly, though seldom indulged in that luxury. The cow should be curried daily like the horse; its hide should be freed from all impurities, and relieved from everything that causes uneasiness. When you see a cow rubbing itself against a post, you may depend on it that the animal is ill kept, and requires a good scrubbing. Irritation of the skin from impurities also causes them to lick themselves, a habit which is injurious, for the hairs taken into the stomach form a compact round mass, which may destroy the animal. If well curried, any danger from this catastrophe is avoided, the health is generally improved, and this improves the quality of the milk, besides increasing the quantity. A cottager might easily make two or three shillings more of his cow weekly by attention to this point; and if he at the same time took pains to preserve all the liquid refuse of the cow-house, he might double that amount. How strange to reflect, that many decent and well-meaning, but ignorant and rather lazily-disposed people, are suffering a loss of four or five shillings weekly from no other cause than this! It is long, however, before old habits are eradicated, and new and better ones established.

Feeding—Modes of.

The cow requires to be supplied with an abundance of food, not to make her fat, which is not desirable, but to keep up a regular secretion of milk in the system. The feeding must be regular, from early morning to night, and pure water must also be offered at proper intervals, if the animal has not the liberty of going to the water herself.

Regarding the nature of the food of cows, although soiling, or artificial feeding in the house, is at all times economical, there can be no doubt that the best milk and butter are produced by cows fed on natural pasture; and although the quantity of milk is not so great, yet the butter has a sweet taste, never to be discovered in the produce of soiled cows. It was formerly the case in Scotland, and the practice is still continued in some parts, to put the cows out to grass in spring, in such an emaciated state, that a considerable part of the best season was gone before they yielded the quantity of milk they would otherwise have done. On well-enclosed farms, it is the custom of many to keep their cows out both night and day, from May till the end of October, so long as a full bite can be obtained; and some bring them into the house twice a day to be milked. In moorish and unenclosed districts, they are put under the charge of a herd through the day, and are brought into the byres during the night. In either case, exposure to wet and cold, or to extreme heats, should be guarded against.

Soiling, or feeding entirely in the house or court-yard, is seldom practised, except by some farmers in arable districts. Although complete soiling is only occasionally resorted to, yet a considerable quantity of rich green food is served out to the dairy stock in their stalls at night, and in the heat of the day, by such farmers as bring their cows into the house at these times. This mode of feeding is more especially followed when the pasture begins to fail; the second crops of clover and tares, cabbages, coleworts, and other garden produce, are all given to the cows in the house at this period. It is upon this system that the whole perfection of the Flemish husbandry is founded, and it could be put in practice, with the most beneficial results, in many other countries. (See No. 32, pp. 509–10.) In Holland, the cows, when fed in the house, have their drink of water invariably mixed with oil-cake, rye, or oatmeal. Dairy cows are allowed to be much injured by being denied a due supply of salt, which is said to improve the quality and increase the quantity of the milk. In the best-managed dairies in Scotland, when the cows are taken in for the winter, they are never put out to the fields until spring, when the grass has risen so much as to afford a full bite. In the moorish districts, however, they are put out to the fields for some hours every day when the weather will permit. In these districts, the winter food is turnips with marsh meadow hay, occasionally straw, boiled chaff, and other refuse from the barn.

In the richer districts, turnips and straw are given, and occasionally some clover hay in spring, or when the cows have calved. Upon this subject nothing need be added, but that the quantity and quality of the milk will be in proportion to the nourishment in the food. White turnips afford a good quantity of milk, but they impart a very disagreeable taste, which may be removed, however, by steaming or boiling the turnips, or by putting a small quantity of dissolved saltpetre into the milk when new drawn. The quality of the milk depends a great deal on the cow, influenced, however, by the food she eats. Linseed, peas, and oatmeal, produce rich milk; and a mixture of bran and grains has been recommended as food in winter. Brewers' grains are said to produce a large quantity of milk, but very thin, the quality being somewhat similar to that sold in large towns, yielding neither good cream nor butter. It has been found of some importance to feed cows frequently—three or four times a day in summer, and five or six in winter, and to give them no more at a time than they can eat cleanly.

What has been stated regarding the feeding of cows applies principally to those kept on dairy farms. In establishments for the supplying of large towns with milk, the method of feeding is somewhat different; there the practice is to feed them chiefly on distillers' wash, brewers' grains, and every sort of liquid stuff that will produce a large quantity of milk, without reference to its quality. The Edinburgh cow-keepers begin to feed with grain, dreg, and bran mixed together, at five o'clock in the morning; feed again at one o'clock afternoon; and a third time at seven or eight o'clock in the evening: grass in summer, and turnips and potatoes in winter, being given in the two intervals. The grass is laid upon the straw, in order to impart to it a certain flavour, and make it palatable; it is eaten after the grass: and in winter, straw or hay is given after the turnips. Part of the turnips and potatoes are boiled, particularly when there is a scarcity of grains. For the mode of feeding in the large London dairies, see the concluding pages of the present number.

The following is mentioned in the 'Farmer's Magazine' as an improved mode of feeding milch cows, near Farnham, in Surrey:—'Go to the cow-stall at six o'clock in the morning, winter and summer, give each cow half a bushel of the mangel-wurzel, carrots, turnips, or potatoes, cut; at seven o'clock, the hour the dairy-maid comes to milk them, give each some hay, and let them feed till they are *all* milked. If any cow refuses hay, give her something she will eat—such as grains, carrots, &c.—during the time she is milking, as it is *absolutely necessary* the cow should feed whilst milking. As soon as the woman has finished milking in the morning, turn the cows into the airing ground, and let there be plenty of *fresh water* in the troughs: at nine o'clock, give each cow three gallons of the mixture (as under—to eight gallons of grains add four gallons of bran or pollard); when they have eaten that, put some hay into the cribs: at twelve o'clock, give each three gallons of the mixture as before. If any cow looks for more, give her another gallon. On the contrary, if she will not eat what you give her, take it out of the manger, for never at one time let a cow have more than she will eat up *clean*. Mind and keep your mangers clean, that they do not get sour. At two o'clock, give each cow half a bushel of carrots, mangel-wurzel, or turnips; look the turnips, &c. over well, before you give them to the cows, as one rotten turnip, &c. will give a bad taste to the milk, and most likely spoil a whole dairy of butter. At four o'clock, put the cows into the stall to be milked; feed them on hay as you did at milking-time in the morning, keeping in mind that the cow, whilst milking, must feed on something. At six o'clock, give each cow three gallons of the mixture as before. Rack them up at eight o'clock. Twice in a week put into each cow's feed at noon a quart of malt-dust.' The writer of these directions adds, that the daily expense of subsisting each cow on the above feed would be about two shillings.

Milking.

Cows are milked twice or thrice a day, according to circumstances. If twice, morning and night: if thrice, morning, noon, and night. They should not go too long unmilked, for, independently of the uneasiness to the poor animal, it is severely injurious.

The act of milking is one which requires great caution; for if not carefully and properly done, the quantity of the milk will be diminished, and the quality inferior—the milk which comes last out of the udder being always the richest. It should therefore be thoroughly drawn from the cows until not a drop more can be obtained, both to insure a continuance of the usual supply of milk, and also to get the richest which the cows afford. Cows should be soothed by mild usage, especially when young; for to a person whom they dislike, they never give their milk freely. The teats should be always clean washed before milking, and when tender, they ought to be fomented with warm water. The milking and management of the cow should, in these circumstances, be intrusted only to servants of character, on whom the utmost reliance can be placed. In the southern and midland counties of England, it is a common practice to employ men to milk the cows, an operation which seems better fitted for females, who are likely to do the work in a more gentle and cleanly manner, which is of essential importance.

The writer in the magazine above quoted, gives the following explicit directions to the dairy-maid in regard to milking:—'Go to the cow-stall at seven o'clock; take with you *cold water* and a sponge, and wash each cow's udder clean before milking; douse the udder well with *cold* water, winter and summer, as it braces and repels heats. Keep your hands and arms clean. Milk each cow as dry as you can, morning and evening; and when you have milked each cow as you *suppose* dry, begin again with the cow you first milked, and drip them each; for the principal reason of cows failing in their milk is from negligence in not milking the cow dry, *particularly* at the time the calf is taken from the cow. Suffer no one to milk a cow but yourself, and have no gossipping in the stall. Every Saturday night give in an exact account of the quantity of milk each cow has given in the week.'

GENERAL TREATMENT OF CATTLE.

Cattle are subject to various diseases, the result of improper treatment, or of causes connected with climate, which it is difficult to avert. By attention to feeding, housing, and cleaning, as already noticed, much may be done to prevent some of the more fatal distempers. Cattle that have passed their lives, both day and night, in the open air, are generally so hardy, that they are not injured by a wetting of the skin, and are liable to few of the complaints of dairy or stall-fed animals. Cows, being compelled to lead an artificial mode of life, are the most delicate in every respect, and require the most careful treatment. They should not be left out all night; and when they return from the field wet, it is always a safe and humane plan to dry them with a wisp of straw. The diseases to which they are most liable are of an inflammatory kind, and for these the veterinary surgeon prescribes bleeding, and perhaps some medicines to be taken internally. Leaving cow-keepers to seek the advice of those professional men, or at least of persons possessing practical skill, we need here allude only to three common disorders for the sake of general information.

Diseases—The Hove.

The hove, or blown, in cattle is a swelling in the paunch, caused generally by eating wet grass or clover in warm weather. The substance ferments, and the membrane becomes distended by the creation of air or gas, which cannot find the means of escape; and if not taken off artificially, the animal will be suffocated. Mr Loudon, in his 'Encyclopædia of Agriculture,' mentions the following methods of relief from this fatal distension:—'There are three modes of relieving the complaint, which may be adverted to, according to the degree of distension and length of time it has existed. These are, internal medicines; the introduction of a *probang* of some kind into the paunch by the throat; and the puncturing it by the sides. 'Dr Whyatt, of Edinburgh, is said to have cured eighteen out of twenty hoved cows, by giving a pint of gin to each. Oil, by condensing the air, has been successfully tried. Any other substance, also, that has a strong power of absorbing air may be advantageously given. Common salt and water, made strongly saline, is a usual country remedy. New milk, with a proportion of tar equal to one-sixth of the milk, is highly spoken of. A strong solution of prepared ammonia in water often brings off a great quantity of air, and relieves the animal. Any of these internal remedies may be made use of when the disease has recently taken place, and is not in a violent degree; but when otherwise, the introduction of an instrument is now very generally resorted to.

The instrument principally in use is a species of probang, invented by Dr Munro of Edinburgh. Another, consisting of a cane of six feet in length, and of considerable diameter, having a bulbous knob of wood, has been invented by Eager, which is a more simple machine, but hardly so efficacious. It is probable that, in cases of emergency, even the larger end of a common cart-whip, dexterously used, might answer the end. But by far the best instrument for relieving hoven cattle, as well as for clystering them, is Read's enema apparatus, which is alike applicable to horses, cattle, and dogs. It consists of a syringe, to which tubes of different kinds are applied, according to the purpose and the kind of animal to be operated upon. There is a long flexible tube for giving an enema to horses and cattle, and a smaller one for dogs. To relieve hoven bullocks effectually, it is necessary not only to free the stomach from an accumulation of gas, but from the fermenting pultaceous mixture which generates it; for this purpose a tube is applied to the extremity of the syringe, and then passed into the animal's stomach through the mouth, and being put in action, the offending matter is discharged by a side opening. When the same operation is performed on sheep, a smaller tube is made use of. The characteristic excellency of Read's instrument is, that there is no limit to the quantity of fluid that may be injected or extracted. The same syringe is used for extracting poison from the stomach of man, for smoking insects, extinguishing fires, and syringing fruit-trees. The introduction of any of these instruments may be effected by the help of an assistant, who should hold the horn of the animal by one hand, and the dividing cartilage of the nose with the other; while the operator himself, taking the tongue in his left hand, employs his right in skilfully and carefully introducing the instrument; the assistant bringing the head and neck into such an attitude as to make the passage nearly straight, which will greatly facilitate the operation.

When no instruments can be procured, or as cases may occur when indeed it is not advisable to try them—as when the disease has existed a considerable time, or the animal has become outrageous, or the stomach so much distended with the air, that there is danger of immediate suffocation or bursting—in these instances the puncture of the maw must be instantly performed, which is called *paunching*. This may be done with the greatest ease, midway between the ilium or haunch-bone, and the last rib of the left side, to which the paunch inclines: a sharp penknife is frequently used; and persons in veterinary practice should always keep a long trocar, which will be found much the most efficacious, and by far the most safe, as it permits the air escaping certainly and quickly, at the same time that it prevents its entrance into the cavity of the abdomen, which would occasion an equal distension. As soon as the air is perfectly evacuated, and the paunch resumes its office, the trocar may be removed; and in whatever way it is done, the wound should be carefully closed with sticking-plaster or other adhesive matter. It is necessary to observe, that this operation is so simple and safe, that whenever a medical assistant cannot be obtained, no person should hesitate a moment about doing it himself.

After relief has been afforded by means of either the probang or the paunching, a stimulant drink may be very properly given: half a pint of common gin, or one ounce of spirit of hartshorn in a pint of ale, or two ounces of spirit of turpentine in ale, may any of them be used as an assistant stimulus. When, also, the cud is again chewed, still some relaxation of the digestive organs may remain; at first, therefore, feed sparingly, and give for a few mornings a tonic.' The apparatus mentioned above, with directions for use, may now be had from the principal makers of or dealers in agricultural implements. The cane tube, to employ in emergencies, no cow-keeper should be without.

Epidemic Murrain.

The malignant epidemic, generally called murrain, is a species of catarrh, affecting the respiratory organs, and is most frequent in damp climates or ill-drained parts of the country. The writer of the work on cattle, already quoted from ('Library of Useful Knowledge'), thus speaks of its nature and remedies:—'There are few diseases that assume, in its earlier or later stages, a greater variety of form; but, disarmed somewhat of its virulence in modern times, or at least not having appeared in all its terrors for some years past [written in 1830], it will generally be distinguished by some or the greater part of the following symptoms:—

There will be cough, frequent and painful, and in many cases for a week or more before there is any other marked symptom. The farmer may not always be aware of this, but he will find it out if he inquires about it; and he will be fully aware of the importance of the fact before we shall have done with this division of our subject.

After a few days, some heaving of the flanks will be added to the cough; the pulse will be small, hard, frequent, and sometimes irregular; the mouth hot; the root of the horn cold; the fæces sometimes hard and black, at others liquid and black, and then very fetid. Presently afterwards, that of which we have to speak again and again, is observed—extreme tenderness along the spine, and particularly over the loins.

The cough becomes more frequent and convulsive, and a brown or bloody matter runs from the nostrils and mouth; the eyes are swelled and weeping; the patient grinds his teeth; there is frequent spasmodic contraction about the nostrils; and the animal rarely lies down, or, if he does, rises again immediately.

The eyes soon afterwards become unusually dull; the pulse remains small, but it has become feeble; the respiration is quicker; the flanks are tucked up; the tenderness on the loins is removed; insensibility is stealing over the frame; and the fæces are more loaded with mucus, and more fetid. The patient moans and lows, and grinds his teeth almost incessantly; the head is agitated by a convulsive motion; blood begins to mingle with the fæces; the breath, and even the perspiration, become offensive; and the poor animal staggers as he walks.

Tumours and boils now, or often earlier, appear on various parts. If they are to come forward, the sooner they rise the better, for much depends on what becomes of them. If the animal has sufficient strength for them to go through the usual process of suppuration, although the sloughing and the stench may be greater than could be thought possible, the beast will have a chance to recover; but if there is not energy to bring these tumours forward—if they become stationary—and most assuredly, if they recede and disappear, the patient will die.

The treatment of this disease is most unsatisfactory. If the farmer could be brought to attend more to this cough in cattle, if here he had recognised the violent and increasing cough, and, although he had not dreamed of murrain, had bled and physicked the beast on account of the cough, the disease would probably have been arrested, or at least its virulence would have abated at that stage.

The early stage even of murrain is one of fever, and the treatment should correspond with this—bleeding. Physic should be cautiously, yet not timorously resorted to. For sedative medicines there will rarely be room, except the cough should continue. Small doses of purgative medicine, with more of the aromatic than we generally add, will be serviceable, effecting the present purpose, and not hastening or increasing the debility which generally is at hand; but if the bowels are sufficiently open, or diarrhœa should threaten, and yet symptoms of fever should be apparent, no purgative must be given, but the sedatives should be mingled with some vegetable tonic. The peculiar fetid diarrhœa must be met with astringents, mingled also with vegetable tonics. In combating the pustular and sloughing gangrenous stage, the chloride of lime will be the best external application; while a little of it administered with the other medicines inwardly, may possibly lessen the tendency to general decomposition. The external application of it should not be confined to the ulcerated parts alone, but it should be plentifully sprinkled over and about the beast; and the infected animal should be immediately removed from the sound ones.'

Red-Water.

This disease, indicated at first by the redness of the urine, is properly inflammation of the kidneys, and arises from an undue determination of blood to these parts of the animal. The cause of this local inflammation is generally connected with the nature of the food. In many instances, it is found to have arisen from the cattle eating plants of a noxious quality, and which, as it appears, are not confined to any particular species of soil. When in its aggravated form, the disease becomes what is called *Black-Water*. On the slightest indication of the early stages of the distemper, the cattle ought to be immediately shifted to different pasture, or housed and stall-fed for a short period; and if this simple precaution prove unavailing in restoring health, each animal affected should be copiously, and if necessary, frequently bled; and let that active treatment be followed up by purgatives, so as to clear out and restore a proper tone to the bowels. Should these means fail, let a skilled practitioner be consulted. On no account listen to the absurd advices of superstitious and ignorant people either on this or any other disease of cow or bullock. In every quarter of the country, there are persons who, from total ignorance of the physiology of cattle, and the natural causes and action of disease, ascribe calamities of this kind to witchcraft or other supernatural influences. Let all such quacks, and their irrational salves, be carefully shunned.

Fattening for Market.

The stall-feeding or soiling of cattle is considered to possess several advantages over feeding in the fields. In field-feeding, the animals waste a certain quantity of pasture by treading and lying upon it, and by dropping their dung, the grass which grows on the dung spots being ever after rejected; the animals also spend time in seeking for the herbage which suits their fancy, and much is allowed to go to seed untouched. In stall-feeding, the whole time is devoted to eating and ruminating, while no food is lost, and the animals are brought to a higher condition. Another important advantage of soiling is, that it uses up the waste straw of a farm as litter, and thus furnishes a plentiful supply of that indispensable article, manure, for the fields. Some feeders tie up their cattle to the stall while preparing for market; but others permit them to roam about on a thick bed of straw in an enclosure in the farm-yard, with a shed to retire to for shelter, the feeding in this case being from racks. Unless for a period during the final process of fattening, the straw-yard method is reckoned the best for keeping the cattle in a healthy state, and consequently for producing beef of the finest kind. The practice of feeding cattle for a considerable length of time, in darkened stalls, on oil-cake, turnips, mangel-wurzel, &c. produces, as is well known, a great deposition of fat, and swells the animals to a monstrous size. The beef, however, of such over-fed cattle is never fine. The fat with which it is loaded easily escapes in cooking, and leaves lean of an inferior quality. The best sign of good meat is its being *marbled*, or the fat and lean well mixed, when brought to the table, and this is not to be expected from beef fed in an unnatural condition.

Speaking on this subject, the writer of the article Agriculture, in the 'Encyclopædia Britannica,' observes—' The age at which cattle are fattened depends upon the manner in which they have been reared, upon the properties of the breed in regard to a propensity to fatten earlier or later in life, and on the circumstances of their being employed in breeding, in labour, for the dairy, or reared solely for the butcher. In the latter case, the most improved breeds are fit for the shambles when about three years old, and very few of any large breed are kept more than a year longer. As to cows and working oxen, the age of fattening must necessarily be more indefinite; in most instances, the latter are put up to feed after working three years, or in the seventh or eighth year of their age.'

Many of the cattle fed for the metropolitan markets, as formerly mentioned, have originally been brought from the Highlands and Isles of Scotland, also from Wales and Ireland. According to the General Report of Scotland, ' the Highland cattle often pass through three different hands or more before they come to the butcher. They are improved at every stage by a greater quantity and better quality of food, instead of being suddenly transported from poor to rich feeding; and while each successive owner applies his produce to the best advantage, and receives a suitable return according to its value from the advance of price, the consumer at last purchases his beef cheaper, and of a much superior quality, than if the cattle had been at once prepared for the shambles at any of the intermediate stages.

The West Highland cattle make this progress oftener than the larger cattle of the north-eastern counties. Many of them are brought to Dumbartonshire and other places at the age of two years and two years and a half, wintered on coarse pastures, with a small allowance of bog-hay or straw, and moved to lower grounds next summer. They are then driven further south, where they get turnips in straw-yards through the following winter, and in April are in high condition for early grass, upon which they make themselves fit for the shambles in the month of June.

The larger varieties of the north-eastern counties do not leave the breeder at so early an age. They are seldom brought to market till they are three or three years and a half old, and then frequently in good condition for being fattened either on grass or turnips. A great many of the Aberdeenshire cattle are bought for the straw-yards of the southern counties, get a few turnips through winter and spring, and are either driven to England in April, or fattened at home in the course of the ensuing summer. The Fife cattle, like the other breeds of the Lowlands, are generally sold to the graziers at three years old, having got a liberal allowance of turnips during the preceding winter.'

Rules for Selecting Cattle.

In selecting cattle for feeding, their qualities may be in some measure known by examining the hide, horns, &c. ' It is well known that the grazier and the butcher judge of the aptitude that any animal has to fatten from the touch of the skin. When the hide feels soft and silky, it strongly indicates a tendency in the animal to take on meat; and it is evident that a fine and soft skin must be more pliable, and more easily stretched out to receive any extraordinary quantity of flesh, than a thick or tough one. At the same time, thick sound hides are of great importance in various manufactures. Indeed they are necessary in cold countries, where cattle are much exposed to the inclemency of the seasons; and in the best breeds of Highland cattle, the skin is thick in proportion to their size, without being so tough as to be prejudicial to their capacity of fattening. It appears, from Columella's description of the best kind of ox, that the advantage of a soft skin is not a new discovery, but was perfectly well known to the husbandmen of ancient Italy.' These are the observations of Sir John Sinclair, who adds the following as a summary of good points to be attended to in choosing cattle:—' They should be—1. Of a moderate size, unless where the food is of a nature peculiarly forcing; 2. Of a shape the most likely to yield profit to the farmer; 3. Of a docile disposition, without being deficient in spirit; 4. Hardy, and not liable to disease; 5. Easily maintained, and on food not of a costly nature; 6. Arriving soon at maturity; 7. Producing considerable quantities of milk; 8. Having flesh of an excellent quality; 9. Having a tendency to take on fat; 10. Having a valuable hide; and lastly, Calculated (should it be judged necessary) for working.' It is thought best to begin to break in draught oxen at three years old, and to give them full work at four.

With respect to judging of cattle by their horns and teeth, we offer the following observations from the 'Cyclopædia of Practical Husbandry, by Martin Doyle:' —' The ordinary guide for ascertaining the precise age of cattle is the horn, which is also indicative of the breed: at three years old (this is laid down as a rule) the horns are perfectly smooth, after this a ring appears near the root, and annually afterwards a new circle; so that, by adding two years to the first ring, the age is calculated; but the contributors to the volume so frequently quoted, have clearly shown that this is a very uncertain mode of judging; "that the rings are only distinct in the cow;" and that "if a heifer goes to the bull when she is two years old, or a little before or after that time, there is an immediate change in the horn, and the first ring appears; so that a real three-year old would carry the mark of a four-year old." "In the bull they are either not seen until five, or they cannot be traced at all;" nor in the ox do they "appear until he is five years old, and they are often confused;" besides, "there is also an instrument called a rasp, which has been said to make many an arm ache a little before a large fair." Without any delusive intentions, however, an ugly set in the horns of young cattle is often remedied by filing a little off the sides of the tips opposite to the direction which it is desired that the horns should take.

Some breeders have an antipathy to horns altogether, and would even carry their dislike so far as to extirpate them from the brows of all their cattle: they can indulge their taste by paring off the tops of the horns when they first break through the skin. Perhaps it is not generally known that the larger and more massive the horn, the thinner the skull.

The age is indicated with unerring certainty by the teeth, to those who have judgment and experience, until the animal reaches the age of six or seven: until two years old, no teeth are cast; at that age two new teeth are cut; at three, two more are cut; and in the two succeeding years, two in each year; at five, the mouth is said to be full, though not completely so until six, because until that period the two corner teeth (the last in renewal) are not perfectly up. The front or incisor teeth are those considered, for a full-grown beast has altogether thirty-two teeth.'

Method of ascertaining the Weight of Live Cattle.

This is of the utmost utility for those who are not experienced judges by the eye; and by the following directions—given in the 'Cattle-Keeper's Guide'—the weight can be ascertained within a mere trifle:—' Take a string, put it round the beast, standing square, just behind the shoulder-blade; measure on a foot-rule the feet and inches the animal is in circumference; this is called the girth; then, with the string, measure from the bone of the tail which plumbs the line with the hinder part of the buttock; direct the line along the back to the fore part of the shoulder-blade; take the dimensions on the foot-rule as before, which is the length, and work the figures in the following manner:—Girth of the bullock, 6 feet 4 inches; length, 5 feet 3 inches; which, multiplied together, make 31 square superficial feet; that again multiplied by 23 (the number of pounds allowed to each superficial foot of cattle measuring less than 7 and more than 5 in girth,) makes 713 pounds; and, allowing 14 pounds to the stone, is 50 stones 13 pounds. Where the animal measures less than 9 and more than 7 feet in girth, 31 is the number of pounds to each superficial foot. Again, suppose a pig or any small beast should measure 2 feet in girth, and 2 feet along the back, which, multiplied together, make 4 square feet; that multiplied by 11, the number of pounds allowed for each square foot of cattle measuring less than 3 feet in girth, makes 44 pounds; which, divided by 14, to bring it to stones, is 3 stones 2 pounds. Again, suppose a calf, a sheep, &c. should measure 4 feet 6 inches in girth, and 3 feet 9 inches in length, which, multiplied together, make 16½ square feet; that multiplied by 16, the number of pounds allowed to all cattle measuring less than 5 feet, and more than 3 in girth, makes 264 pounds; which, divided by 14, to bring it into stones, is 18 stones 12 pounds. The dimensions of the girth and length of black cattle, sheep, calves, or hogs, may be as exactly taken this way as is at all necessary for any computation or valuation of stock, and will answer exactly to the four quarters, sinking the offal, and which every man, who can get even a bit of chalk, can easily perform. A deduction must be made for a half-fatted beast of 1 stone in 20, from that of a fat one; and for a cow that has had calves, 1 stone must be allowed, and another for not being properly fat.'

THE DAIRY.

The dairy should be cool, airy, dry, and free from vermin of all kinds. To prevent the intrusion of flies, the windows or ventilators ought to be covered with a fine wire gauze. The floor should be laid with smooth glazed tiles, and also the lower part of the walls; the benches on which the milk-pans are to be placed are best when made of stone or slate, and about 30 inches broad. The ceiling should be at least 8 feet from the floor, and finished in every respect like that of an ordinary dwelling-house. A slate roof is preferable to one of tile, as it tends to keep the temperature more equable. Cleanliness is of the most essential consequence in dairy management, and, if not strictly looked after, may cause considerable loss. It is this which has raised the produce of the dairies of Holland so much in public estimation. Every article in which milk is placed, more especially when made of wood, ought to be washed in boiling water, with a little soda or lime dissolved in it. If milk should happen to sour in any dish, the acid thus generated will injure any which may be afterwards put into it; but if washed with water in which an alkali has been dissolved, the acid will be neutralised or destroyed.

The utensils of a dairy are very numerous. The principal are milk-pails, shallow coolers for holding the milk, sieves for straining it through after it is taken from the cow, dishes for skimming the cream, churns for making the butter, scales, weights, &c. For making cheese, there are likewise ladders, vats, tubs, curd-breakers, and presses; and various other articles will be required, which it is almost impossible to enumerate. In form, these vessels, with a few exceptions, are alike throughout Great Britain; and even in other countries there is little variation. The majority of them are made of wood; but in some of the best dairies in England and Scotland, it is now the practice to have the coolers made of cast-iron, wood lined with tin in the inside, or glazed earthenware. Maple is the wood generally used in England for the manufacture of these dishes; both from its lightness, and being easily cut, it can be finished in a neater style. In Holland, the milk dishes are very commonly made of brass; and certainly brass or iron is to be preferred to wood, because the dishes make from either of these materials are more durable, and can be easier cleaned. It has been objected to earthenware vessels that, being glazed with lead, the acid of the milk acting upon the glaze forms a very noxious poison. This, however, is scarcely correct; it would require a much stronger acid than that of milk to decompose the glaze; and in some parts of England lead has been long used, and never objected to. Zinc pans, which have been recommended for their cheapness as well as for their cool and cleanly qualities, are also pretty generally used; and latterly, since the abolition of the duty on glass, this material is spoken of as likely to supersede all others. Though somewhat objectionable on the score of brittleness, glass is undoubtedly to be preferred to wood in point of cleanliness, and to any metallic substance, like zinc or lead, which might be acted upon by the lactic acid, and so produce compounds of a deleterious nature. It may be added, however, that in all cases of ordinary management, neither zinc nor lead vessels can ever be so extensively acted upon by the acid of the milk as to produce any lactate capable of affecting the human system.

Cheese-presses are usually made of stone of various weights, according to the size of the cheese. Granite is preferred for this purpose, on account of its great weight. A lever was a method long practised, one end of which being placed in a hole in the wall, the sinker acted as a fulcrum, and one or two unhewn stones, hung on the end of the pole, produced the pressure. Another kind of press consisted of a stone weight placed upon the sinker, which was raised and depressed either by a block and tackle or a screw. The kind most commonly used at present is a lever with a double wheel, which occupies little space, is easily worked, and allows of the weight being better regulated than by a stone placed upon the sinker.

Churning is now, in all large dairy establishments, performed by machinery, worked either by horse or water power, or attached to a thrashing-machine, if there is one in the dairy. Churns vary in size from ten to fifty, and even one hundred gallons, according to the size of the establishment. The plunge-churn, which has the appearance of a barrel placed on its end, is that most commonly used—the plunge being worked by a lever connected with a shaft and crank, moved by a wheel outside. The common hand-churns are of various forms, either upright with a plunge, or horizontal with horns inside, which are turned by an iron handle. A churn formed like a cradle is much used in Canada, and has been strongly recommended for adoption in this country. It is rocked regularly by a child sitting astride, who may thus be usefully employed while amusing himself. Great care should be taken to wash churns thoroughly with boiling water, both immediately after they have been used, and before they are again to be put in operation; and those churns which admit of being easily cleaned are always to be recommended, even although they should not be so elegant in construction.

Milk.

Milk consists of three materials blended together, called in science the butteraceous, lactic, and serous kinds of matter, which can be separated by artificial means, so as to form *butter*, the milk called *buttermilk*, and serum or whey. The whey is little else than water, slightly saline, and is generally the chief ingredient in the milk. When taken from the cow, milk should be removed to the dairy or milk-house, and after being sieved, placed in shallow pans, to throw up the butteraceous matter termed cream, which, like all fatty substances, being lightest, floats on the top.

The following observations on milk and its management, made by Dr Anderson, in his 'Recreations,' are worthy of the consideration of cow-keepers :—

'Of the milk drawn from any cow at one time, that part which comes off at the first is always thinner, and of a much worse quality for making butter, than that afterwards obtained; and this richness continues to increase progressively to the very last drop that can be obtained from the udder.

If milk be put into a dish, and allowed to stand till it throws up cream, the portion of cream rising first to the surface is richer in quality and greater in quantity than that which rises in a second equal space of time; and the cream which rises in the second interval of time is greater in quantity and richer in quality than that which rises in a third equal space of time; that of the third is greater than that of the fourth; and so of the rest: the cream that rises continuing progressively to decrease in quantity and decline in quality so long as any rises to the surface.

Thick milk always throws up a much smaller proportion of the cream which it actually contains than milk that is thinner; but the cream is of a richer quality; and if water be added to that thick milk, it will afford a considerably greater quantity of cream, and consequently more butter, than it would have done if allowed to remain pure; but its quality is at the same time greatly deteriorated.

Milk which is put into a bucket or other proper vessel, and carried in it to a considerable distance, so as to be much agitated, and in part cooled, before it be put into the milk-pans to settle for cream, never throws up so much or so rich cream as if the same milk had been put into the milk-pans, without agitation, directly after it was milked.

From these fundamental facts, the reflecting dairyist will derive many important practical rules. Some of these we shall enumerate, and leave the rest to be discovered. Cows should be milked as near the dairy as possible, in order to prevent the necessity of carrying and cooling the milk before it is put into the creaming dishes. Every cow's milk should be kept separate, till the peculiar properties of each are so well known as to admit of their being classed, when those that are most nearly allied may be mixed together. When it is intended to make butter of a very fine quality, reject entirely the milk of all those cows which yields cream of a bad quality, and also keep the milk that is first drawn from the cow at each milking entirely separate from that which is last obtained, as the quality of the butter must otherwise be greatly debased, without materially augmenting its quantity. For the same purpose, take only the cream that is first separated from the first drawn milk. Butter of the very best quality can only be economically made in those dairies where cheese is also made; because in them the best part of each cow's milk can be set apart for throwing up cream, the best part of this cream can be taken in order to be made into butter, and the remainder, or all the rest of the milk and cream of the dairy, can be turned into cheese. The spontaneous separation of cream, and the production of butter, are never effected but in consequence of the production of acid in the milk. Hence it is, that where the whole milk is set apart for the separation of cream, and the whole of the cream is separated, the milk must necessarily have turned sour before it is made into cheese; and no very excellent cheese can be made from milk which has once attained that state.'

We now pass on to a consideration of the most valuable ingredient in dairy produce; namely—

Butter,

which is made of cream, freed from its milky and serous properties. This is effected by churning. Some imagine that no butter can be good except such as is made from fresh cream; but this is a mistake, as cream requires to have a little acidity before the butter will form. The length of time which the cream should stand before churning has never been clearly ascertained; from three to seven days, however, may be considered as the proper period. A more important matter than the length of time which cream requires to stand is the degree of temperature at which the cream will turn into butter. This has been ascertained from experiment to be from 45 to 75 degrees of Fahrenheit. In Holland, when the cream is too cold, hot water is put into the churn to raise the temperature to 70 or 75 degrees. The best quality of butter is obtained at a temperature of 51 degrees, according to experiments performed by Mr Pooler; and the greatest quantity at a temperature of 56 degrees. During the process of churning, the agitation will increase the heat to about five degrees more than it was when the cream was put into the churn. Mr Pooler is of opinion that the greater quantity of butter is obtained by the increased heat causing more milk to remain amongst the butter; and this of course must decrease its quality.

In some of the dairies in the neighbourhood of Edinburgh, and in all those near Glasgow, the butter is made by churning the cream and the milk together. This is done in order to obtain the buttermilk, the demand for which is always great in large cities. When the milk and cream are to be churned together, the milk is kept in the coolers for from twelve to twenty-four hours, and then poured into a milk-tub. It remains here until required for churning; and will, during this time, have coagulated. If a certain quantity of milk is put into the milk-tub, and has coagulated before any more has creamed, the coagulated milk must in no way be disturbed, or if the two quantities are mixed together, too much fermentation may be the consequence. The milk is not churned till it has become acid; and when once coagulation has taken place, it should be churned as early as convenient. If the milk has not fermented before churning, the buttermilk will keep for a much longer time, will have an agreeable taste, and will bear to be mixed with a little water. When the milk has fermented before being churned, the buttermilk will never be so good, nor will it keep for such a length of time as in the former case.

The operation of churning, whether it be of cream alone, or cream and milk, is performed in the same manner. The milk requires more time than cream to complete the process, from two to three hours being considered necessary, while cream alone may be effectually churned in an hour and a half. It is necessary that the operation should be slow in warm weather; for if done too hastily, the butter will be soft and white. If the cream is at too high a temperature, the churn should be cooled with cold spring water, to reduce it to the proper degree of heat. In winter, again, the operation of churning should be done as quickly as possible, the action being regular; and the churn should be warmed, to raise the temperature of the milk or cream. The air which is generated in the churn should be allowed to escape, or it will impede the process by the froth which it creates.

After the churning is performed, the butter should be washed in cold spring water, with a little salt in it, two or three times, to extract all the milk which may be lodging about the mass. It is said by some that the butter retains its sweetness much longer when no water is used; and others affirm that the washing improves the flavour. The extraction of the milk from butter will reduce its weight; but it appears from the experiments of Mr Pooler upon the temperature of the cream, that the less milk which is in the butter its quality is proportionably improved. Kneading and beating the butter too much render it tough and gluey. After the milk has been carefully extracted, if the butter is to be salted, it should be mixed with the finest salt, in the proportion of ten ounces to the stone of fourteen pounds, more or less, according to the time the butter is to be preserved. The butter and salt should be well mixed together with the hand; and in Ireland it is customary to add a little saltpetre. A compound of one part sugar, one part nitre, and two parts of the best Spanish salt, finely powdered together, has been highly recommended for preserving butter. It is used in the proportion of one ounce to the pound: and it is said to give a flavour to the butter which no other known ingredients can impart.

For making butter casks or kegs, the wood of the lime-tree is highly recommended, as containing no acid; and after it the white oak and the ash. When wood contains acid, it acts powerfully upon the salt in the butter, converting it into brine. Fir has also been recommended for making casks; and indeed any wood will answer if boiled for a few hours, for by this process the pyroligneous acid will be entirely taken out.

In salting, the butter should never be put into the firkins in layers; but the surface should be left every day rough and broken, so as to unite better with that of the succeeding churning. The quality may likewise be better preserved by covering it from the air with a clean linen cloth dipped in pickle, and finally placing it in a cool situation.

Buttermilk.

This is the liquid which remains in the churn after removing the butter. If milk has been employed for churning, the buttermilk is thin, poor, and easily sours; but if from the churning of cream, the buttermilk is more thick and rich, and is considered by many a delicious beverage. Good buttermilk is at all events exceedingly wholesome and nutritious. In Ireland, it is largely used at meals with potatoes; in Scotland, it is more frequently employed as a relish with oatmeal porridge; and for this purpose large quantities are brought to Edinburgh, Glasgow, and other towns, from the adjoining rural districts. In England, the buttermilk of farmers is usually employed in feeding pigs. Latterly it has been used in conjunction with carbonate of soda in the preparation of a light and wholesome household bread.

Clouted Cream.

This is a preparation of the rich milk of Devonshire, and may be said to be a kind of half-formed butter, such is the solidness of its consistency. In Vancouver's 'Survey of Devonshire,' the following is described as the mode of preparing this delicious article:—'The milk is put into tin or earthen pans, holding about ten or twelve quarts each. The evening's meal is placed the following morning, and the morning's milk is placed in the afternoon, upon a broad iron plate heated by a small furnace, or otherwise over stoves, where, exposed to a gentle fire, they remain until after the whole body of cream is supposed to have formed upon the surface; which being gently removed by the edge of a spoon or ladle, small air-bubbles will begin to rise, that denote the approach of a boiling heat, when the pans must be removed from off the heated plate or stoves. The cream remains upon the milk in this state until quite cold, when it may be removed into a churn, or, as is more frequently the case, into an open vessel, and then moved by the hand with a stick about a foot long, at the end of which is fixed a sort of peel from four to six inches in diameter, and with which about twelve pounds of butter may be separated from the buttermilk at a time—the butter in both cases being found to separate much more freely, and sooner to coagulate into a mass, than in the ordinary way, when churned from raw cream that may have been several days in gathering; and at the same time will answer a more valuable purpose in preserving, which should be first salted in the usual way, then placed in convenient-sized egg-shaped earthen crocks, and always kept covered with a pickle, made strong enough to float and buoy up about half out of the brine a new-laid egg. This cream, before churning, is the celebrated clouted cream of Devon.'

Cheese.

Cheese may be made from cream alone, or from the whole milk; the object in either case being in the first place to separate the serum from the other materials.

This is effected by curdling the cream or milk by the infusion of an acid, the refuse being the serum or whey, which is of scarcely any value. No acidulous substance is found so suitable for curdling milk as *rennet*, which is formed of the gastric juice of a calf that has been fed on milk. Some persons preserve the maws or stomach-bags of calves with the curd contained in them; others employ the stomach-bags alone, putting a few handfuls of salt into and around them. They are then rolled up, and hung in a warm place to dry, and are kept for some time before they are used. The stomach is never made use of in Gloucestershire until it is a twelvemonth old; for, if used before this, it is said to swell the cheese, making it full of *eyes* or holes. The usual way of preparing the rennet in England is to add to every six skins or stomachs two gallons of brine, and two lemons, which take away any unpleasant taste, and give the rennet an agreeable flavour. A large quantity is made at a time; and it is never used until it has stood at least two months. The method of preparing a good-flavoured rennet, recommended by the late Mr Marshall, is as follows:—

'Take the maw of a newly-killed calf, and clean it of its contents, salt the bag, and put it into an earthen jar for three or four days, till it forms a pickle; then take it from the jar, and hang it up to dry: after which it is to be replaced in the jar, the covering of which should be pierced with a few holes to admit the air, and allowed to remain in the jar for twelve months. When wanted for use, a handful each of leaves of sweet-brier, dog-rose, and bramble, with three or four handfuls of salt, are to be boiled together for a quarter of an hour, when the liquid is to be strained off, and allowed to cool. The maw is then to be put into the liquid, together with a lemon stuck round with cloves; and the longer it remains in the liquid, the stronger and better will the rennet be. Half a pint of the liquid is sufficient to turn fifty gallons of milk.'

As almost every dairy county in England has its own particular method of steeping and salting the maws and preparing the rennet, we shall only give that pursued in Ayrshire, the most important dairy district in Scotland. The stomach of the calf is examined, and all impurities, such as straw, removed from the curdled milk. Two handfuls of salt are then put into and around the bag, which is hung in a warm place to dry thoroughly. It is seldom used before it is a year old, and even a longer period is thought to improve it. When wanted to prepare rennet, the bag is cut into small pieces, and put into a jar, with a handful or two of salt and a quantity of boiled soft water, cooled down to about sixty-five degrees, or new whey taken off the curd is put into the jar. The quantity of water or whey will vary according to the quality of the yirning; and if it is that of a new-dropped calf, three English pints will be enough; but if fed for four or five weeks, two quarts will be about the quantity required. This is allowed to stand in the jar for two or three days, and is then strained off, and another pint of water placed upon the maw, which, after standing three days, is added to the first infusion. If any impurities appear in the liquid, it should be carefully strained through a sieve, and the whole can be bottled and used as wanted. A glassful of whisky is sometimes put into each bottle; but this is not common. The liquid thus prepared may be used either immediately, or kept months if required, and a table-spoonful will coagulate thirty gallons of milk in the course of ten minutes; whereas the English rennet requires nearly three hours to effect the same purpose.

Dunlop cheese has of late come into very general repute; and although nowhere so well made as in the parish in Ayrshire from which it derives its name, it is now manufactured in Galloway, in the counties of Renfrew, Lanark, and Ayr, and is extending to others. The cheeses are made of various sizes, from a quarter to half a hundredweight; and the process of making them is as follows:—Sweet milk for Dunlop cheese is composed of all the milk as it is yielded by the cows, without having the cream separated from it. When so many cows are kept upon a farm that a cheese can be made every time they are milked, the milk is passed through a sieve into the vat, and formed into a curd by the rennet. But when the cows are not so numerous as to afford milk sufficient to form a cheese at each milking, it is put into the coolers about six or eight inches deep. At the next milking, the cream is skimmed off, and without being heated, the milk is put into the curd-vat along with that just drawn from the cows. The milk is then raised to a temperature about blood heat, or in summer to 90 degrees, and in winter 95 degrees. If coagulated much warmer, the curd becomes too adhesive; some of the butteraceous matter is lost in the whey, and the cheese will be found dry, tough, and tasteless. If too cold, on the other hand, the curd, which is then soft, does not part readily with the serum, and the cheese is so wanting in firmness that it is difficult to get it to keep together. Even after the utmost care has been taken to extract the whey and give solidity to the cheese, holes, which in provincial language are termed *eyes*, whey-drops, and springs, frequently break out, and render the cheese either rancid or insipid.

It is not enough that the milk is brought to a right temperature when the rennet is applied, but the milk must be kept neither too hot nor too cold from the time it is taken from the cow. The temperature of the milk-house ought to be kept as equal as possible, never rising above 55 nor sinking below 50 degrees. In operations so critical as those of the dairy, where any material alteration in the temperature will affect the quality of the cheese, this ought at all times to be ascertained. Instead of this, the general practice is for the dairymaid merely to pass her fingers through the milk, than which nothing can be more uncertain. A thermometer ought not only to be in every milk-house, but also in every byre, as extremes of heat or cold, or sudden changes in the temperature, have a great effect upon the secretion of milk.

About a table-spoonful of the liquid rennet is considered sufficient for 100 quarts of milk, and the curd is formed by it in twelve or fifteen minutes; but in some dairies, the curd does not appear in less than forty-five or sixty minutes, although double the quantity of rennet is used. This must be owing either to a want of strength in the rennet, or from some peculiarity in the herbage upon which the cows have been fed. The curd, when formed, should be broken with the skimming-dish or the hand as soon as possible, but without pressing, as the least violence has been found to make it come off white, and thus weaken the quality of the cheese. The whey may be run off by lifting the tub gently on its edge, and allowing it to flow into a vessel placed beside the tub. The curd should then be allowed to stand until the whey has gathered in another part, and this is also poured off.

When quite freed from the whey, and the curd has acquired a little consistence, it is cut with the cheese-knife, gently at first, and more minutely as it hardens, after which it is put into the drainer, a square vessel with small holes in the bottom, and a cover to fit inside. The lid is placed upon the curd, with a cloth thrown over it, and pressure is applied according to the quantity of curd; and in this state it is allowed to stand for about half an hour. It is then cut into pieces about two inches square; the whey is again discharged, and double the former weight is placed upon it. This process of cutting is smaller every half hour, and increasing the weight until the pressure is 100 pounds, is continued for three or four hours. It is then cut very small, and thoroughly salted; thirteen ounces of salt to twenty-four pounds English of the curd being sufficient.

A clean cheese-cloth, rinsed in warm water and wrung out, being then placed in the chessel, the curd is put in, and half a hundredweight laid on it for an hour. It is then put under a press of two hundredweight, where it remains during an hour and a half, after which it is taken out, and a fresh cloth placed in the chessel, The cheese is then placed upside down, and laid, with increased weight, under the press, letting it remain three or four hours in the press at a time, and at each shifting getting a clean dry cloth. Some have shortened the process of pressing by placing the cheese, when it comes from the press for the first time, into water heated to about 95 or 100 degrees, where it remains till the water becomes milk-warm. The cheese is then dried well, and again placed under the press.

When ultimately taken from the press, the cheeses are generally exposed for about a week to a considerable degree of drought, turned over every twenty-four hours, and rubbed with a dry cloth. They are then removed to the store-room, which should be in a cool exposure, between damp and dry, without the sun being allowed to shine on them, or a great current of air admitted—this gradual mode of ripening being found essential to prevent the fermenting and swelling of the cheese and cracking of the rind. The mode of sweating cheeses, after they come from the press, and before they are laid up to dry, although common in England, is not approved of nor practised in Ayrshire. Yet Dunlop cheeses do not crack in the skin, except when the milk has begun to acidify before being coagulated, or when they are exposed to too much drought at first. Whey springs, or eyes, are seldom seen in the cheeses of Ayrshire. Cheese, like butter, is sometimes coloured with an infusion of annato, but the practice is far from being common. The Dunlop or Ayrshire cheeses have not so high a flavour and spicy taste as some of the English, owing perhaps to the inferiority of the pasture, and to the greater pains taken in the English dairies to give the cheese an acrid taste.

Cheshire Cheese.—It has been remarked, that although good imitations of the cheese made in the English counties have been produced elsewhere, yet in no trial has a cheese possessing the true Cheshire flavour been made. This is attributed to the abundance of the saline particles in the earth, resulting from the numerous salt springs in that county. Cheshire is almost entirely a dairy county. It is said to possess 32,000 milch cows; the quantity of cheese made annually is estimated at 11,500 tons; and the average quantity afforded by each animal at 300 pounds. In making the cheese, the practice followed is to set the evening's milk apart till the following morning, when the cream is skimmed off, and two or three gallons put into a brass pan, which is immediately placed in hot water, and rendered scalding hot. Half of the milk thus heated is poured upon the night's milk, and the other half mixed with the cream, which is rendered thinner by the mixture. This is done by the dairywoman while the other servants are milking the cows; and the morning's milk being immediately added to that of the previous evening, the whole mass is set together for cheese. The rennet and colouring being then put into the tub, the whole is well stirred, and a wooden cover put over the tub, with a linen cloth thrown over it. It in general requires an hour and a half before the milk curdles; and if the cream should rise to the surface in this time, the whole must be again well stirred, which is done every time the cream rises, until coagulation takes place.

When the curd is formed, if it be firm, it is cut with the cheese-knife, and then cut across, making the incisions about an inch distant from each other. The curd is then broken by the dairywoman, until every part of it is made as small as possible, about forty minutes being generally spent in this process, when the curd is left about half an hour to subside, covered over with a cloth. After this, the curd is put in a favourable position in the tub to drain, and a weight of about sixty pounds put upon it, in order to press out the whey, which is drained to the lower side of the tub and ladled out. When well drained, the curd is turned upside down, and pressed as before. It is cut into pieces of about nine inches square, which are piled one above another, and pressed both with the hand and the weight, so long as the whey continues to flow.

These pieces are then cut into three parts of about the same size, which are broken very small, and salted at the rate of three handfuls to each. They are then put into a cheese-vat, furnished with a coarse cheese-cloth. The curd is heaped in the vat in a conical shape, the cone being covered with a cloth, to prevent any curd from falling off. As soon as the curd adheres together, a weight of about sixty pounds is put upon it, and several iron skewers are stuck through it by holes in the sides of the vat. These holes are made in order to allow any whey remaining in the curd to escape. The weight and skewers are then removed, and the curd is broken as small as possible half way down the vat. The pressing and skewering are again repeated, and a clean cloth is put over the upper part of the curd, which is then taken out of the vat, and put into it again upside down, and broken half way down as before. When no more whey can be extracted, the curd is turned in the vat, and rinsed in warm whey. The curd is still kept above the edge of the vat, being bound round with strong tape to keep it in a proper shape. The cheese is next put into the press, which has generally the power of fourteen or sixteen hundredweight, and is then well skewered with strong wires, eighteen or twenty inches long, and sharp at the points. The vat is furnished with holes on the sides to receive the skewers; and after being about half an hour in the press, the cheese is again turned, and supplied with a clean cloth. It is turned again and again several times for forty-eight hours, each time supplied with a clean cloth, and is then put mid-deep into salt, its top covered with salt, where it remains for three days, its position being reversed each day. When taken out of the vat, it is put into a wooden hoop or girth of the same breadth as the thickness of the cheese, and is placed on the salting-bench, where it stands about eight days, being well salted during that time. The cheese is then washed in lukewarm water, and after being wiped, is placed on the drying-bench, where it remains about seven days; it is then again washed and dried as before, and rubbed all over with sweet butter. After this, it is placed in the warmest part of the cheese-room, and rubbed each day with sweet butter for the first seven days.

These cheeses vary in size, being in some dairies nearly 140 pounds in weight. The quantity of salt made use of during the process is uncertain; three pounds to a cheese of sixty pounds is thought to be about the amount; but much of this is lost in the salting-house. Whether the cheese acquires much saltness during the steeping and rubbing, is uncertain, though much salt is expended in these operations.

The double Gloucester cheese, which is held in such high repute, is almost wholly made in the vale of Berkley in Gloucestershire. Its excellence is said to depend much upon the quality of the land, and the great attention which is paid to the management of the dairies. The quantity of cheese made in this vale annually is about 1200 tons, and each cow is estimated to yield 350 pounds. It is usually made in the months of May, June, and July, and the process of manufacturing is as follows:—

When the curd—which is seldom prepared from artificially-heated milk, but, if possible, from the milk as it is drawn from the cow, and when it has fallen to about 85 degrees—is considered firm enough for breaking, it is cut gently and slowly into squares of about an inch; and after standing, to allow the whey to gather, it is again cut at this time into larger pieces than before, and slowly at first. This cutting is gradually quickened, the incisions being made nearer to each other. The lumps of curd are lifted with the skimming spoon in one hand, and cut with a knife in the other hand, while suspended. The curd is now allowed to settle about a quarter of an hour, when the whey is taken from it by being poured through a fine hair sieve, the dairymaid at the same time cutting the curd, so that all the whey may escape. The curd is then pressed down with the hand into vats, covered with large cheese-cloths of fine canvas, and placed in the press for half an hour. It is then put into a mill, which crumbles it to small pieces, thus saving the labour of squeezing and rubbing with the hands—an operation which is thought to be a great improvement in the manufacture of cheese.

The whey is next completely extracted, and the curd put as compactly as possible into the vat, heaped above the vat just so far that it can be pressed down to a level with the edge. A cheese-cloth is then spread over the vat, and a little hot water thrown over the cloth, which has a tendency to harden the outside of the cheese, and prevent it from cracking. The curd is next turned out of the vat into the cloth, and the inside of the vat being washed in whey, the inverted curd with the cloth is returned to the vat. The cloth is then folded over, and the vat put into the press for two hours, when it is taken out, and dry cloths applied through the course of the day. It is then replaced in the press until salted, which is generally performed about twenty-four hours after it is made. In salting, the cheese is rubbed with finely-powdered salt; and this is thought to make the cheese smoother and more solid than when the salting process is performed upon the curd. The cheese is after this returned to the vat, and put under the press, in which more than one are placed, the newest one at the bottom, and the oldest on the top. The salting is repeated three times, twenty-four hours being allowed to intervene between each; and the cheese is finally taken from the press to the cheese-room in the course of five days. In the cheese-room it is turned over every day for a month, when it is cleaned of all scurf, and rubbed over with a woollen cloth, dipped in a paint made of Indian red or Spanish brown and small beer. As soon as the paint is dry, the cheese is rubbed once a week with a cloth. The quantity of salt employed is about three and a half pounds; and one pound of annato is sufficient to colour half a ton of cheese.

'There is nothing very peculiar in all this process,' says a standard authority, 'except the more than usually slight agitation of the milk before it is set with the rennet, and the great care with regard to the degree of temperature. Something perhaps may be attributed to a less degree of squeezing with the hand in bruising the curd, when a great deal of the fatty matter of the cheese may be pressed out, the knife being more used than the hand in dividing it. The principal characteristics of the Gloucester cheese are its richness, and its smooth and oily texture, instead of breaking when cut, and its retaining fatty matter so perfectly in the operation of toasting.

The "single Gloucester" is the skim-milk cheese; the "double Gloucester," or "best making" cheese, is manufactured from the pure or unskimmed milk; although it is not unusual in a large dairy to set aside sufficient milk to afford cream and butter enough for the family, and afterwards to add it to the next day's milking. These are sometimes called "coward" cheeses; they are either thin, weighing about 16 lbs. per cheese, or thick, averaging from 30 lbs. to 40 lbs. The best "single Gloucester" is either the "two-meal cheese," made of equal portions of unskimmed and skimmed milk, or sometimes two portions of skimmed milk and one part of pure or "coward" milk. The inferior cheese, acknowledged to be the skim-cheese, is what its name imports it to be; and the dairymaid usually skims it often enough before she is allowed to convert it into curd.'

Stilton cheese is made by putting the night's cream, without any portion of skimmed milk, into the next morning's milk; but those who wish to make it very fine, add still more cream; and thus its richness depends upon the quantity of cream made use of. Butter is also said sometimes to be used in its manufacture. The rennet is then added without any colouring; and when the curd has formed, it is taken out without being broken, and put whole into a sieve or drainer. In the drainer it is pressed with weights until all the whey is extracted, and when dry, put into a hooped chessel. The outer coat being salted, it is then put into the press, and when sufficiently firm, it is taken out of the chessel, and bound tightly in a cloth. This cloth is changed every day until the cheese is quite dry, when it is removed; and the cheese requires no further care except occasional brushing and turning. The Stilton cheeses, although small—not weighing more than twelve pounds—require two years to bring them to full maturity.

Parmesan cheese is manufactured in that part of Italy which lies between Cremona and Lodi, comprising the richest portion of the Milanese territory. The cows are kept in the house nearly all the year round, and fed in summer with cut grass from the rich irrigated meadows of the country. Some of the cheeses are so large as to contain nearly 180 pounds; and the milk of 100 cows is required to produce one of this size. This cheese is made from the milk of the evening, which is skimmed in the morning and at noon, and the milk of the morning, which is also skimmed at noon. These two milks are put together into a large copper caldron, which is hung on the arm of a lever, and can be taken off and put on the fire at pleasure. The milk is heated in this vessel to about 120 degrees, and then removed from the fire, and kept quiet until the internal motion has ceased.

The rennet is then added, and in an hour the curd will have formed, when it is again put on the fire and heated to a temperature of 145 degrees. While heating, the mass is briskly stirred, till the curd separates in small pieces, when part of the whey is run off, and a little saffron added to colour the cheese. When the curd is sufficiently broken, nearly the whole of the whey is taken out, and two pailfuls of cold water are thrown in. The temperature is thus reduced so far as to allow the dairymen to collect the curd, by passing a cloth under it and gathering up the corners. It is now pressed into a frame of wood, placed on a solid platform, with a heavy weight on the top. In the course of the night the curd cools, parts with the whey, and assumes a firm consistence. The next day one side is rubbed with salt, and the succeeding day the cheese is turned, and the other side rubbed in the same manner, this alternate salting being continued for forty days. After this, the outer surface of the cheese is pared off, the fresh surface rubbed with linseed oil, the convex side is coloured red, and the cheese is fit for sale.

It appears that this highly-esteemed cheese is altogether made from skimmed milk, and yet all the pores are filled with an oily substance. This seems too rich to be imparted by the butteraceous matter of milk which has been deprived of its cream, and it is generally supposed that some portion of oil is mixed with the curd. This, however, has not been ascertained to be the case.*

Swiss Cheese.—The finest cheese made in Switzerland is that of Gruyere, in the canton of Friburg. It is rich in quality, and generally flavoured with a powdered dry herb, the *Melilotus officinalis*. The cheeses weigh from forty to sixty pounds each, and are exported in large quantities. Mr Laing, in his work, 'Notes of a Traveller,' thus alludes to the primitive dairy operations of the small pastoral farmers in Switzerland:—'Each parish has its *alp*—that is, its common pasture for the cows of the parish—and each inhabitant is entitled to a cow's grazing, from June to October, on this common pasture. Few, however, have cows in sufficient number to repay the labour of attending them at the summer grazing in the alps. The properties are too small, in general, to keep more than five or six cows all winter; and few can keep more than three. Yet these small proprietors contrive to send cheeses to market as large as our Cheshire dairy farmers with their dairy stocks of forty or fifty cows; and, as the price of Gruyere cheeses shows, incomparably better in quality.

Each parish in Switzerland hires a man, generally

* For our information upon the manufacture of cheese in the English counties, we have been indebted to the British Husbandry and the different county reports; and for the account of the Parmesan cheese, principally to the Journal de Physique.

from the district of Gruyere, in the canton of Friburg, to take care of the herd, and make the cheese; and if this important functionary should really come from Gruyere, all that he makes is called Gruyere cheese, although made far enough from Gruyere. One cheese-man, one pressman or assistant, and one cow-herd, are considered necessary for every forty cows. The owners of the cows get credit, each of them, in a book daily, for the quantity of milk given by each cow. The cheeseman and his assistants milk the cows, put the milk together, and make cheese of it; and at the end of the season each owner receives the weight of cheese proportionable to the quantity of milk his cows have delivered. By this co-operative plan, instead of the small-sized, unmarketable cheeses only, which each could produce out of his three or four cows' milk, he has the same weight in large marketable cheese superior in quality, because made by people who attend to no other business. The cheeseman and his assistants are paid so much per head of the cows, in money or in cheese, or sometimes they hire the cows, and pay the owners in money or cheese.

In October, the cows are brought home, and the home grass-lands having been mown for hay twice during the summer, the winter food is provided; and a very small area of land keeps a cow, when the home grass has not been burdened with the summer grazing. The pasture in these alps, or summer grazings, is abundant and rich. In some of the upper valleys, inhabited winter as well as summer, but in which the corn crops are secondary, and dairy produce the main object—as, for instance, Grindewalde—a man with a house suitably situated is permanently established for receiving the milk of the neighbourhood. Each family takes care of and milks its own cow or cows, keeps the milk wanted for family use, and sends the rest of it daily to the cheeseman, who gives each family credit for the milk delivered each day; and the cheese made during the season is divided, or very usually the cheese is marketed, and the money divided; and in this way cheeses of great weight are manufactured, although no one cow-owner possesses milk sufficient to make one of marketable size.

I went one warm forenoon, while ascending the Rhigi, into one of these conjoint dairy houses. From the want of dairymaids or females about the place, and the appearance of the cow-man and his boys, I thought it prudent to sit down on the bench outside of the smoky dwelling-room, and to ask for a bowl of milk there. It was brought me in a remarkably clean wooden bowl, and I had some curiosity, when, clean or dirty, my milk was swallowed, to see where it came from. The man took me to a separate wooden building; and instead of the disgusting dirt and sluttishness I had expected, I found the most unpretending cleanliness in this rough milk-room; nothing was in it but the wooden vessels belonging to the dairy, but these were of unexceptionable nicety; and all those holding the milk were standing in a broad rill of water led from the neighbouring burn, and rippling through the centre of the room, and prevented, by a little sluice, from running too full, and mingling with the milk. This burn running through gave a freshness and cleanliness to every article; although the whole was of rude construction, and evidently for use, not show. The cows were stabled, I found, at some distance from the milk-house, that the effluvia of their breath and dung might not taint the milk. Cheese is almost the only agricultural product of Switzerland that is exported; and it is manufactured by these small farmers certainly as well, and with as much intelligence, cleanliness, and advantage, as by large farmers.'

Whey.

Whey, or the thin watery serum of milk, is of a pale-greenish hue, and saline in taste, and forms an agreeable beverage when cool. Some dairy farmers in England are in the habit of extracting a little butter from it; but with careful management, this practice would be quite unnecessary, as it is only when the milk has been coagulated too hot that any quantity of butter will remain in this liquid. In Scotland, the whey is used as food by the farmers and their families in making oatmeal porridge; and a saving of nearly one-third of meal is effected when the porridge is made of whey instead of water. By boiling, what is called float-whey is obtained, which, when mixed with a little sweet milk, is thought little inferior to curd. Whey is also very valuable in feeding swine; and it is estimated that the whey of three or four cows will, in the course of one season, with little additional solid food, fatten a pig to the weight of twelve or fourteen stones.

LONDON DAIRY MANAGEMENT.

The quantity of fresh milk annually consumed in the British metropolis was lately calculated to be 39,420,000 quarts, costing £985,500, and being the produce of 12,000 cows, kept principally in large dairy establishments in all parts of the environs. The milk is generally of the best kind when drawn from the animals; but, between the dairy and the consumer, it passes through several hands, each of whom takes a profit upon it, and increases the quantity of saleable liquid by large infusions of water, chalk, &c. In the condition it usually reaches the public, it is shamefully adulterated—a fraud which could be readily checked, were the police empowered to employ Donné's or some other kind of *lactometer*, and to seize every quart found beneath the standard indication. The charge of deteriorating the quality of the article is seldom made, however, upon the cow-keepers, whose establishments are, for the most part, models of good management. As it may be interesting to our readers to have some account of these large dairies, we present the following particulars:—

The two largest dairy establishments are those of Mr Flight (known as Layrock's dairy) and of the representatives of the late Mr Rhodes. Flight's is one of the curiosities of London; it covers fourteen acres of ground, surrounded by a high wall, and including buildings for the different purposes required. In the cow-house there are upwards of 400 cows, the whole of which are fed in stalls. The food is very properly varied: at one time they have mangel-wurzel; then they have turnips, carrots, cabbages, and clover; and when fattening for market, they are fed on oil-cake and other articles. All are curried daily. Adjoining the cow-house is an hospital for unwell cows, or cows which are calving. The milk-house is kept beautifully clean, being scoured daily with hot water.

With respect to Rhodes' dairy, which is situated at Islington, Mr Loudon, in his 'Encyclopædia of Agriculture,' has condensed the following description of its extent and mode of management from various sources:—'The number of cows kept exceeds, on an average of the year, 400: at one time these individuals are said to have had upwards of 1000 cows in their different establishments. The surface on which the buildings are placed is a slope of two or three acres, facing the east; and its inclination is about one inch in six feet. The sheds run in the direction of the slope; as well for the natural drainage of the gutters, and the more easily scraping, sweeping, and wheeling out of the manure, as for supplying water for drinking to small cast-iron troughs, which are fixed in the walls, at the heads of the cattle, in such a manner as that the one trough may be supplied from the other throughout the whole length of the shed. The sheds are twenty-four feet wide; the side walls about eight feet high; the roof of tiles, with rising shutters for ventilation, and with panes of glass, glazed into cast-iron skeleton tiles, for light. The floor is nearly flat, with a gutter along the centre; and a row of stalls, each seven and a half feet wide, and adapted for two cows, runs along the sides. The cows are fastened by chains and rings, which rings run on upright iron rods, in the corners of the stalls; the common mode being departed from only in having iron rods instead of wooden posts. A trough or manger, formed of stone, slate, or cement, of the ordinary size of those used for horses, and with its upper surface about eighteen inches from the ground, is fixed at the head of each stall. Four sheds are placed parallel and close to each other, and in the party walls are openings, about a foot in breadth and four feet high, opposite each cow. The bottom of these openings is about nine inches higher than the upper surface of the troughs, and is formed by the upper surface of the one-foot-square cast-iron cisterns, which contain the water for drinking. Each cistern serves two cows, which of course are in different sheds, but adjoining and opposite each other. All these troughs are supplied from one large cistern by pipes, in a manner which can be so readily conceived that we shall not stop to offer a description. Each of these troughs has a wooden cover, which is put on during the time the cows are eating their grains, to prevent their drinking at the same time, and also from dropping grains in the water.

At the upper end, and at one corner of this quadruple range of sheds, is the dairy, which consists of three rooms, of about twelve feet square: the outer or measuring-room; the middle or scalding-room, with a fireplace and a boiler; and the inner or milk-and-butter-room, separated by a passage from the last. At the lower end of the range is a square yard, surrounded by sheds; one for fattening the cows when they have ceased to give milk, and the others for store and breeding pigs. The pigs are kept for the purpose of consuming the casual stock of skim milk which occasionally remains on hand, owing to the fluctuations in the demand. This milk is kept in a well, walled with brick laid in cement, about six feet in diameter, and twelve feet deep. The milk becomes sour there in a very short time; and, as is well known, is found most nourishing to the pigs when given in that state. Breeding swine are found most profitable, the sucking pigs being sold for roasting. Beyond this yard is a deep and wide pit or pond, into which the dung is emptied from a platform of boards projecting into it. The only remaining building wanted to complete the dairy establishment is a house or pit for containing the exhausted malt (grains), on which the cows are chiefly fed. Messrs Rhodes have a building or pit of this description at some distance, where they have a smaller establishment. There are a stackyard, sheds, and pits for roots, straw, and hay; a place for cutting hay into chaff; cart-sheds, stables, a counting-house, and other buildings and places common to all such establishments, which it is not necessary to describe.

The dairy cows are purchased newly calved in the market held in Islington every Monday. They are kept as long as they continue to give not less than two gallons of milk a day, and are then fattened on oil-cake, grains, and cut clover hay, for the butcher. The short-horned breed is preferred, partly for the usual reason of being more abundant milkers than the long-horns, partly because the shortness of their horns allows them to be placed closer together, and partly because this breed is more frequently brought to market than any other. The Ayrshire breed has been tried to the number of 150 at a time, and highly approved of, as affording a very rich cream, as fattening in a very short time when they have left off giving milk, and as producing a beef which sold much higher than that of the short-horns. The difficulty, however, in procuring this breed was found so great, that Mr Rhodes was obliged to leave it off. The length of time during which a cow, treated as in this establishment, continues to give milk, varies from six months to the almost incredible period of two years. We were assured of there being at this moment several cows among the 330 which we saw, that had stood in their places even more than two years, and continued to give upwards of one gallon of milk daily.

The treatment of the animals differs from that in most other establishments. The cows are never untied during the whole period that they remain in the house. In most other establishments, if not in all, stall-fed cows or cattle are let out at least once a day to drink; but these animals have clear water continually before them. They are kept very clean, and the sheds are so remarkably well ventilated, by means of the openings in the roofs, that the air seemed to us purer than that of any cow-house we had ever before examined; probably from its direct perpendicular entrance through the roof, this, in moderate weather, being certainly far preferable to its horizontal entrance through the side walls.

The principal food of the cows in Rhodes' dairy, as in all the other London establishments, consists of grains; that is, malt after it has been used by the brewer or the distiller. As the brewing seasons are chiefly autumn and spring, a stock of grains is laid in at these seasons sufficient for the rest of the year. The grains are generally laid in pits bottomed and lined with brickwork set in cement, from ten to twenty feet deep, about twelve or sixteen feet wide, and of any convenient length. The grains are firmly trodden down by men, the heaps being finished like hay-ricks, or ridges in which potatoes are laid up for the winter, and covered with from six to nine inches of moist earth or mud, to keep out the rain and frost in winter and the heat in summer. As a cow consumes about a bushel of grains a day, it is easy to calculate the quantity required to be laid in. The grains are warm, smoking, and in a state of fermentation when put in, and they continue fit for use for several years; becoming somewhat sour, but they are, it is said, as much relished by the cows as when fresh. It is common to keep grains two or three years; but in this establishment they have been kept nine years, and found perfectly good. The exclusion of the air almost prevents the increase of the fermentation and consequent decomposition. What is called distiller's wash—which is the remainder after distillation of a decoction of ground malt and meal—is also given to cows, but more frequently to such as are fattening than to those in milk. Salt is given at the rate of two ounces each cow a day. It is mixed with the grains, which are supplied before milking, about three o'clock in the morning; and in the afternoon, about two o'clock, just before milking. Of green food or roots, portions are supplied alternately with the grains; and in winter, when tares or green grass cannot be procured, after the turnips, potatoes, or mangel-wurzel have been eaten, a portion of dry hay is always given.

The produce of this dairy is almost entirely milk and cream, for private families and for public hospitals and other institutions. A number of the public establishments are supplied directly from the dairy by contract; but private families are principally supplied by milk-dealers: these have what are called milk-walks—that is, a certain number of customers, whom they call upon with supplies twice a day; and they are thus enabled to ascertain the average of what their customers consume, and to contract with Messrs Rhodes for this average. The latter calculate the number of cows sufficient to give the dealer the supply wanted, and this number the dealer undertakes to milk twice a day—namely, at three o'clock in the morning, and at three in the afternoon. The milk is measured to the dealer, and should he have milked more than his quantity, it remains with the dairyman; but should the cows have been deficient in the quantity, it is made good from the milk of other cows, milked on account of the contracts of the establishment. As the supply of the cows and the demand of the dealers are continually varying, it often happens that considerable quantities of milk remain on the dairyman's hands, frequently, we are told, as much as sixty or seventy gallons a day. This quantity is placed in shallow earthen vessels, to throw up the cream in the usual manner: this cream is churned, and the butter sold. The skimmed milk, as well as the buttermilk, are, as is usual in English dairies, given to the pigs.

THE SHEEP—GOAT—ALPACA.

In the *Ruminant* order of the Mammalia, a distinguished place is given to the sheep, the flesh and wool of which have been recognised as alike of the greatest use to man from the earliest ages. In our own country, within the last half century, the different breeds have been improved by the growing intelligence, skill, and industry of the farmers; and their management has, under high patronage, been brought to a degree of perfection perhaps nowhere else attained. It may be added that, as the sciences of anatomy, physiology, botany, and chemistry are every year throwing new light on those laws of nature which regulate the structure, health, nutrition, and reproduction of the Animal Kingdom, we may entertain the hope of still further improvement in this department of rural economy.

BREEDS OR VARIETIES OF THE SHEEP.

The numerous varieties of sheep that now exist in different parts of the globe, have all been reduced by Cuvier into four distinct species:—1. (*Ovis Ammon*)—the Argali; this species is remarkable for its soft reddish hair, a short tail, and a mane under its neck. It inhabits the rocky districts of Barbary and the more elevated parts of Egypt. 2. (*Ovis tragelaphus*)—the bearded sheep of Africa. 3. (*Ovis musmon*)—the Musmon of Southern Europe. 4. (*Ovis montana*)—the Mouflon of America; but this species, which inhabits the Rocky Mountains of North America, is now believed to be identical with the Argali, which frequents the mountains of Central Asia, and the higher plains of Siberia northwards to Kamtchatka. This leaves only three distinct species of wild sheep as yet discovered.

It is still a point in dispute from which of these races our domestic sheep have been derived; nor is the question of great practical importance, though its solution is very desirable in a physiological point of view. Whether the wild races may be regarded as of one species, as some naturalists contend, or of different species, according to others, the best judges are next to unanimous that the domestic races of this country are of one species; and what are called different breeds are nothing more than varieties, the result of different culture, food, and climate. The influence of these conditions, in diversifying the character and condition of sheep, will be adverted to under their proper heads. The following may be regarded as the principal breeds reared in this country:—

1. *The Shetland sheep*, inhabiting those islands from which they derive their name, and extending to the Faroe Islands and the Hebrides. In general, they have no horns. The finest fabrics are made of their wool, which resembles a fine fur. This wool is mixed with a species of coarse hair, which forms a covering for the animal when the fleece proper falls off. A similar variety is known to inhabit the most northerly parts of Europe, from which it is supposed the fine-wooled sheep of our northern islands and Highlands have been derived. They are hardy in constitution, and well adapted to the soil and scanty pastures on which they are reared, but would ill repay their cultivation in Lowland districts.

2. *The Dun-wooled breed*, the colour of which is not confined to the wool, but extends to the face and legs. They seem at one time to have been cultivated very extensively, and remnants of them still exist in Scotland, Wales, and the Isle of Man.

3. *The Black-faced heath breed*, which, being the most hardy and active of all our sheep, are the proper inhabitants of every country abounding in elevated heathy mountains. They have spiral horns, their legs and faces are black, with a short, firm, and compact body; their wool is coarse, weighing from 3 to 4 lbs. per fleece; they fatten readily on good pastures, and yield the most delicious mutton, weighing from 10 to 16 lbs. per quarter. They still exist in considerable numbers in the more elevated mountains of Yorkshire, Cumberland, Westmoreland, Argyleshire, and the central Highlands of Scotland.

4. *The Moorland sheep of Devonshire*—sometimes termed the Exmoor and Dartmoor, from the different districts of Devonshire in which they are reared—have horns, with legs and faces white, wool long, with a hardy constitution, and are said to be well adapted to the wet lands which they occupy. Their wool weighs about 4 lbs. the fleece; but they are rather small, and in some respects ill-formed.

5. *The Cheviot breed*, deriving their name from the Cheviot mountains, in which they are said to be indigenous, are longer and heavier than the black-faced. Their wool is fine; a medium fleece weighs about 3 lbs.; a carcase, when fat, weighs from 12 to 18 lbs. per quarter. Their faces are white; their legs are long, clean, and small boned, and clad with wool to the hough. Their only defect of form is a want of depth in the chest; yet, with this exception, their size, general shape, hardy constitution, and fine wool, are a combination of qualities in which, as a breed for mountain pasturage, they are yet unrivalled in this country.

6. *The Horned varieties of fine-wooled sheep of Norfolk, Wiltshire, and Dorset.*—The members of this breed have short wool, in which they differ from the black-faced sheep and moorland sheep of Devonshire, and from the Cheviot, in having large spiral horns. They are not much lighter than the Cheviots, but they are ill formed, and thin, flat in the ribs, and slow feeders; a medium fleece weighs about 2 lbs. It is believed that the South-down will eventually displace them. The Wiltshire sheep are still heavier than those of Norfolk, being the largest of our fine-wooled sheep; they are said to thrive well in the downs of Wiltshire, but are also giving ground to the South-downs. The Dorset sheep have horns, white faces and legs; their three-year-old wethers weigh from 16 to 20 lbs. per quarter; their wool is less fine, but heavier than that of Wiltshire, weighing from 3 to 4 lbs. the fleece. One of the peculiar advantages of this breed is, the ewes admit the ram at so early a period that they generally have lambs in the months of September and October—a stock which finds a ready market in large towns for winter consumption.

7. *The Ryeland breed*, deriving their name from a southern district in Hertfordshire, which at one time was regarded as incapable of growing anything but rye. The members of this variety are white-faced, and without horns; their general form is tolerable; they fall short of the improved breeds, in being more flat in the ribs, and less level in the back; their wool is fine, weighing from 1½ to 2 lbs.; their mutton is delicate; they arrive soon at maturity, and fatten easily, and weigh from 12 to 16 lbs. per quarter: this breed has been crossed by the Spanish Merino. The offspring of this cross were at one time in high fame in England, under the name of the Anglo-Merino; and though their wool is said to have been of a fine quality, the breed has for long declined in popular favour.

8. *The South-down breed.*—The members of this section have no horns; their legs and faces gray. They have fine wool, which is from two to three inches in length, and weighs from 2½ to 3 lbs. per fleece; they are slightly deficient in depth and breadth of the chest, but their mutton is excellent, and highly flavoured; they are kindly feeders, and when fat, their average weight may be stated at from 15 to 18 lbs. per quarter. They have, from time immemorial, been reared upon

the chalky soils of Sussex, but are now widely extended, and thrive excellently not only on the chalk downs and light soils of England, but on the sheltered lawns of Scotland. In a note to the author from Lord Pitmilly, near St Andrews, are the following facts:—'I generally keep about a score of South-down ewes for early lambs; they pasture in the lawn with the black-faced wethers kept for family use. The lambs dropped early in winter 1839–40 not being wanted, were sent to Edinburgh; ten of the ewes lambed again in September 1840, and again in March 1841. Some of them had twin lambs; all did well. The September lambs I sold in August 1841, when eleven months old, at 30s. a-piece. I ascribe the fact of the ewes thriving so well to the dry ground, and to their being put every night, summer and winter, into a shed, and well bedded; they have no extra food, except at lambing time, when they get a little oil-cake or sliced turnip.' The above facts are highly deserving the attention of breeders of this variety of sheep, testifying as they do to the greatest degree of fecundity of which we have yet any authentic account.

9. *The Merino breed*, which is supposed to have been originally from Africa. Marcus Columella saw a variety from that country at some of the games exhibited at Rome. He procured some of them for his own farm, crossed them with the breeds of Tarentum, and sent the offspring of this cross to Spain. In Spain they soon rose to such perfection and celebrity, that they attracted the attention of breeders of stock in other nations, and this breed may now be found in every part of the globe. They were imported into England for the first time in 1788. The Ryeland and other fine-wooled breeds of England were crossed by Merino rams in 1792. The Merino breed of rams were cultivated with great care by George III. The sales of his majesty's stock, which commenced in the year 1804, attracted such general attention in England that a society was formed for promoting the breed in 1811; but the high expectations which were formed of the result of this cross with native sheep were far from being realised. The quality of the wool of the native sheep was improved, but the increased value of the fleece was an inadequate compensation for defects in the character of the animals themselves, which proved less hardy than the parent stock, were slow feeders, and very defective in form.

The Merinos that have been naturalised in this country retain their natural character, except that they become larger in the carcass, and the wool longer and heavier, than in Spain; but the Merino, as a feeding animal, is too small and ill-formed, and the mutton deficient both in quantity and quality. These points have given rise to some controversy; but in the forcible language of Professor Lowe—'It is vain that some breeders still contend for the superiority of the pure Merino; the general judgment of farmers is against them, and with perfect reason.'

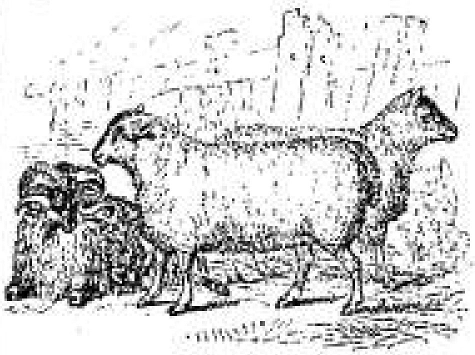
The Merino sheep are cultivated in Spain and Germany with a greater regard to the wool than to the weight and value of the animal; but the farmers in England think it more profitable to raise the weight and value of the mutton, and it is believed, by those well qualified to judge, that the best Merinos under the more rigorous climate of Britain would never yield mutton equal in quality to that of Spain. The wool of this breed is finer than that of any other sheep. In Spain, the fleece of the ram weighs 8 lbs., and that of the ewe 5 lbs.; but this wool having such a large quantity of yolk, which absorbs every kind of impurity with which it comes in contact, it loses three-fifths of its weight by being properly washed. In Australia, whither Merinos have been imported, the breed has not only improved in size and weight, but the wool produced is quite equal to the finest sorts of Europe—the result of a mild and equable climate, and not ungenerous pasture.

10. *The Devonshire Notts, Romney Marsh, Old Lincolnshire, Teeswater, and Old Leicester sheep.*—The Devonshire Notts consist of two varieties: the one is called the Dun-faced Notts, from the colour of the face; this is a coarse animal, with flat ribs and crooked back, but it yields a fleece weighing 10 lbs., and when fat, weighs 22 lbs. per quarter when only thirty months old. The second variety is called the Bampton Notts; it resembles the former in many respects, but is easier fed, yields less wool, and has a white face and legs.

The Romney Marsh breeds are very large animals, with white faces and legs, and yield a heavy fleece, the quality good of its kind. Their general structure is defective, the chest being narrow, and the extremities coarse. The result of their being crossed by the New Leicester is still a point in dispute—one party alleging, that though the quantity of wool has been lessened, and the size of the animal diminished by the cross, yet the tendency to fatten and their general form have been much improved. On the other hand, some well-informed breeders contend, that besides the loss of the quantity and quality of the wool, the constitution of the animal is rendered less fitted to the cold and marshy pastures on which it feeds.

The Old Lincolnshire breed are large, coarse, ill-shaped, slow feeders, and yield indifferent mutton, but a fleece of very heavy long wool. The Teeswater breed were originally derived from the preceding, and pastured on the rich lands in the valley of the Tees, from which they derive their name; but Professor Low remarks, that 'it is entirely changed by crossing with the Dishly breed, and that the old unimproved race of the Tees is now scarcely to be found.' They are very large, and attain a greater weight than almost any other breed—the two-year-old wethers weighing from 25 to 30 lbs. per quarter, and yielding a long and heavy fleece.

The Old Leicester is a variety of the coarse long-wooled breeds. On rich pastures they feed to a great weight; but being regarded as slow feeders, their general character has either been changed by crossing, or altogether abandoned for more improved varieties.



Black-faced—Leicester—South-down.

11. *The New Leicester and Improved Teeswater breeds.*—Mr Bakewell of Dishly, in the county of Leicester, has the honour of forming this most important breed of sheep. He turned his attention to improving the form of feeding animals about the year 1755. The exact method he followed in forming his breed of sheep is not accurately known, as he is said to have observed a prudent reserve on the subject. But we now know that there is but one way of correcting the defective form of an animal—namely, by breeding for a course of years from animals of the most perfect form, till the defects are removed, and the properties sought for obtained. The great properties of the New Leicester for the farmer, are their early maturity and disposition to fatten, in which they excel all other breeds. They are less in size than several other breeds, and their wool is deemed inferior to the Cheviot; but they are now reared with great success in almost every part of England and in the colonies of Australia, whither they and the South-downs were early imported.

That class of sheep now known by the name of the

Improved Teeswater, is derived from the old breed. Its improvement has been chiefly effected by crossing with the New Leicester. They are not so large as the older race, but are still the largest of our improved breeds; productive in lambs, and yield a good fleece; yet their form renders them less fitted for general cultivation than the New Leicester.

CHOICE OF BREEDS.

If the farmer has rendered himself master of the constitution and character of the different breeds of domestic sheep, already given, and with the general and peculiar character of the climate, soil, and pasturage of the locality on which he is to settle, the selection of the breed that will, upon the whole, yield him the highest profit, will not be a matter of very difficult calculation. But should an error be committed on this head in the first trial, very slight experience would enable a practical farmer to correct it, unless he belong to that class of persons—unfortunately too numerous—to whom the lessons of history and experience convey neither knowledge nor correction.

The breeds best adapted to the soil and climate of the different districts of Great Britain, are arranged by Professor Low in the following manner:—1st. The sheep of the mountains, lower moors, and downs; and 2d. The sheep of the plains. The sheep of the first class have sometimes horns, and sometimes want them. The finest of them have no horns—namely, the Cheviot and South-down. One of them, the black-faced heath breed, has coarse wool; another of them, the Moorland sheep of Devonshire, has long but not coarse wool; and all the others have short and fine wool.

Of the moorland and down breeds, as they may be called, the hardiest is the black-faced heath breed; and this property points it out as the most suitable for a high and rugged country, where artificial food cannot be procured. The breed next to this in hardy properties, but surpassing it in the weight of the individuals, is the Cheviot. Where the pasture contains a sufficiency of grasses, this breed deserves the preference over any other known to us for a mountainous country. The next breed deserving of cultivation is the South-down. This breed is suited to the chalky and sandy downs of the south of England. It is in this respect a very valuable breed, but it is unsuited to the more rough and elevated pastures to which the black-faced and Cheviot are naturally adapted.

The moorland and down breeds appear to be the most deserving of cultivation in this country. Of the larger breeds of the plains, the New Leicester is the best adapted to general cultivation, and wherever an improved system of tillage is established, this admirable breed may be introduced. The Leicester, the Cheviot, and the black-faced, have for long been regarded as the breeds best adapted for the different districts of Scotland. That these three breeds have nearly stood in the same numerical ratio to one another for some years, is a good proof that each has been placed in that locality best fitted by nature for promoting its health and productiveness. The Leicester is admirably adapted to the rich alluvial soils of our cultivated plains; the Cheviot breed is peculiarly fitted for the grassy mountains chiefly formed of the transition series of rocks; then our most elevated mountain ranges are formed mainly of primitive rocks, and covered with coarse herbage and heath, on which none but the black-faced, the most active and hardy of our breeds, could survive.

The above arrangements have generally been acquiesced in as the best possible by the farmers of Scotland. But the claims of South-downs for the middle range of the Highland pastures in Scotland have been urged, in the following terms, by an agriculturist of long experience and high standing in his profession—namely, Mr Watson of Keillor:—"Having, during the last twenty-five years, been in the management or possession of a considerable breeding flock of South-down ewes, varying at different times from 500 to 1000 in number, and during that period having had good opportunities of drawing close comparisons betwixt that and the other breeds of mountain sheep—namely, the Cheviot and black-faced—I have come to the conclusion (and am acting upon it in my own practice), that from a pasture ranging from 500 to 1200 feet above the level of the sea, having a moderate portion of green sward, the rest whin and heather, there can be no more profitable stock of sheep kept than a flock of South-downs of the best sort. My chief reasons for having preferred this breed are, that the South-down sheep, although naturally spirited and active, are easily controlled by a good shepherd; can go over more ground for their food than any other kind of sheep, without stopping their growth; and when tried by severe storms in winter, will brave it better than even the black-faced Highland sheep; and although reduced very low in spring, sooner pick up condition than the other short-wooled sheep. As a proof of the South-downs' tendency to fatten, when put to good keep, I may mention a fact, that while I have seldom been able to produce a fat Cheviot ewe the same season that she has reared a lamb, I never fail to make good fat of the cast South-downs off grass. Their wool is so closely matted on their backs, and about the head and neck, as to be almost impervious to rain or snow; hence so soon as the storm ceases, they appear dry and comfortable, their coat not the least disordered, and altogether free from that *droukit* (Anglice, drenched) appearance which longer-wooled sheep exhibit even for days after a winter storm.

In all my experience, the South-down sheep have kept remarkably healthy. I have never seen an instance of rot in my flock; while, during the last twenty years, I have been forced to clear off a lot of Cheviot and also of black-faced ewes from that incurable disease. This, however, may have been owing more to the unsoundness of the pasture from which I got them, than from any peculiarity of the animals themselves. My average loss in the South-down lot has invariably been much under that of any other sheep I have bred. They are hardy, and easily managed at lambing-time; affectionate mothers, and, on moderate keep, give a great quantity of milk; and if there is any inducement for early lambs, they will go with the ram almost as soon as the lamb is weaned. When crossed with a well-bred Leicester ram, and brought into good keep, they produce perhaps the most profitable lamb that is bred, taking wool and carcass into account. I have for the last ten years put all the ewes I could spare from pure breeding to this sort of crossing, lambing the ewes on turnips in spring, then turning them, as soon as the season would permit, to the hill pasture (the Sidlaws) till weaning-time, when the lambs are brought to the in-field pastures, and put to turnips for the winter, on which food they are kept for about 2d. per week each, and kept on the earliest grass in spring; so that in a month or six weeks after they are clipped, they are fit for the butcher, who values this cross almost as high as the pure-bred South-down. The wool is of the finest quality for combing, and fetches the highest price of any British-grown wool—generally from 2s. to 2s. 2d. per lb.; and the clip in a good season will average about 6 lbs. At sixteen months old, I have never realised less than 40s. each, wool and mutton. In Smithfield this cross is much sought after.

On lands where folding is found necessary, the South-down submits to this treatment better than any other breed of sheep; such, indeed, in all cases where I have put them to the test, is their spirit and hardiness, that nothing short of ill-treatment seems to injure them. Combining these facts, I can have no hesitation in recommending a South-down flock of sheep in preference to every other, on such situations as I have now described—namely, too high to be occupied during the whole season by a flock of Leicesters, and under that level above which only the native black-faced breed can be expected to thrive.

So far as I know, it is not yet sufficiently ascertained by experience how far a cross betwixt the South-down and Leicester may be carried, so as to keep up the activity of the former with the well-known fattening qualities of the latter. Another train of breeding through the black-faced and South-down sheep, whose habits seem so much akin, seems likely to succeed. By this cross, improvement in quality of wool would be gained, while that of the mutton would not be deteriorated.' On the other side, Professor Low remarks—'The South-down breed is best suited to the chalky and sandy downs of the south of England. It is in this respect a very valuable breed; but it is unsuited to the more rough and elevated pastures to which the black-faced and Cheviot are adapted.'

In Ireland, the breed of sheep has been much improved since the beginning of the present century. About that time, Mr Cully attended the celebrated fair at Ballinasloe, and thus describes the Irish sheep of that period:—'I am sorry to say I never saw such ugly sheep as I saw there. The worst breeds we have in Great Britain are much superior. One would almost imagine that the sheep breeders in Ireland have taken as much pains to breed awkward sheep, as many of the people in England have taken to breed handsome ones. I know nothing to recommend them except their size, which might please some old-fashioned breeders, who can get no kind of stock large enough. But I will endeavour to describe them, and leave my readers to judge for themselves. These sheep are supported by very long, thick, crooked gray legs; their heads long and ugly, with large flagging ears; gray faces, and eyes sunk; necks long, and set on behind the shoulders; breast narrow and short; hollow both before and behind the shoulders; flat-sided, with high narrow herring backs; hind-quarters drooping, and tail set low. In short, they are almost in every respect contrary to what a well-formed sheep should be.' But an immense improvement was soon effected by Mr St George, and Mr Astley of Odston, who imported a valuable selection from the flocks of the best breeders of the new Leicesters; and by carefully breeding from these, their sheep soon obtained a degree of perfection little inferior to those of England. They soon began to let their tups at very high prices. They let thirty rams in 1800 at £1744. One of them was to have been 150 guineas. Mr Cassan, near Tipperary, was the person who had hired this famous animal, and had the misfortune of having him murdered the night after he had arrived at his farm, by some malignant opposer of the new breed.

The Irish sheep, since the introduction of the improved breeds, are now able to compete in the markets with the English breeders. There is no entry in the books of the Custom-house of sheep exported from Ireland farther back than the year 1797, and in that year there is an entry of 1875. The number had increased in 1811 to 26,029; and the sheep exported from Ireland to Liverpool in 1831 was 134,762; and in 1832 amounted to 44,260; and, in addition to this immense number of sheep, 20,000 lambs, in good market condition, annually cross the Irish Channel. And at the Fair of Ballinasloe, the number of sheep exhibited range from 80,000 to nearly 100,000. The most valuable sheep husbandry in Ireland exists at present in Roscommon, Galway, Clare, Limerick, and Tipperary. But with all this advance, there is much still to be done in the management of sheep in Ireland. The soil and climate are in many places peculiarly adapted for sheep husbandry. And from the progress Ireland has made within the last forty years, there need be no misgivings regarding her future eminence in sheep husbandry. Could the native talents and energies of Ireland be directed to the cultivation of the soil, arts, and commerce, instead of being perverted and enfeebled by fierce and feverish political agitation, from the genius of her people, the richness of the soil, the mildness of the climate, her geographical position, the number of her ports and harbours, the facilities for inland navigation, she might soon rival in wealth and civilisation the most favoured nation of Europe.

IMPROVEMENT OF BREEDS.

The first point of essential importance to be attended to by the sheep farmer is the selection of a breed whose size and constitutional qualities best accord with the climate and the pastures on which they are to feed. An error of any magnitude in these respects would be attended with fatal effects both on the health and productiveness of the flock, and thus ruin the finances of the farmer.

It is true that sheep can exist in almost every country, and may be said to reach nearly from the equator to the poles. They are found approaching the eternal snows and icy barriers of the arctic regions; they are found at great elevations in the Cordilleras of South America, and in the still more elevated Himalaya Mountains of Asia. Yet though sheep can be reared within an immense range of latitude and temperature, it is equally true that the climate and soil fix the limits within which our domestic breeds can be cultivated with advantage. Climatic influences wear down the rocks, and thus forms the soil; hence the natural pastures of all countries.

The climate, and the condition of existence which it induces, affect, with irresistible force, the structure, health, and reproductiveness of men and animals from the equator to the poles. The laws of nature cannot be transgressed with impunity. But this condition being accurately adjusted, the next objects which the sheep farmer ought to keep steadily in view are the quantity and quality of the mutton and the wool. Nature has perhaps forbidden that the same sheep should, in any circumstances, yield the greatest weight of the best mutton, and a fleece of the greatest value. The farmer will be able easily to determine, from the country, climate, and various other considerations, to which of these he should direct his chief attention. In England, for example, the farmer finds it more profitable to promote the weight and quality of the mutton than the wool; while the farmer in Spain, Germany, and Australia, finds it his interest to attend more to the wool than the mutton.

The properties most desirable in the sheep are—1. Size; 2. Form; 3. Early maturity; 4. Constitutional hardiness; 5. Productiveness; 6. Disposition to fatten; and 7. Lightness of offal.

1. The size of the sheep must be regulated by the climate, the pasture, and the steepness or levelness of the lands on which it is to feed. One rule never to be violated is, that the size of the sheep should bear some reference to the nature of the pasture: and very heavy sheep are unsuited to very elevated and precipitous mountain ranges. On this subject, a practical question of very considerable importance is still undetermined, and that is, what is the ratio of food consumed by a large animal and one of moderate size. The result of an experiment is given by Dr Parry, where it is stated, that by breeding small sheep instead of large ones, the numbers were increased from 660 to 890 ewes and lambs, and the profit from £450 to above £724. But this experiment, and all others that have been tried, have never, in our opinion, contained all the elements necessary to determine the question with anything like philosophical accuracy.

2. The *form* of the sheep should consist of that happy combination of anatomical structure on which the health and productiveness of the animal depend; and the points of practical men must be tested by this internal anatomical structure. That eminent surgeon, Mr Cline, in his Communications to the Board of Agriculture, states—'That the lungs of an animal are the first objects to be attended to, for on their size and soundness the health and strength of an animal principally depend; that the external indications of the size of the lungs are the form and size of the chest, and its breadth in particular; that the head should be small, as by this the birth is facilitated, and affords other advantages in feeding, and as it generally indicates that the animal is of a good breed; that the

length of the neck should be in proportion to the size of the animal, that it may collect its food with ease; and that the muscles and tendons should be large, by which the animal is enabled to travel with greater facility; and the bones should be small and clean.'

We may here add a description of the best proportions of a Cheviot ram, by the late Mr Culley of Northumberland:—'His head should be fine and small; his nostrils wide and expanded; his eyes prominent, and rather bold and daring; ears thin; his collar full from the breast and shoulders, but tapering gradually all the way to where the neck and head join, which should be very fine and graceful, being perfectly free from any coarse leather hanging down; the shoulders broad and full, which must at the same time join so easy to the collar forward, and chine backward, as to leave not the least hollow in either place; the mutton upon his arm or fore-thigh must come quite to the knee; his legs upright, with a clean fine bone, being equally clear from superfluous skin and coarse hairy wool, from the knee and hough downwards; the breast broad and well forward, which will keep his fore-legs at a proper wideness; his girth or chest full and deep, and instead of a hollow behind the shoulders, that part, by some called the fore-flank, should be quite full; the back and loins broad, flat, and straight, from which the ribs must rise with a fine circular arch; his belly straight, the quarters long and full, with the mutton quite down to the hough, which should neither stand in nor out; his twist or junction of the inside of the thighs deep, wide, and full, which, with the broad breast, will keep his four legs open and upright; the whole body covered with a thin pelt, and that with fine bright soft wool. The nearer any breed of sheep comes up to the above description, the nearer they approach towards excellence of form; and there is little doubt but if the same attention and pains were taken to improve any particular breed that has been taken with a certain variety of the Lincolnshire, the same advantages would be obtained.'

3. *Early maturity* is a property of great importance to the farmer who breeds and feeds all his own sheep for the shambles; they not only make a quicker return for their food, but yield a higher profit to the breeder than slow-feeding animals. This valuable property of early maturity can be induced by breeding, food, and treatment. The new Leicester variety possesses this property in a higher degree than any other of our domestic breeds, and they also yield a greater quantity of mutton on the same quantity of food.

4. *Constitutional hardiness*, in a rigorous climate, and in bleak and elevated mountains, in which artificial food cannot be obtained, is an indispensable quality. But a farmer will seldom make a wrong selection in circumstances so obvious.

5. *Productiveness* is a property which characterises some varieties of sheep and other animals; it may be extended by careful selection in breeding, and from food and treatment. Pets have almost invariably twin lambs. The draft ewes from the mountains of Scotland have generally twins when taken to a milder climate, and kept on superior food.

6. *Disposition to fatten* is a property of very great importance to feeders, as his sheep can be made fit for the market both in a shorter period and with a less quantity of food. None of our domestic breeds possess this quality in greater perfection than the New Leicester; this quality also may be ascertained by examining the depth and breadth of the chest, according to Sir John S. Sebright. And the great physiologist John Hunter found that easy corpulence was concomitant with small bones; it is also accompanied with a pliable, soft, and mellow skin.

7. *Lightness of offal.*—It is obvious that to whatever extent the weight of the offal, or uneatable portion of the carcass, can be diminished, the value of the animal is increased. The perfection of an animal is, when the dead weight of all the eatable parts approaches the nearest to the weight of the animal when alive.

Principles of Breeding.

The fundamental and essential principles of improving any of our domestic animals by breeding, consist in a skilful selection of those males and females, the union of whose qualities will remove the defects and induce the properties desired. The sheep farmer can neither raise nor keep his flock in the highest perfection of which the climate and pasture admit, without a rigid adherence to this primary principle. It was upon this principle that Bakewell formed his celebrated breed of sheep, and it is the only principle upon which any breed can be raised to the highest perfection of which it admits. *Breeding in and in*, as it is called, has given rise to a long controversy, which our increasing knowledge of the physiology of the animal economy, and a wider induction of facts, carefully observed and accurately recorded, will speedily bring to a final close. The facts now collected from a wide surface, and attested by men skilled in the sciences of physiology and anatomy, as well as by practical breeders of live-stock, establish the important fact, that breeding by too near affinities, the offspring degenerates. It is a law of nature, and applies to men and animals, and even plants. The accurate experiments of Mr Knight establish the fact, that in the vegetable as well as in the animal kingdom, the offspring of male and female plants, when not related, possess always more strength and vigour than those of near affinities. Sir John S. Sebright tried many experiments by breeding in and in with dogs, fowls, and pigeons, and found that the offspring uniformly degenerated. Sir John Sinclair relates an experiment with pigs, which he carried so far that the females almost ceased to breed; and if they did breed, the offspring was so small and delicate, that they died as soon as they were born. To breed, therefore, from the same race, but of different families, is now established as the only system that will secure the highest results in the different breeds.

Crossing is a means of improving a breed that requires many concurring circumstances to insure success. The climate and the food must accord with the size and constitution of the animal to be produced. To increase the size of sheep, without augmenting or improving their food, would be a ruinous enterprise, and in the face of all principle. The attempt to increase size by crossing with heavier rams from another country, requires also great care that the food and climate be adapted to the condition and character of the expected race; for it is in proportion as size is gained by crossing, that delicacy of constitution and liability to disease are increased. The constitutional qualities of a race of sheep will not accommodate themselves to the soil or climate of a country differing much in pasturage and temperature from that on which it has been long a native, without time, great care, skill, and attention. Were we to cross our mountain Cheviot ewes with Leicester rams, the offspring would labour under two fatal disadvantages—a constitution too delicate for the climate, and a size above the pasture. An attempt was made in Scotland some years ago to raise the quality of the wool of our mountain sheep by crossing them with Cheviot rams, and the result, so far as then developed, was a complete failure.

It is now generally admitted that the male has a higher influence on the character of the offspring than the female. This law is in beautiful accordance with that beneficent design so visible in the arrangements of nature, as it enables man to bring the domestic animals to their most profitable condition in a far shorter period than if the law had been reversed. There is another fact apparently well established, that the male, by one connection, has a higher influence on the second generation than the actual father. This shows that no important change in the character of any breed can be effected, unless the crossing is continued until the fourth or fifth generation.

Age of the Parents; its Effects on the Sex of the Offspring.—Some very interesting experiments were begun some years ago, the result of which, so far as they go, tend to establish, as a general law of nature, that the offspring of a young ram and ewe, of from four to five years old, will in general be feminine, while that of an old ram and young ewe will in general be masculine. Could such a law be practically acted upon, it would be of immense advantage to breeders of stock in every country, but particularly to breeders of stock in such a country as Australia, in which the rapid increase of the number of stock is an object of such importance. There is an able paper on this curious subject in the first number of the 'Quarterly Journal of Agriculture,' containing the results of the experiments made in France, from which the following facts and views are extracted:—'M. Charles Giron de Buzareingues proposed, at a meeting of the Agricultural Society of Severac, on the 3d of July 1826, to divide a flock of sheep into two equal parts, so that a greater number of males or females, at the choice of the proprietor, should be produced from each of them. Two of the members of the society offered their flocks to become subjects of his experiments; and the results have now been communicated, which are in accordance with the author's expectations. The first experiment was conducted in the following manner:—He recommended very young rams to be put to the flock of ewes from which the proprietor wished the greater number of females in their offspring, and also, that during the season when the rams were with the ewes, they should have more abundant pasture than the others; while to the flock from which the proprietor wished to obtain male lambs chiefly, he recommended him to put strong and vigorous rams four or five years old. The following tabular view contains the result of these experiments, which are strongly in favour of the views of M. Giron:—

FLOCK FOR FEMALE LAMBS.			FLOCK FOR MALE LAMBS.		
Age of the Mothers.	Sex of the Lambs.		Age of the Mothers.	Sex of the Lambs.	
	Males.	Fem.		Males.	Fem.
Two years old,	14	26	Two years old, .	7	3
Three years, .	16	29	Three years, .	13	14
Four years, .	5	21	Four years, .	23	14
Total, .	35	76	Total, .	43	31
Five years and older, . .	18	8	Five years and older, . .	25	24
Total, .	53	84	Total, .	68	55
N.B.—Three twin births in this flock. Two rams served it, one fifteen months, the other nearly two years old.			N.B.—No twin births in this flock. Two strong rams, one four, the other five years old, served it.		

The general law, as far as we are able to detect it, seems to be, that when animals are in good condition, plentifully supplied with food, and kept from breeding as fast as they might do, they are most likely to produce females; or, in other words, when a race of animals is in circumstances favourable for its increase, nature produces the greatest number of that sex which, in animals that do not pair, is most efficient for increasing the number of the race. But if they are in a bad climate, or on stinted pasture, or if they have already given birth to a numerous offspring, then nature, setting limits to the increase of the race, produces more males than females. Yet, perhaps, it may be premature to attempt to deduce any law from experiments which have not yet been sufficiently extended. M. Giron is disposed to ascribe much of the effect to the age of the ram, independent of the condition of the ewe.' The author of this treatise has uniformly observed, that in every favourable season, when his stock was in high condition, he had a much larger number of female lambs than of males; and in one of the most favourable seasons that has occurred during his own personal experience, the female lambs exceeded the males to the number of ninety, in a flock of 600 ewes. The ewes had no artificial food at any season of the year; they lived entirely on the natural grasses of our mountain pastures. They got bog and lea hay in snow storms, but nothing else.

GENERAL MANAGEMENT.

The management of sheep must be varied according to the nature and character of the breed, the soil and climate, character of the pastures, natural or artificial, the position of the farm in reference to markets, and whether all the sheep upon the farm can be prepared for the butcher, or must all be sold lean, as is the case with those farmers whose flocks subsist entirely on the natural grasses of our mountain pastures; and whether early lambs would be profitable or otherwise. These and many other circumstances must regulate the proper time for admitting the rams to the ewes; hence the lambing season, the proper time for washing, shearing, dipping, smearing, &c. Different names are applied to sheep at different periods of their age. A young sheep remains a *lamb* from birth till the first smearing time. From this till the first clipping it is called a *hog*. From the first to the second clipping it is termed a *gimmer*. It is now called a *young ewe*, till it bears its first lamb. When male sheep are cut, they are denominated *wedders*; and, according to their age, are called wedder hogs, &c. At three years old, the wedder is in its prime for mutton.

Lambing.

The period at which sheep begin to breed is in the autumn of the second year after birth, when both rams and ewes are at their maturity. In the British islands, the company of the ram is permitted at the beginning of October. The ewe goes with young about 152 days, or between twenty-one and twenty-two weeks, and consequently the lambing season is at the beginning of March. It is of high importance that sheep, during gestation, should be managed with peculiar gentleness and care, the rash use of the dog being attended with the most pernicious consequences. The ewes should be well but not overfed, as the ewes being in too high condition greatly increases the risk in lambing. Though parturition, being a natural process, cannot be regarded as a disease, still, in the sheep, as well as in many of our domestic animals, it is attended with some risk; and in certain states of the atmosphere, and ewes in too high condition, the loss is often very considerable from inflammation.

'As the period of parturition approaches,' observes an intelligent writer in the 'Penny Cyclopædia,' 'the attention of the shepherd should increase. There should be no *dogging* then, but the ewes should be driven to some sheltered enclosure, and there left as much as possible undisturbed. Should abortion take place with regard to any of them, although it does not spread through the flock as in cattle (see No. 38, p. 596), yet the ewe should be immediately removed to another enclosure, and small doses of Epsom salts, with gentian and ginger, administered to her, no great quantity of nutritive food being allowed.

The ewes should now be moved as near home as convenience will permit, in order that they may be under the immediate observation of the lamber. The operation of *clatting*, or the removal of the hair from under the tail and around the udder, should be effected on every long-wooled ewe, otherwise the lamb may be prevented from sucking by means of the dirt which often accumulates there, and the lamber may not be able at all times to ascertain what ewes have actually lambed. The clatting before the approach of winter is both a useless, cruel, and dangerous operation.

The period of lambing having actually commenced, the shepherd must be on the alert, yet not unnecessarily worrying or disturbing the ewes. The process of nature should be permitted quietly to take its course, unless the sufferings of the mother are unusually great, or the progress of the labour has been arrested during several hours, or eighteen or twenty hours or more have passed since the labour commenced. His own experience, or the tuition of his elders, will teach him the course which he must pursue.

If any of the newly-dropped lambs are weak, or scarcely able to stand, he must give them a little of the milk which at these times he should always carry about him, or he must place them in some sheltered warm place; in the course of a little while, the young one will probably be able to join its dam. The lambing field often presents at this period a strange spectacle. 'Some of the younger ewes, in the pain and confusion and fright of their first parturition, abandon their lambs. Many of them, when the udder begins to fill, will search out their offspring with unerring precision; others will search in vain for it in every part of the field with incessant and piteous bleating; others, again, will hang over their dead offspring, from which nothing can separate them; while a few, strangely forgetting that they are mothers, will graze unconcernedly with the rest of the flock.

The shepherd will often have not a little to do in order to reconcile some of the mothers to their twin offspring. The ewe will occasionally refuse to acknowledge one of the lambs. The shepherd will have to reconcile the little one to its unnatural parent, or to find a better mother for it. If the mothers obstinately refuse to do their duty, they must be folded by themselves until they are better disposed; and, on the other hand, if the little one is weak and perverse, it must be repeatedly forced to swallow a portion of her milk, until it acknowledges the food which nature designed for its sustenance.'

Male lambs are cut nine or ten days after birth. Weaning, or removal from the mother, takes place from three to four months after birth, according to circumstances. In weaning, the ewes and lambs must be separated so far that they will not hear the bleatings of each other. The lambs are at first put on the tenderest herbage that can be selected. Some ewes may have so much milk, that the udders will swell when deprived of the lambs, and this requires to be attended to by the shepherd at this trying season of his labours.

Food—Tending—Shelter.

The best kind of food for sheep is nutritious grassy pasture, growing on a dry and firm soil. The sheep is most assiduous in picking up food, and will range over a great space in quest of the herbage which it is fond of. In the Highlands of Scotland, and in Australia, where the herbage is scanty, the sheep-farm requires to be very large: twelve miles in length and breadth is no unusual size of a Highland sheep-farm. In countries liable to be covered with snow in winter, grass, hay, or some other vegetable material must be preserved for the subsistence of the flocks when their ordinary walks are under a snowy mantle. Natural meadow hay and turnips are used in Scotland for winter keep when ordinary resources fail; and the employment of these, in the case of heavy drifts, sometimes saves large numbers of sheep. If the flock can be conveniently driven to a cleared hay-field, such is done in preference to carrying food to the animals: there should be one field for the rams and another for the lambs, or for sheep in a weakly condition. A general rule for sheep intended for the butcher is, that they should never be allowed to turn lean, but be kept in a constant state of improvement; and that kind of food should be selected that will bring the animals to the highest profit in the shortest time and at the least expense. In well-managed store farms, sheep are now allowed many kinds of food little thought of in former times, as sliced turnips, oil-cake, &c.; and are, besides, provided with troughs of pure water, and a trough of salt, that they may lick when their taste leads them to that indulgence. In all artificial feeding, the food should be free of dirt or any insect spawn.

Heedless farmers are sometimes apt to purchase and keep more sheep than they can conveniently feed on their grounds, which causes a serious evil. To overstock a farm, where artificial food cannot be obtained, is one of the most fatal errors a farmer can commit. It does not merely diminish the quantity, but also fouls and deteriorates the quality of the food. A farm may be overstocked for a few years, but death will by and by not only lessen the numbers, but diminish to a great extent the health and productiveness of those that survive. Avarice and ignorance have tempted not a few farmers to carry on this unequal struggle against the laws of nature and humanity for years, but it has always ended, as it ever must, either in the farmer's ruin, or reformation of his plan.

The tendency which most sheep have to ramble, renders it necessary for them to be attended by a shepherd and his dog. The duties of a shepherd are very irksome, and require to be performed by a man of firm resolution, good temper, and discretion. To keep the flock within bounds may be troublesome, but much may be done in the way of preventive; and at all events, the sheep must not be harassed and chased as if they were so many wild beasts. Being naturally of a timid and gentle nature, the sheep ought to be treated with a degree of gentleness, and taught rather to look up to their shepherd as a friendly protector than a tyrant. Lazy shepherds, who do not exercise a judicious foresight in keeping the flock to its ground, try to remedy the evil by hounding the dog after the stragglers, besides giving no small toil to their own limbs in running. We are desirous to lay it down as a rule, well known to all good shepherds, that there should be *only a rare and cautious use of the dog*. Much also depends on the dog being of the proper breed (see No. 42), and well trained to his duty. A good dog gives little tongue; he is seldom heard to bark: his great knack consists in getting speedily and quietly round the further extremity of the flock, and then driving them slowly before him in the direction which his master has pointed out. A wave of the hand in a certain direction, and the word *There*, are usually enough as a sign. Under-bred dogs bark at and fly upon the poor animals, chasing them hither and thither without any rational purpose. All such dogs should be destroyed, as unfit for the important duties which they are intended to perform. A first-rate shepherd's dog is invaluable to the store farmer, and no reasonable price should be grudged to obtain one.

In those districts which are exposed to storms, it is important to afford shelter to the flocks. Where there are jutting or overhanging rocks or bushes, the sheep will crowd under their lee, and so far protect themselves from harm; but where the country is bare, it will be necessary to erect artificial walls or enclosures of turf and stone, to which they can be led in cases of emergency. On the exposed hill-sides of Scotland it is usual to build circular folds, locally termed *stells*, of sufficient size for a *cut*, or parcel of sheep. The stell is a rude enclosure, formed of a stone and turf wall about four feet in height, and is placed on a piece of ground known to be seldom drifted. Besides these, there should be on every sheep farm ample and conveniently-situated folds for the various sortings of sheep, such as for weaning lambs, shearing, and drafting or drawing out any animals required. Such folds are ordinarily constructed of *flakes*, or movable wooden palings, and occasionally of rope netting.

Shearing—Wool.

The winter coat of the sheep begins to be ragged in spring or early in summer, while the lambs are in course of being suckled; and towards June, the wool is seen to be falling off in lumps, or caught in every bramble. To save the wool in time, and relieve the animal, it is the practice to shear them about the middle of June, when the lambs have been weaned, and the weather is genial. In any case, however, it should not be done till the new wool is observed to be pushing off the old. Previous to shearing, all the sheep should be collected, and washed in a running brook or pool, to rid the fleece of impurities. Some shepherds employ a little soap in this operation. On being washed, the animals should be put into a clean field or fold to dry. Fine weather should be selected for washing. The shearing is performed a day or two after, by means of large shears made for the purpose. In shearing, care should be taken not to break or tumble the wool, but to take off the fleece neatly, and without injuring the skin of the animal.

Mr Walter Buchanan has written directions to the wool-growers of Australia respecting the management of wool, many of which are of general application:—

It is of great importance that the fleece should be well washed, that the wool may be brought to market with as bright a colour as possible. Every convenience, and a very plentiful supply of pure water, should therefore be provided, a running stream being most desirable. The preferable mode of washing is that which is performed before shearing, according to the German manner. Some growers have tried the plan of washing after the fleeces have been shorn and sorted, and, as is supposed, to have used tepid water, following the French and Spanish method; but this has not been approved of by the buyers generally, and particularly by those who buy for combing purposes.

The breaking of the fleece and washing after shearing give the wool more the appearance of Spanish than of German wool, and it is consequently reduced to a lower standard of comparison. It is well known that the sheep of those German flocks that are best washed are, after that operation, driven into some shed strewed with clean litter, or penned up with hurdles on clean grass; that the utmost care is taken to prevent their exposure to dirt, or whatever else might tend to sully their whiteness; and that they are not shorn until a sufficient degree of moisture is deposited in the fleece, by perspiration, to impart a soft handle to the wool. It may here be added, that it is very important, if possible, to prevent the sheep from filling their fleeces with grass seeds, broken leaves, and other extraneous substances, which cannot be removed in the operation of washing, and which are productive of labour and expense in every process of manufacturing; in some cases, indeed, rendering wool almost unsaleable. It may be here observed, that so conscious are the Spaniards of the superiority of the German mode of washing and assorting, that they are now making every effort to introduce it.

In order to assimilate the Australian wool as much as possible with the German, in preparing it for market, the fleeces should not be broken, but merely divested of the breech and stained locks, and so assorted or arranged, that each package may contain fleeces of the same character as to colour, length of staple, fineness of hair, and general quality.

If the washing has been performed at the same time and place, and with an equal degree of care, the colour is likely to be uniform, and it will then only be necessary to attend to the separation of the fleeces as to length, fineness, and general quality: but if a larger grower has flocks of different breeds, and fed on different soils, care should be taken that the fleeces be separated, first as to colour, and then again as to length of staple, fineness, &c.

The fleeces being assorted as already suggested, should be spread one upon another, the neck of the second fleece being laid upon the tail of the first, and so on alternately, to the extent of eight or ten fleeces, according to their size and weight. When so spread, the two sides should be folded towards the middle, then rolled together, beginning at each end, and meeting in the centre, and the roll or bundle so formed held together by a slight packthread. The bagging should be of a close, firm, and tough nature. The material hitherto most generally used has been sail canvass, which very ill resists bad weather on a long voyage; and when received here, even in favourable condition, is so dry and crisp, that it will tear like paper: a thicker, twilled, more flexible, and tough material, would be preferable. The size and form of the package may be in length about nine feet, and width four feet, sewed up on the two long sides and at one end, the other end being left open, and the sheet so formed being suspended, with the open end upwards, to receive the bundles, made up as before directed, which are to be put in one at a time, one of the flat sides of the roll or bundle being put downwards, and so on in succession, being well trod down, until sufficiently filled for the mouth to be closed. This is the German mode of packing; but it is doubtful whether smaller packages, of the dimensions that have been hitherto sent from the two colonies, may not be more convenient for so long a voyage. The operation of screwing should be discontinued where it has been practised, as the screw pressure, and remaining compressed during the voyage, occasion the wool to be caked and matted together in a manner that is highly prejudicial to its appearance on arrival. The practice also of winding up each fleece separately, and twisting a portion into a band, is productive, in a minor degree, of the same prejudicial effect; and it is to avoid this that the making German bundles of eight or ten fleeces is suggested.'

Qualities of Wool.—Improving the quality of the wool, or at least of not allowing it to deteriorate, is now an object of as great importance to the British store farmer as in raising the weight of the carcass. The finest wools are those purchased for making broad cloths, merino, and mousseline-de-laine fabrics (*laine* is the French word for wool). 'The wool of which good broad cloth is made,' observes Dr Ure in his Dictionary of Arts, 'should be not only shorter, but, generally speaking, finer and softer than the worsted wools, in order to fit them for the fulling process;' and to judge of this degree of fineness, great nicety of discernment is required. 'There are four distinct qualities of wool upon every sheep: the finest being upon the spine, from the neck to within six inches of the tail, including one-third of the breadth of the back; the second covers the flanks between the thighs and the shoulders; the third clothes the neck and the rump; and the fourth extends upon the lower part of the neck and breast down to the feet, as also upon a part of the shoulders and thighs to the bottom of the hind-quarter. These should be torn asunder and sorted immediately after the shearing, or at all events before being prepared for the roving or spinning-frame.

The harshness of wools is dependent not solely upon the breed of the animal, or the climate, but is owing to certain peculiarities in the pasture, derived from the soil. It is known that in sheep fed upon chalky districts, wool is apt to get coarse; but in those upon a rich loamy soil, it becomes soft and silky. The ardent sun of Spain renders the fleece of the Merino breed harsher than it is in the milder climate of Saxony.

All wool, in its natural state, contains a quantity of a peculiar potash soap, secreted by the animal, called in this country the *yolk*, which may be washed out by water alone, with which it forms a sort of lather. It constitutes from 25 to 50 per cent. of the wool, being most abundant in the Merino breed of sheep; and however favourable to the growth of the wool on the living animal, should be taken out soon after it is shorn, lest it injure the fibres by fermentation, and cause them to become hard and brittle. After being washed in water somewhat more than lukewarm, the wool should be well pressed, and carefully dried.'

The quantity of wool imported annually into the United Kingdom, a large portion (21,000,000 lbs.) of which is now from Australia, has latterly been about 65,000,000 lbs.—a quantity not nearly equal to that produced from native flocks. As the imported wools are chiefly of a finer quality than those of native growth, so far is the large importation from injuring the British wool-growers, that it is the means of giving them higher prices for their commodity. It has been satisfactorily shown by clothmakers before a parliamentary committee, that unless they imported foreign wool to mix with that of Britain, they could not produce the finer class of goods, and consequently that British wool would be much less in demand.

Smearing.

Smearing is a process of anointing the skins of sheep with certain ingredients, principally for the purpose of rendering the animal less liable to injury from winter cold (the unguent being a slight counter-irritant), and of destroying the vermin which lodge among the roots of the wool. Smearing with a mixture of tar and butter was general in Scotland in former times. The proportions varied in different districts; but in general six pounds of butter to a gallon of tar were deemed sufficient for twenty sheep. The time for laying on this salve was in the end of October and beginning of November, before the rams are admitted to the ewes, which, in the mountain farms of Scotland, is in general about the 23d of November. The smearing with butter and tar has very much declined of late years, and various other preparations—such as butter and oil, turpentine, arsenic with a solution of soft soap, and various other baths—are used instead of butter and tar. Which of the various baths now in use are the best, it would be difficult to determine, as each has its advocates. On this, as on other subjects, the store farmer, without running rashly into experiments, ought to have his mind open to well-considered improvements, and adopt such measures as are supported by respectable authorities placed in similar conditions of climate, food, nature of stock, and demand.

DISEASES OF SHEEP.

The sheep, in a state of domestication, is subject to a great variety of diseases; but the most formidable, and by far the most destructive, is

The Rot.

It is unfortunate that in the early stages of rot the disease gives no external intimation of having commenced its destined fatal career; for it is at the beginning of most diseases that human skill is most efficacious in arresting their progress. But sheep in the early stages of the rot, instead of showing symptoms of disease and decay, acquire a great tendency to fatten, which has been turned to advantage by Mr Bakewell and others. But after the disease has undermined the general health, the animal becomes listless, and unwilling to move, leaves its companions, and sinks rapidly in flesh; its eye becomes sunk, dull, and glassy; the wool comes easily from the skin; the breath becomes fetid; the bowels variable, at one time loose, with a black purging, and at another costive; the skin becomes yellow, and sometimes spotted with black; emaciation now becomes more rapid; general fever is induced, and death ensues. There are various methods by which practical men endeavour to ascertain the incipient symptoms of the disease, but the two following are the most general:—

The first is, by handling the sheep on the small of the back, and if the flesh feel firm and solid, the animal is judged sound, but if the flesh feel flabby and soft, and give a crackling sound when rubbed against the ribs, the animal is unsound. The other method is by examining the small veins at the corners of the eyes, and if filled with yellow serum instead of blood, the animal is pronounced unsound; but the greatest practical tact and talent will not always insure success in discovering the early stages of this insidious disease.

Appearances on Dissection.—The whole cellular tissue is filled with a yellow serous fluid; the muscles are pale, and appear as having been macerated, being soft and flabby; the kidneys are infiltrated, pale, and flaccid; the mesenteric glands distended with a yellow serous fluid; the lungs filled with tubercles; the heart enlarged and softened; the peritoneum thickened; the bowels are often distended with water, and sometimes grown together. But the liver is the primary seat of the disease; its whole structure is in different states of disease; one part is scirrhous and indurated, and another soft and ulcerated; and the biliary ducts are filled with flukes. This appears to be the origin of the disease which has involved so many organs, and effected such a vast derangement of the whole animal frame.

Causes.—In endeavouring to ascertain the cause of this disease, it seems natural to begin by inquiring whether those parasites which are found in such numbers in the biliary ducts of the liver are the cause or effect of the disease. The parasites named the liver-fluke (the *fasciola* of Linnæus, the *Distoma hepaticum* of Rudolphi, the *planaria* of Goese) are not peculiar to the sheep, but have been found in the biliary ducts of the goat, deer, ox, horse, ass, hog, dog, rabbit, guinea-pig, and various other animals, and even in the human being. The parasite is of a brownish-yellow colour, and resembles a small sole divested of its fins; in size it may be seen from that of a pinhead to an inch and a quarter in length, and half an inch in breadth. It is supposed to be a hermaphrodite, as no distinction of sex has yet been made out: in scientific language, it increases, like many of the lowly-organised animalcules, by self-division and gemmation. The spawn or eggs of this parasite are found in great numbers in the biliary ducts of the liver; those eggs are also found in every part of the intestinal canal, and very often seen in the dung of a sound sheep, though always numerous in that of a diseased one. This animalcule, and many other of the *entozoa*, have never been found out of the intestines; but this is not positive proof that they cannot or do not exist out of the body. Mr Blacklock, in his very valuable treatise on sheep, after laying flat all his opponents, comes to the following conclusion:—'From all this data, the conclusion must at once be drawn, that as living flukes cannot reach the liver from without, they must of necessity be produced only in particular states of the animal they inhabit: how they originate we cannot of course determine, and this is not the place to hazard a physiological conjecture; but it will be found that their appearance in the bile is always preceded by tuberculous deposits on the lungs and liver.'

That Frommen found the fluke-worm in the fœtus of the sheep, is a strong fact, but not decisive; for Mr Blacklock must know that although he is anatomically correct when he states that there is no direct vascular communication between the fœtal and maternal side, yet the indirect communication may be sufficient. And besides this, Mr Blacklock's own views on this point are extremely unphilosophical, as when he says—'That living flukes cannot reach the liver from without, they (the flukes) must of necessity be produced only in particular states of the animal they (the flukes) inhabit.' This is just saying that the flukes inhabit the animal before its particular states produce them. This must mean that the eggs of the fluke exist in the liver of the sheep, ready to be hatched by the peculiar states of the animal; and as these eggs could not, according to Mr Blacklock, reach the liver from without, the only other alternative is, that the liver lays the eggs when in a healthy state, and hatches them when diseased. This wont do: equivocal generation is absurd. But the limits prescribed forbid the author pursuing this interesting inquiry further: he must simply state his belief that the ova of the fluke are not generated by the liver of the sheep, but find their way to that organ by means not yet ascertained; but these ova are not vivified in the liver except under certain states of that viscus. The ease with which Mr Bakewell could induce rot in his sheep, by putting them on ground which he had previously flooded for that purpose, shows that other circumstances must concur to produce the disease. It is not caused by scanty food, as has often been alleged, for sheep may be starved to death without producing rot: the fact that the sheep has an extraordinary tendency to acquire fat in the early stages of the disease, shows that the causes act as a stimulant at first, and originate a slight degree of inflammation in the liver, as the first step in the progress of this fatal disease. But the numerous and well-attested facts now obtained from various climes and countries, lead to the conclusion that the nature of the soil and pastures, and the character of the seasons, are the chief agents in causing rot. This view is confirmed by the fact, that rot is most prevalent in wet seasons, and is nearly confined to lands subject to be occasionally flooded with water at certain seasons of the year, and to soils naturally moist and marshy. Moist and level lands of retentive soil, from which water is slowly evaporated by the sun, and a temperature favourable to the decomposition of vegetable matter—on such lands, when not thoroughly drained, rot may be said to be indigenous, while on lands that are dry and hanging the disease is unknown. The nature of the plants which the soil produces is not so important as the plants being kept in a morbid state by that degree of moisture and heat favourable to their decomposition. These views will be amply verified by any one who will take an accurate survey of the midland, eastern, and southern counties of England, in which the disease is most destructive. Besides supporting the views here advocated, the following passage from the pen of M. Hammond, the founder of the veterinary school in Egypt, is highly interesting to every sheep farmer:—'It appears every year in Egypt after the falling of the Nile, and it follows and keeps pace with the subsidence of the waters; desolation and death accompany it wherever it passes, and it annually destroys at least 160,000 sheep. As soon as the waters of the Nile subside, the pastures which were submerged are speedily covered by a tender rushy grass; the sheep are exceedingly fond of it, and they are permitted to feed on it all day long; in the course of a very little time they begin to get fat, when, if possible, they are sold; their flesh is then exceedingly delicate, but soon after this the disease begins to appear, and the mortality commences. The disease is more frequent and fatal when the sheep are first turned on the newly-recovered pasture, than when the ground becomes dried and the rushy grass harder. But if the sheep pasture in the midst of mud, or on the borders of the marshes and canals, rot attends every step; the rot does not occur in elevated countries, where the sheep feed on dry aromatic herbage. The Bedouin Arabs sell all the sheep which they can before they quit the Nile, for then they are in high and prime condition, after which they lose not a moment in reassembling their flocks and driving them back to the desert.'

Prevention and Treatment.—If the true causes of rot have been accurately given, every farmer has in his own hands the most efficient means for its prevention; on all lands that can be defended from being flooded with water, and on all lands whose levels admit of thorough drainage, the manner and amount of drainage must be determined by the position of the land, whether level or hanging, and by the character of the soil, and the quantity of the moisture to be removed; and on all these points each farmer must decide for himself, or be guided by the advice of a competent judge. The only indispensable rule is, that the drainage must be thorough, in order to be effectual; and if the drainage is carried to this point, the farmer will have the pleasure to see the rot, that dreadful scourge of his flock, disappear. This important point is established by practical men whose testimony cannot be impeached, that there would be no rotten sheep found, even upon the most spongy lands in the country. The treatment of rot is confined to narrow limits, from the curious fact that sheep, in the early stages of rot, acquire fat with singular rapidity; and the best thing the farmer can do, as soon as he finds his flock tainted, is to sell them to the butcher for what they will bring in the market. From the condition of the sheep, this forced sale may be attended with considerable loss, but it will be a loss inferior to that sustained in the fruitless attempt to effect a general cure.

Tainted flocks have recovered, it has been alleged, by being sent to pasture on salt marshes; but though the efficiency of such pasture were admitted, it is a remedy which only a few farmers could obtain. To change the flock to a more dry and elevated part of the farm, when this is practicable, has been attended with favourable results. The free use of salt is universally admitted to be the best medicine within the reach of the farmer for checking the progress of this deadly disease. That many cures have been effected by the proper use of salt, is attested by persons of the highest character and intelligence. Sir John Sinclair states that at Mr Mosselman's farm at Chenoi, beyond the Wavre, he found that salt was used for sheep, and that by allowing them to lick it, the rot was completely cured. And as the only explanation of sheep taking on fat rapidly, in the early stage of the disease, is, that the digestive organs are stimulated for a time by inflammation of the liver, perhaps the disease might be checked *in limine* by copious bleeding; but the disease can scarcely ever be detected at that period in which bleeding would be proper, and bleeding late in this, as in almost all diseases, is fatal. But in this disease the sheep farmer must direct his energies and care to the prevention rather than the cure, though some of the remedies just mentioned may be of service at the beginning: yet from the insidious nature of the disease, it can undermine the constitution, before it is perceived, to that extent which no known remedies can restore, so that every sheep farmer must rest his hopes of safety not in curatives, but in the vigorous use of the means of prevention.

Braxy.

Braxy, or sickness, is an inflammatory disease, whose ravages are chiefly confined to hogs, and those in the highest condition are most liable to be attacked. This disease is not nearly so destructive as it was formerly, when hogs were hirsled. This has been accounted for by alleging the inexperience of hogs in selecting their food, and their tendency to feed too much on the succulent parts of their pasture. Braxy, being entirely an inflammatory affection, may be excited by a variety of causes, such as drinking cold water in a heated state; any great or sudden change of temperature; by hail, snow, or rain; feeding on soft rank grasses, which are apt to excite fermentation, and by extrication of gas, distending the stomach, thus originating inflammation, and sometimes producing sudden death by pressure on the diaphragm. One very frequent cause of braxy is that kind of frosty mornings which load the pastures with hoar-frost. The hogs, from feeding chiefly on dry and binding pastures at that season of the year (from November till March), eat the succulent spots of grass laden with hoar-frost very greedily; and thus the temperature of the stomach is so suddenly lowered to icy coldness, that violent inflammation is immediately produced, and death often ensues in a few hours. In the list of the causes of braxy, the improper use of the dog must not be omitted. It is as clear as a sunbeam that nothing is more calculated to produce inflammation than violent heating a sheep by incessant use of the dog at seasons of the year so liable to sudden and great falls of temperature.

Symptoms.—The animal appears uneasy, often lying down and rising up, standing with its head down and back raised, taking no food, but often drinking water; fever then ensues, when the pulse becomes strong and quick, respiration laborious and rapid, the skin hot, and the fleece clapped; the eyes are languid, watery, and half-closed; by and by it ceases to follow the flock, and soon dies.

Appearances on Dissection.—On opening the body, the appearances vary, according to the parts affected. Sometimes only the reed is affected, and all the rest of the viscera appear perfectly healthy, and the flesh not at all affected. In other cases, the effects of violent inflammation are visible through the whole of the viscera, and the entire flesh of the animal is in a state of rapid putrefaction.

Treatment.—From the nature of the disease, it is obvious that the first and most effective remedy is prompt and copious bleeding from the jugular veins; this being effected, the constipation of the bowels must be removed. The best purgative for this purpose is Epsom salts, two ounces for a dose, dissolved in warm water, and followed by thin warm gruels; these remedies would generally prove effectual if applied at an early stage of the disease; but in a large flock of mountain sheep the disease is frequently not observed by the shepherd till too late for any remedy. The best preventive of the disease in mountain sheep is skilful and attentive herding, by preventing the young sheep from fastening too much on marshy succulent spots, and by seeing they graze regularly over every part of the pasture, and be allowed perfect repose for rumination, undisturbed by the dog.

Sturdy.

The proximate cause of this formidable disease is hydatids formed in the brain, or by an accumulation of water or serum in the ventricles of the same organ. Many ingenious writers both in France and in our own country have favoured the public with a few facts and much speculation to account for the manner in which hydatids reach the brain, and the causes of the accumulation of water in the ventricles; but none of these speculations are in the least degree satisfactory, and many of them can be shown to be absurd, from the known anatomy and physiology of the brain of the sheep. Many plans have been adopted to extract the hydatids from the brain. Hogg, the Ettrick Shepherd, was successful by the use of the wire. He says, 'When I was a youth, I was engaged for many years in herding a large parcel of lambs, whose bleating brought all the sturdies in the neighbourhood to them, and with whom I was exceedingly plagued; but as I was frequently knitting stockings, I fell upon the following plan:—I caught every sturdied sheep that I could lay my hands upon, and probed them up the nostrils to the very brain with one of my wires, and I beheld with no small degree of pleasure, that by this simple operation I cured many sheep to different owners; but I kept all my projects to myself, for I had no authority to try my skill on any of them;' and he adds, 'that several years passed before I failed in this operation in any one instance. Nothing approaching this success, however, has ever attended the operation in the hands of any of Mr Hogg's disciples; though, when the hydatid is situated in the ventricles, or in the upper portion of the brain, some farmers and shepherds have acquired such tact in the use of the wire as to cure considerable numbers.

The operation performed with the trocar, and various other instruments that have been used, is liable to many inconveniences and great danger. If the hydatid is situated in the base of the brain, it cannot be reached by the nostril; then there is great danger of rupturing some of the numerous blood-vessels of the brain, and thus producing inflammation—a disease as fatal as the one attempted to be cured. The use of the trephane is also attended with difficulty and danger. It lays open at once an immense vacuum in the brain to the action of the atmosphere, and its consequent irritation, and hence the risk of inflammation. When the situation of the hydatid can be ascertained by the softening of a portion of the skull, to destroy the vitality of the hydatid by perforating it with the trocar or other sharp instruments, is perhaps the method attended with the least danger of exciting inflammation, and hence the most likely to succeed. But the extent to which the disease must have injured the brain, before the softening of the bone to reveal the position of the hydatid, is an insuperable evil, diminishing the chances of success in any mode of conducting the operation that can be devised. There is no medicine that can justly be regarded as of any avail. But carefully-observed and accurately-recorded facts may yet throw some light on the remote causes of this formidable disease, under that higher anatomical and physiological knowledge which has within these few years been brought to bear on the diseases of our domestic animals.

Pining.

This disease, it is said, was unknown in this country before the sheep-walks were thoroughly drained and the moles exterminated. If this statement is correct, the cause of the malady must obviously be too dry and binding pasture; and in accordance with this view, constipation of the bowels is always present in this disease. To open the bowels freely, and change to a more nutritive pasture, are the obvious remedies; and when both can be readily applied, they seldom fail of complete success.

Dysentery.

This disease begins with violent discharges from the bowels of a green slimy mixture, which in progress of time becomes mixed with blood. It has often been confounded with diarrhœa, from which it differs in many particulars. Diarrhœa attacks young sheep, particularly hogs, occasioned by a sudden rush of grass in the spring, or from too sudden a change from a scanty to an over-rich pasture; when such are the causes of diarrhœa, the mere change to a drier pasture will effect a cure. But dysentery attacks old sheep, and generally does not commence till June or July. Many writers allege that this disease is highly contagious, but the best established facts do not sustain the allegation. The disease prevails in fouled pastures, and in seasons characterised by a peculiar state of the atmosphere with regard to heat and moisture, a certain combination of which renders the malady so fatal to our army, especially in tropical climates. In the treatment of this disease, bleeding is a proper remedy in an early stage; but if late, gentle purgatives alone must be used: Epsom salts or castor oil, with twenty-five to thirty drops of laudanum, are the best purgatives. Mr Stevenson also used an infusion of logwood, and doses of ipecacuanha, in numerous cases with great effect.

Trembling.

Trembling, or Louping Ill, in mountain flocks, is a disease caused by cold east winds, which are prevalent in April and May, and at which season this disease, after a bad winter, is often very destructive. The animal sometimes leaps from the ground and falls down dead; but more generally it is seized with trembling, loses the power of its legs, and lies on its side, grinding its teeth, and moving its limbs with great violence. The appearances on dissection are very uniform; great congestion of blood in the liver and lungs, and particularly the heart, which is invariably gorged with dark blood; and the brain is also sometimes congested; the whole flesh of the body is as white as if the animal had been killed by the usual process of bleeding.

These appearances, and various experiments, led the writer of this paper to view the disease as the effect of a lost balance in the circulation; the cold east wind acting on the surface of the animal when she is just beginning to return from the lowest point by the coming grass, drives the blood from the surface, congests the lungs and liver, and overpowers the action of the heart with a rush of dark vinous blood. The numbness of the limbs, caused by the heart being unable to send the circulation to the extremities, has led some writers to regard the disease as a kind of palsy.

Treatment.—Copious bleeding in the first stage of the attack will often restore the balance of the circulation; but if the animal has been affected some time, it is often difficult to obtain a sufficient quantity of blood, which has been thrown from the surface upon the heart and other internal organs. In this state the animal must be put into a tub of hot water at 98 degrees, which will cause the blood to flow, and thus restore the action of the heart, and tend to restore the balance of the circulation. After a sufficient quantity of blood has been drawn, doses of Epsom salts, dissolved in warm water, and followed with thin warm gruels, must be given till the bowels are freely opened. The prompt application of these remedies on the first attack of the disease would in general be successful; but like many other diseases of sheep, it is not observed till the action of the heart has become too feeble for any remedies to restore the lost balance of the circulation. The same views of the nature, causes, and treatment of this destructive disease are supported by numerous facts and experiments brought forward by Mr Tod, in his prize essay, published in the 'Transactions of the Highland Society of Scotland.'

Foot-Rot.

This is a disease most prevalent in luxuriant meadows, and in all soft grassy lands saturated with moisture. The opinions entertained regarding the causes of this disease are discordant in the extreme. Some writers contend that it is comparatively a modern disease, and was first mentioned by two French physicians, M. Etienne and M. Leibault, who published some cases of the disease in 'La Maison Rustique' in the year 1520. Lulin says that it was brought from Piedmont to Geneva in the year 1766, and that the foot-rot did not exist among Swiss sheep before that period; and in a report of the management of Flemish sheep in 1763, published by authority, foot-rot is not once mentioned. In our own country, it is mentioned by Sir Anthony Fitzherbert in the year 1523. But whatever may have been its history and progress in other countries, it was very prevalent in Great Britain in 1749. Ellis, who wrote in that year, says 'that it raged particularly in the counties around the metropolis. The ewes were seized with foot-rot, which was communicated to other sound ewes and to the lambs which they suckled; and most of the meadows are so much infected with this sheep malady, that few of the suckling ewes are ever clear of it in a greater or less degree, and the pain and anguish thereof keeps them poor in flesh, and lessens their milk; so that two or three ewes thus affected give no more milk than one full milch ewe that is in perfect health.'

It will aid the reader to follow with greater clearness the following discussions regarding the nature and causes of foot-rot, to have first a correct view of the healthy anatomical structure of the foot of the sheep, at least in so far as this very formidable disease is concerned. 'There are some points of importance,' says that eminent veterinary surgeon Mr Dick, 'to be kept in view, in order to understand properly either the functions of the foot of the sheep, or the nature of the diseases to which it is liable. The foot presents a structure and arrangement of parts well adapted to the natural habits of the animal. It is divided into two digits or toes, which are shod with a hoof composed of different parts, similar in many respects to the hoof of the horse. Each hoof is principally composed of the crust or wall, and the sole. The crust, extending along the outside of the foot round the toe, and turning inwards, is continued about half way back between each toe on the inside. The sole fills the space on the inferior surface of the hoof between these parts of the crust, and being continued backwards, becomes softer as it proceeds, assuming somewhat the structure of the substance of the frog in the foot of a horse, and performing at the same time analogous functions. The whole hoof, too, is secreted from the vascular tissue underneath. There are, besides, two supplementary digits at the fetlock. Now this diversity of structure is for particular purposes. The crust, like that in the foot of the horse, being harder and tougher than the sole, keeps up a sharp edge on the outer margin, and is mainly intended to resist the wear and tear to which the foot of the animal is exposed.'

This structure of the foot of the sheep is extremely well adapted to Alpine ranges, which are the native abodes of the sheep in their natural state. 'Dwelling by preference,' in the language of Mr Wilson, 'among the steepest and most inaccessible summits of lofty mountains, among its native fastnesses, it is seen to bound from rock to rock with inconceivable swiftness and agility.'

From these facts, it is easy to perceive how our domestic sheep are subject to foot-rot, when confined to a limited range on soft and rich pastures, and in wet and grassy lands. In these situations, the growth of the crust of the hoof exceeds the wear and tear, and soon overlaps the sole, and in this situation is either rent or broken off, when sand or dirt reach the vascular parts of the foot, and hence inflammation is produced. The animal then becomes lame, suppuration takes place, and ulcers discharge fetid matter; and if these ulcers go on unchecked, they throw out fungous granulations; and if these be allowed to go on, the hoof falls off. When the disease reaches to this extent, the constitutional disturbance is very great from high inflammatory fever, and the animal rapidly loses flesh, and if unrelieved, dies of fever and starvation.

Such being the nature and causes of the disease, the author of this paper thinks the views of Mr Dick rest upon a more secure and philosophical foundation than any other writer that has come under his observation. And if these views are admitted, the treatment and means of prevention are very obvious. To pare away all the detached hoof, and dress the diseased part with some caustic, perhaps the muriate of antimony, has the greatest weight of authority. But as prevention is in all cases to be preferred to cure, the shepherd should keep a vigilant eye upon the flock, and pare regularly on lands that require it. By the simple means here recommended, the writer has prevented the disease from injuring his flock of sheep for more than twelve years, though the lands were subject to the disease. But if foot-rot be as virulently infectious as it is affirmed to be by a whole host of writers, many of whom are men of high character and attainments, very different means both of prevention and treatment must be adopted. As the decision of the question, whether foot-rot be infectious or non-infectious, is of great practical importance to every sheep-farmer, the evidence on both sides of the question would require to be stated with perfect candour, in order to arrive at the truth. In so far as evidence has been produced, the argument inclines to the side of those who contend for the non-contagiousness of the disease. Mr Dick very reasonably asks, 'Has any one ever attempted to produce the disease by inoculation? If it is highly infectious, surely it will at once be produced by inoculation. But this is not such an easy matter as one would expect, from a disease which is supposed to infect a whole field, and that, too, even if it be of five hundred acres in extent. Gohier, a French veterinarian, first applied a piece of horn from a diseased foot, covered with the matter, to the sole of a sound foot, without effect; secondly, he rubbed a diseased foot against a sound one, without effect; thirdly, he pared the sound foot, and having applied a piece of diseased hoof, the disease afterwards appeared; but in this case the foot afterwards got well of itself, and there seems to have been a doubt in the mind of Gohier as to whether it was truly foot-rot or not. Other French veterinarians have tried similar experiments, and particularly Vielhan of Tulle, and Favre of Geneva; and although I have not seen an account of their experiments, it is said they succeeded in producing the disease by inoculation. Now, it will be asked, Is not this a sufficient proof of its infectious nature? I answer that it is not. It appears to me that this is a strong proof against it. If it is produced with so much difficulty by the direct application of matter, is it not absurd to suppose that a few sheep with diseased feet should infect a whole field. I have not seen an account of the manner in which the experiments of the French veterinarians have been performed; I know not what quantity of matter was employed, neither have we any account of counter-experiments, nor whether any were tried to prove if a similar effect would not have been produced by the application of any other morbid matter; for example, whether the matter of grease from the heels of horses, or from thrushes, would not have produced similar effects. I have little doubt of such being the case; that suppuration might be produced by inoculating with that, or almost any other matter, if, in the operation, the wound was made sufficiently deep; nor would I doubt that disease would be produced if matter was spread over the foot in sufficient quantity, and applied for a sufficient time.' The same writer continues—'I repeat, that it is absurd to suppose that; if applied to the hoof, it would produce the disease. The hoof is not governed by the laws of living matter; it is totally insensible, and it has not a circulation, neither has it nerves; it absorbs moisture only like a piece of inert matter, and it is not acted upon as a living part. Matter from the foot of a diseased sheep might as well produce the disease in a tree; nay, even more likely, because it is a living body, which the hoof is not. Why, then, are we to suppose the hoof to be acted upon by matter from diseased feet, and that, too, after the matter has been exposed to the influence of the atmosphere? But rain and sun, we must suppose, have no influence upon it. Arsenic may be diluted with water to such an extent as to be swallowed with impunity, but water seems to increase the virulence of the matter of foot-rot. It is true that heat and moisture will reduce, after sufficient exposure, animal matter to a putrid mass of the same consistence and properties, but the influence of these agents is lost upon the matter of foot-rot. The plague is now known not to be so infectious as it was once thought to be, but the foot-rot will still infect the most extensive domains. The upas-tree may annihilate the existence of all that comes within its pestiferous shade, but what is that to the infection of the foot-rot, when a single sheep will contaminate a mountain! Nay, it will act even upon parts totally devoid of vitality; and such, too, is the eccentricity of its action, that it will allow its neighbouring toe to escape, and still infect the whole ground. But I need not discuss this point farther at present, as I trust I have already shown that all ideas of its infectious nature are merely chimerical.'

In support of these views, Mr Black, farm overseer to his Grace the Duke of Buccleuch, states that he had thirteen score of black-faced sheep, the greater part of which was affected with foot-rot, and many of them crawling about upon their knees. He turned them into a drier pasture, on which were seven score of Leicester and Cheviot sheep. All of the diseased sheep except four speedily recovered, and not one of the Leicesters or Cheviots was infected. This is a very strong fact, from the pressure of which the contagionists cannot easily escape.

The Scab.

This frequent and very mischievous disease has annoyed the cultivators of sheep in different parts of the world from time immemorial. It is mentioned by Ovid, Livy, and in the 'Georgics' it is very graphically described by Virgil. In our own country it is mentioned by our earliest writers; and in Italy, France, and Germany, there is scarcely a writer on sheep who does not describe this prevalent and ruinous disease.

Symptoms.—The sheep becomes restless, scratching itself, tearing off the wool with its teeth, and rubbing violently against any post, stone, or gate. When the skin is carefully examined, there are seen numerous pustules, which, having broken and run together, form large patches of scab. The back and shoulders are generally first affected. The general health of the animal sinks in proportion to the extent of the eruption and the virulence of the disease, and if allowed to proceed unchecked, it brings on general inflammation, and the animal dies in a most miserable condition.

It is now ascertained that this disease in sheep is caused by minute insects of the class *acari*. M. Walz, a German veterinarian, has given a very curious and interesting account of the operations of these acari, which are said to burrow in the skin of the sheep, and reappear again about the sixteenth day with a numerous brood. These young insects commence operations at once, and propagate in the same manner, till the poor sheep sinks under myriads of his destroyers. The work of M. Walz contains drawings of these insects, highly magnified. The subject deserves farther investigation, being of great importance to the sheep farmer.

The treatment of scab is thus rendered very simple—the destruction of the insect which caused it. Infusions of tobacco, hellebore, or arsenic, have all been employed with success. In bad cases, the mercurial ointment has been applied with the happiest effect. A very good receipt is a decoction of tobacco and spirit of turpentine, with a little soft soap and sulphur vivum.

The only caution necessary to be given in the use of any of these remedies is, to take care that they be brought thoroughly in contact with every part of the skin of the affected animal, lest any of the burrowed acari escape. And all folds or sheds in which infected sheep have been confined, and all gates, posts, and other rubbing places, must undergo thorough purification. Besides the acari, sheep are liable to be attacked by various other insects, such as the flesh-fly, and a species of aphis called the sheep-louse. The maggot only prevails in the moist and warm summer months, but increases in numbers with amazing rapidity, and requires great watchfulness on the part of the shepherd, as they soon destroy a large portion of the skin and flesh of the sheep if unchecked. The aphis also creates great irritation; but both species are easily destroyed by any of the preparations already detailed. The tick (*Acarus reduvius*) is also a very formidable insect to sheep. It almost buries itself in the skin, and adheres so firmly by six legs, very muscular and powerful, and so armed with serrated claws, that it can scarcely be disengaged from its hold, but will yield, like most of the parasites which infest the sheep, to the application of a mercurial preparation.

THE GOAT.

Goats form one of the families of the *ruminant* order of mammalia. The common domesticated goat is usually about the size of the sheep, though less round in form, and is marked by keen eyes, long hair, and generally bent horns. The males, called familiarly in England *billies*, have a long beard; but the females, or nannies, are seldom provided with that appendage. Whether in a state of nature or tamed, the goat is remarkably swift and agile, and will browse fearlessly on the most rugged precipices. We find, from ancient writers, that goats have long formed part of the stock of mountain-herdsmen, and were tended with even greater care in former than in present days. In many respects, indeed, the animal is valuable. Its skin is convertible to several useful purposes, and the flesh of the full-grown goat is good, though scarcely equal in quality to that of the sheep. But it is for the milk chiefly that the goat is prized; the qualities of that secretion being not only very nutritious, but even medicinal. Where cottagers have not the means of keeping a cow, a goat will be found a very useful animal, being easily fed, and contented with grasses which are rejected by the cow and the sheep. To those peasants who live in the neighbourhood of mountainous countries, the trouble and expense of keeping a couple of goats will be nothing, as they will find sufficient nourishment in the most heathy, rough, or barren grounds. Heaths also which are unfit for any kind of pasture, will afford this animal an ample supply of food; and it requires no care or attention, easily providing for itself proper and sufficient food. In some countries, goats render considerable service to mankind, the flesh of the old ones being salted as winter provision, and the milk is used in many places for the making of cheese. The flesh of the kid is highly palatable, being equal, if not superior in flavour, to the most delicate lamb.

In Britain, the goat produces generally two young at a time, sometimes three, rarely four. In warmer climates it is more prolific, and produces four or five at once, though the breed is found to degenerate. The time of gestation is five months. The male is capable of propagating at one year old, and the female at seven months, but the fruits of a generation so premature are generally weak and defective: their best time is at the age of two years, or eighteen months at earliest. A goat is accounted old at six years, although its life sometimes extends to fifteen.

If goats are properly trained, they will return to their owners twice a day to be milked, and prefer sleeping under a roof when accustomed to it. The milk of the goat is sweet, and not so apt to curdle upon the stomach as that of the cow; it is therefore preferable for those whose digestion is but weak. The peculiarity of this animal's food gives the milk a flavour different from that of either the cow or the sheep; for, as it generally feeds upon shrubby pastures and heathy mountains, there is a savoury mildness in the taste, very pleasing to such as are fond of that aliment. The quantity of milk produced daily by a goat is from three half pints to a quart, which yields rich and excellent cream. If properly attended to, a goat will yield milk for eleven months in the year. In several parts of Switzerland, Wales, and the Highlands of Scotland, the goat is the chief possession of the inhabitants. On those mountains where no other useful animal could find subsistence, the goat contrives to glean sufficient living, and supplies the hardy natives with what they consider a varied luxury. They lie upon beds made of their skins, which are soft, clean, and wholesome; they live upon their milk, with oat-bread; they convert a part of it into butter, and some into cheese; and the flesh furnishes an excellent food, if killed in the proper season, and salted. They are fattened in the same manner as sheep; but taking every precaution, their flesh is never so good or so sweet in our climate as that of mutton. It is otherwise between the tropics. The sheep there becomes flabby and lean, while the flesh of the goat rather seems to improve, and in some places is cultivated in preference to that of the sheep. The cream of goat's milk coagulates as easily as that of cow's, and yields a larger proportion of curd. The cheese is of an excellent quality, and high flavoured; and although to appearance it looks poor, it has a very delicate relish, and strongly resembles Parmesan cheese. Some farmers have been in the practice of adding a little goat's milk to that of cows, which materially improves the flavour. In winter, when native food becomes scarce, the goat will feed upon turnip-peelings, potato-peelings, cabbage-leaves, and other refuse of a house. In addition to the other products yielded by the goat, its tallow, we should mention, is also an article of some importance. It is much purer and finer than that of sheep, and brings a high price, being calculated to make candles of a very superior quality.

Cobbett advocates the keeping of a goat by cottagers. 'There is one great inconvenience belonging to goats—that is, they bark all young trees that they come near; so that if they get into a garden, they destroy everything. But there are seldom trees on commons except such as are too large to be injured by goats; and I can see no reason against keeping a goat where a cow cannot be kept. Nothing is so hardy; nothing is so little nice as to its food. Goats will pick peelings out of the kennel and eat them. They will eat mouldy bread or biscuit, fusty hay, and almost rotten straw, furze bushes, heath thistles; and indeed what will they not eat, when they will make a hearty meal on paper, brown or white, printed on or not printed on, and give milk all the while! They will lie in any dog-hole. They do very well clogged, or stumped out. And then they are very healthy things into the bargain, however closely they may be confined. When sea-voyages are so boisterous as to kill geese, ducks, fowls, and almost pigs, the goats are well and lively; and when no dog of any kind can keep the deck for a minute, a goat will skip about upon it as bold as brass.'

In Britain, no attempts have been made, at least successfully, to introduce foreign breeds of goats, although in France this has been done to a considerable extent. The Cashmere goat, famous for its long silky hair or wool, has been brought to the country mentioned, and there bred with the Thibet goat, a hardier species, but almost equally esteemed for its wool. The manufactures producible from this material, as the Cashmere shawls have long testified, are scarcely to be surpassed for fineness, and yield immense prices. It is probable that, in our warmest districts, a cross of these foreign goats with the common breed might be successfully and advantageously effected.

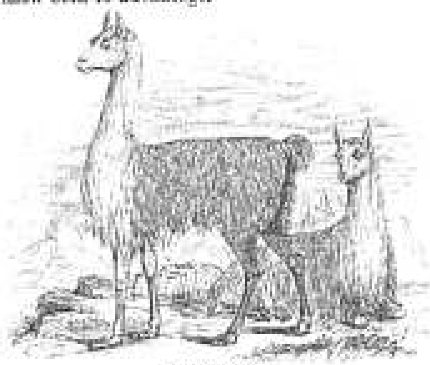
THE ALPACA.

Attempts are now making, under the most respectable auspices, to introduce the alpaca, or Peruvian sheep, as it is popularly termed, into the number of our domestic animals. As the subject is one of very considerable importance, in a national as well as individual point of view, we propose offering a few explanatory observations.

Nature, as is well known, furnishes animals expressly suited to the climate, vegetable productions, and other circumstances connected with the locality which they are destined to inhabit. The Andes, and other high mountain ranges and slopes of South America, are accordingly provided with several species of sheep, adapted, by their habits, to these lofty regions of scanty vegetation, and which so materially differ from the sheep of this and other European countries as to seem a perfectly distinct tribe of animals. The two most common of these South American sheep are the llama and alpaca, and they abound most extensively in Peru. The llama is somewhat taller than the alpaca, and though in some respects a remarkable animal, its peculiarities are not such as to render it so especially interesting as the alpaca, for purposes of practical utility, out of its native regions. The alpaca, which it is proposed to domesticate in Britain, is an animal combining the appearance of the common European sheep with that of the goat, and partly of the deer and camel. Like the sheep, the alpaca is lanigerous or wool-coated; in its general structure it is light, and possesses limbs adapted for springing and leaping like the goat; it resembles the deer in skin, flesh, and general appearance; and though without the camel's deformities, it is gifted, like him, with patience and docility, being often used as a beast of burden by the natives of South America (See No. 26, p. 402). The height of the alpaca is from three to four feet, when measured from the ground to the top of the back; the eyes are large, black, soft, and expressive; the animal has no horns; the neck is long, slender, curved backwards, and finely set; the head handsome, and the muzzle and ears lengthened; the hoof is horny, and divided; the tail short, and resembling what is called a switch-tail; the body has a tapering towards the loins, resembling that of the greyhound; and, as regards other points, the alpaca has partly the characters of the sheep (its incisors on the lower jaw, for example, and six molar teeth on each side), and partly those of the camel (the most remarkable being a similar reservoir in the stomach for fluids, suiting the creature to an arid climate). To common observers, the alpaca might seem to be a fine tall goat, with a small head and no horns, but of more gentle and fleecy appearance than that animal.

The wool of the alpaca forms, of course, a point of peculiar importance, taking into view the proposal for introducing the animal into Great Britain. The colour of the wool varies considerably, the majority of the tribe being of a tint intermediate between black and brown, while others are of a pure white. The texture is admitted on all hands to be peculiarly fine. In a memoir on this subject, written by Mr W. Walton (author of a small volume entitled 'The Alpaca,' and published by Blackwood, Edinburgh), the wool is thus described:—

'With the polite assistance of the secretary of the Polytechnic Institution, I was enabled to examine the anatomical structure of three samples of alpaca wool through a lens magnifying one million times. The colours of those subjected to the power of the microscope were white, black, and gray. When thrown upon the disk, each filament appeared equal in thickness to a man-of-war's topsail hallyard; perfectly distinct, and the fibrous structure more evident than in the wool of common sheep. White was the first sample tried, and it produced an effect at the same time singular and pleasing. The surface appeared polished and distinguished by a glittering brightness, almost, I could say, refulgence, which is wanting in sheep's wool. The general results produced by afterwards showing the black sample were the same, excepting that the shade on the disk was more opaque, and the brilliancy of each filament somewhat diminished. The gray exhibited a medium between these contrasts, and helped to show both to advantage.



The Alpaca.

There are instances of alpaca wool measuring thirty inches long; frequently it is seen twenty inches, and it averages from eight to twelve. In the samples, there appeared to be no under wool—no closer and immediate covering. No shorter hair or wool could, in fact, be perceived; the very reverse of what is observed when a morsel of an elk's or camel's coat is examined. Alpaca wool is also straighter than that of sheep, never appearing in those spiral curls which distinguish our piles, more particularly when the bearer of the fleece has been smeared. The smallness of the fibre, its softness and pliability, coupled with its elasticity, equally add to its value. There is, in the mass, what is technically called a *trueness* that is, an equal growth and an exemption from shaggy portions, accompanied by a soundness, by which is meant the general strength of the fibre—properties certainly of the first import to the manufacturer. In consequence of this characteristic disposition, alpaca wool breaks less in the act of combing, is freer from shreds, spins easily, and not being so harsh or so stubborn, does not injure the machinery so much. The thread spun with it is also finer and truer. In the manufacture of fine goods, it is agreed that the pile cannot be too soft or too silky, provided the strength of the fibre is not impaired. As well as I could, I have compared the strength of a filament of alpaca with those of other wools, and found it the strongest; and as it is devoid of that irregularity of surface—the knots and joints which some persons liken to those of a bamboo cane—the cloth made from it must consequently be less harsh to the touch.'

But the qualities of the alpaca wool for manufacturing purposes do not rest upon mere conjecture. 'The merits of alpaca wool have for some time past attracted the notice of manufacturers, and consequently of merchants; and through the advice of Mr Danson, and other enterprising individuals, the importations of it have within the last eight years considerably increased. Intelligent merchants on the spot, and engaged in the trade, assert that the total amount imported during the seven years ending December 1843 exceeded twelve millions of lbs. During his tour in Scotland, Mr Danson urged the expediency of introducing the alpaca into the Highlands, and pointed out the benefits which would accrue from this measure. In illustration of his views, he exhibited samples of the wool, and specimens of articles manufactured in England from it, imitating silk, some as black as jet, although of the natural colour, and without the aid of dye. He very ably contended that this wool would not enter into competition with that of our ordinary sheep, and, from the fineness and transparency of the filament, was peculiarly well adapted for the fine shawl trade of Paisley and Glasgow.' Even these trials have been made under disadvantages, for the alpaca wool has only reached this country in a dirty, and also in a mixed state, the wool of inferior breeds forming almost always a large proportion of the bales containing it. Another advantage consists in the greater weight of the fleece; for according to the authority now quoted, 'it ranges from 10 to 12 lbs.; whereas that of our full-grown sheep seldom exceeds 8 lbs., and in the small breeds from 4 lbs. downwards. From the larger size of the animal, and the increased surface consequently covered, the alpaca necessarily yields most wool; and it has already been ascertained that on British pastures the weight improves. At the Royal English Agricultural show held at Liverpool in July 1844, a sample of black wool was exhibited, taken from an alpaca belonging to the Earl of Derby's flock, the staple of which appeared to be about a foot long; when his lordship's farm-agent expressed his conviction that the same animal had then 17 lbs. upon its back.'

The value of the wool being once determined, the next question is, Have we space and food for the alpaca in Britain? On this point, after some arguments in proof of his views, Mr Walton reaches the following conclusions, which appear to be essentially correct:—'We therefore have, and must continue to have, large tracts, neither cropped with grain nor depastured by cattle, consisting of chains of barren hills, running in various directions through the United Kingdom, moors, heath, moss lands, &c. wholly unproductive, the amount of which may be set down at from twelve to fourteen millions of acres. And would it not be highly expedient to stock these lands with another domestic animal, yielding a commodity of such a nature as to reward the farmer for his care, and besides triple in value by the beneficial application of labour—an animal requiring no additional subsistence for its support, and consequently not likely to interfere with any cattle already on our farms?' Besides, if an improved race of domestic animals could be put even into our occupied lands, would it not be advisable to do so, even at the cost of diminishing the existing breeds?

Another material question is, Could the alpaca *live* in this country? 'Although delicate in appearance, the alpaca is perhaps one of the hardiest animals of the creation. His abstinence has already been noticed. Nature has provided him with a thick skin and a warm fleece, and as he never perspires, like the ordinary sheep, he is not so susceptible of cold. There is therefore no necessity to smear his coat with tar and butter, as the farmers are obliged to do with their flocks in Scotland—a process which, besides being troublesome and expensive, injures the wool, as it is no longer fit to make into white goods, nor will it take light and bright colours. "The Highland hills," says the Ettrick Shepherd, "are for the most part of a pyramidal form, very high, and commonly so steep and rugged, that to the eye of the traveller they have an appearance perfectly tremendous. The sides and banks of the glens and rivulets are commonly covered or mixed with a rich short grass, intermingled with numberless aromatic herbs and flowers. The extensive flats and sloping declivities around the bottom and lower parts are covered with a coarse mossy turf, interspersed with thin sapless heather, which has stood in the same squalid form since the time that it first made its appearance on the retreat of the universal deluge, mixed with some of the moss-stalks called ling and deer-hair." This is the description which so experienced a man as the Ettrick Shepherd gives of "that vast range of stupendous mountains, deep glens, and trackless forests which," he says, "at the first view every unprejudiced man must acknowledge nature never intended for the rearing of cattle; and where no one," adds he, "will hesitate whether sheep or goats are the most feasible stock." What pen could have sketched a more faithful picture of the Andes mountains—those high and secluded regions, inaccessible to other animals, where the alpaca lives "an inmate of the cloud and storm," gathering subsistence from edible plants which otherwise would be left to wither on the land!' We are aware of only one doubtful circumstance as to the successful domestication of the alpaca in any of the British islands, particularly in the Highlands—this is the *humidity of our climate*. If the alpaca can resist damp as well as our South-downs, we shall have nothing to fear on the score of hardiness in other respects.

Mr Walton alludes to the strong enamel on the alpaca's teeth, as fitting the creature peculiarly for rocky and mountainous pasturage. In the case of snow-storms, too, on our elevated ranges, by which so many of our common sheep are apt to be smothered every severe winter, the remarkable docility of the alpaca renders him almost secure, with little comparative toil to the herdsman. 'Peruvian sheep have, in fact, an unerring foresight of the coming danger, long before their tender (if they happen to have one) sees above him a threatening cloud, or dreams of a drift. Instinctively they know the safest side of a crag, as if they saw the point of the compass from which the storm was approaching; and thus admonished, collect their young, and fly to the *stell* which nature provided for them, even before the conflict of the elements and the raving of the wind shall have commenced. If within reach, the alpaca asks protection at the cottage door where at other moments he had been welcomed.' Again—'Another great advantage in the alpaca is, that he is not liable to the many diseases incidental to common sheep, and which have so often raged like a pestilence among the tenants of the Scotch hills. In Peru, where the circumstances are as near as possible alike, the llama and alpaca are not hurt by changes of diet incidental to the seasons. This may arise partly from their greater abstemiousness and discernment, and partly from their having a wider range, and consequently more choice of food. It is, however, a fact, which I have ascertained from natives, that the Peruvian breeds are not so liable to bowel complaints as ours; and their constitution being much stronger, they are consequently less affected by sudden transitions from one food to another. The distemper called pining, or daising, very usual in the west of Scotland, which occasions a thinness of blood, and when, though the animal continues to feed greedily, it pines away to a mere skeleton, is unknown on the Andes; neither are the fawns there liable to the many accidents which attend the feeding, herding, and folding of lambs among us. As regards vermin, they are much clearer.' With respect to other diseases, though the alpaca is not exempt from some of them, its hardy constitution seems to render their influence less extended and destructive.

In reality, the experiment of keeping the alpaca in Great Britain has already been tried on a considerable scale, and the wool has been found to be even improved by the change of site. 'The Earl of Derby, with that patriotic spirit and splendid taste which have distinguished him through a long life, also stepped forward among the first breeders, and his lordship has now at Knowsley a little flock of llamas and alpacas, amounting to fourteen, two of which were bred on the spot, whose wool is finer, softer, and more beautiful than that on the backs of their parents. The proof that the wool improves with our pasture is, in fact, established in this instance. The young are eight-and-twenty months old, and already the first has wool upon it six inches long. A fine male alpaca, shorn three years ago, has at present a coat upon it from eighteen to twenty inches long, thus proving that the wool grows from six to eight inches yearly, if regularly shorn. Speaking of the practicability of introducing the Peruvian sheep more generally, in a letter addressed to William Danson, Esq. of Liverpool, who, accompanied by a friend, visited Knowsley at the beginning of the current month [April 1841], his lordship says, that "he certainly knows of nothing likely to prevent the propagation of the animal in this country. On the contrary," he adds, "the gentlemen will see in these grounds living specimens that they can and will do so, one female having produced in each of the two last seasons, and the young are doing well." His lordship then expresses his anxious desire "to obtain the remainder of the species, more especially the vicuna." Already does this interesting animal adorn the pleasure-grounds of the Marquis of Breadalbane at Aberfeldy, Perthshire; J. J. Hegan, Esq. Harrow Hall, Cheshire; Charles Tayleure, Esq. Parkfield, near Liverpool; Mr Stephenson of Oban; R. Bell, Esq. Villahouse, near Listowel, county Kerry; A. G. Stirling, Esq. Craigbarnet, near Glasgow; and others.'

From the tone in which this notice has been drawn up, it may be observed that the statements before us have been convincing in our eyes, in so far at least as regards the propriety of making fair and full experiments on the subject of the alpaca. This animal, we conceive, without infringing materially on the keeping of sheep, might prove the means of enlarging the profession of the pastoral farmer, and of varying, extending, and improving our manufactures. From the alpaca wool which we do procure at present, yarn is spun, which the French import at from 6s. to 12s. per lb. In conclusion, we give a few additional words from Mr Walton. 'When we consider the great improvement which we have attained in sheep's wool, there is every reason to look for a similar success in that of the alpaca; and in devising means to increase the productive power of the country, we ought never to forget that there have been periods in our history when we were dependent upon foreign supplies for the raw material required for our woollen manufactures, and that the best way to be independent, is not to be under the necessity of buying that which it is in our own power to grow. The task of obtaining suitable breeds of the alpaca is by no means a difficult one; and in our attempts to naturalise them, we ought to feel the more encouraged when we reflect on the recent changes in the growth and supplies of sheep's wool, and how soon a farming stock propagates under judicious management. It must be equally borne in mind, that in using alpaca wool, we are not competing with that of our own sheep, but rather with that of the Angora goat (mohair) and silk; and the manufacture, it has been ascertained, does not cost half so much as that of the latter.'

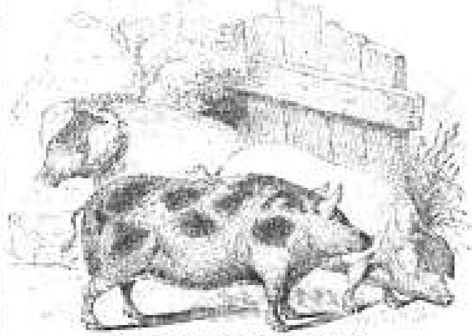
One other point calls for notice. Our present breeds of sheep are of essential importance as food to man. The flesh of the alpaca is spoken of as excellent by Acosta, Garcilasso de la Vega, and other writers on Peru. General O'Brien, an Irish gentleman in the Peruvian service, speaks of the flesh as 'delicious,' and likely also to improve much on the animal being placed on milder pastures than those of the Andes. In point of flavour, alpaca meat has, by good judges, been compared to North American venison, and even to our heath-fed mutton. The nature of pasture unquestionably affects both the quality and taste of meat; and there is, therefore, every reason to expect that, fed upon our downs or heaths, the alpaca would yield a good and marketable flesh, thus increasing our supply of one of the necessary commodities of life. In this kind of stock the breeder would find another good quality; namely, the largest quantity of flesh on the least possible weight of bone. The quarters weigh from 35 to 45 lbs., or nearly triple those of an ordinary sized sheep.

PIGS—RABBITS—POULTRY—CAGE-BIRDS.

As a source of sustenance and emolument to the humbler classes of society, the pig is only second in importance to the cow, and in many instances is found to be more available and useful than that animal. As an object of natural history, it is placed amongst the *Pachydermata* or thick-skinned order of the Mammalia—the hog, wild boar, and probably also the peccary of South America, being varieties of the same family (see ZOOLOGY, p. 140). The most remarkable characteristic of the common pig is its long roundish snout, furnished with a strong cartilage at the extremity, for the purpose of grubbing in the earth for roots and other kinds of food. The feet are cloven, and each possesses four toes, two of which are large, and furnished with stout hoofs, the other two being small, posteriorly situated, and scarcely touching the ground. The body is of a cylindrical form, low set, and thinly covered with bristles, which rise into a strong mane in many of the varieties. The tail is small, short, and in general twisted, and in some varieties is altogether wanting; the ears are either large and pendulous or short and pointed. The jaws of the pig are powerful, and the teeth with which they are furnished are very formidable, particularly in the wild varieties. Swine do not ruminate, and from this and other peculiarities, they can feed either on vegetable or animal substances—thus forming a kind of link between the herbivorous and carnivorous classes of animals. They are, in fact, omnivorous, and scarcely any sort of food comes amiss to them: the term 'voracious' is that most commonly applied to them.

BREEDS—GENERAL MANAGEMENT.

The breeds of pigs most esteemed in Great Britain are the Berkshire, Chinese, and Improved Essex. These are also the breeds best marked by distinctive features; though by crossings, and peculiarities of feeding and position, varieties differing in a slight degree from one another have been raised up in almost every county in England. The Berkshire breed, the parent stock of most of them, is of a reddish-brown tint, with black spots; moderately large ears, inclining forward, but erect; is deep in the body, with short legs and small bone; arrives early at maturity, fattens easily, and with remarkable rapidity. This variety, under good management, grows to an enormous weight. Culley mentions a Berkshire hog, fed by Mr Lawton of Cheshire, which measured, from the point of the snout to the tail, nine feet eight inches; its height at the shoulder was four feet five inches and a half. When living, this huge animal weighed twelve hundredweight two quarters and ten pounds; and when slaughtered, cleaned, and otherwise dressed by the butcher, ten hundredweight three quarters and eleven pounds, or eighty-six stones eleven pounds! The Chinese breed, generally speaking, is of small size. 'The body,' says a recent authority, 'is very nearly a perfect cylinder in form; the back slopes from the head, and is hollow, while the belly, on the other hand, is pendulous, and in a fat specimen, almost touches the ground; the ear is small and short, inclines to be semi-erect, and usually lies rather backward; the bone is small, the legs fine and short; the bristles are scarcely deserving of the name, being so soft, as rather to resemble hair; the colour is usually white, sometimes black, and occasionally piebald. The white sort are deemed preferable, from the superior delicacy of their flesh. The face and head are unlike those of any other description of swine, somewhat resembling those of a calf; hence this variety, if once seen, will not be readily forgotten. Chinese hogs are good feeders, arrive early at maturity, and feed fat, so to speak, on less food, and become so circumstanced, fatter, and heavier within a given time than any of our European varieties.' The recently-Improved Essex ranks high, for certain purposes, amongst our British breeds of swine. The improvement is said to be due to a cross between the old Essex and the Neapolitan pig; but it is probable also that the Chinese or Berkshire has had something to do in the work of regeneration. The Essex pig is described as up-eared; has a long sharp head; a long and flat carcass, with small bone; colour most frequently black, or black and white; and skin delicate, and almost bare of hair. He is a rapid feeder, but requires a greater proportion of food than the weight he attains to justifies; besides which, he has the character of being restless and discontented. The sows are good breeders, and produce litters of from eight to twelve; but they have the character of being indifferent nurses.



Old British—Berkshire—Chinese.

Besides the above varieties—which are at present the favourites at our Agricultural Exhibitions—the gigantic white and black breed of Cheshire, the white pigs of Suffolk and Hampshire, and the piebald hogs of Sussex and Shropshire, may be mentioned as the best known among the district-breeds of England. They are coarser, generally speaking, than the Berkshire and Chinese. Both of these have been pretty extensively introduced into Scotland, where a less valuable white breed appears to have been earlier located, if not indigenous. There is also a small gray pig, apparently aboriginal, which feeds in herds on the natural pasture on the Highland hills, and furnishes very sweet flesh. By artificial feeding, it can be raised to a considerable bulk. But the breed most commonly esteemed both in England and Scotland, is a mixture of the Chinese dark-coloured swine with the Berkshire, or some of the large varieties of British swine. This cross possesses many good qualities, and is peculiarly prolific. Either belonging or allied to the Berkshire variety, is the Hampshire *brock*, a small black pig suitable for cottagers, for it is easily fed and fattened, and is therefore highly esteemed. In Ireland, where the native pig is described as 'tall, long-legged, bony, heavy-eared, coarse-haired, and by no means possessing half so much the appearance of domestic swine as they do of the wild boar,' the breed has been greatly improved of late years, and the old unprofitable stock is rapidly disappearing. The improved Irish breeds are now so nearly alike to those of England, that they are not readily distinguishable from each other.

Choice of a Pig.

By whatever name the crop or breed may be called, the following *points* are enumerated by Mr Richardson as those by which the rearer should be guided in his choice of a pig. 'In the first place, sufficient depth of carcass, and such an elongation of body as will insure a sufficient lateral expansion. Let the loin and breast be broad. The breadth of the former denotes good room for the play of the lungs, and a consequent free and healthy circulation, essential to the thriving or fattening of any animal. The bones should be small, and the joints fine. Nothing is more indicative of high breeding than this; and the legs should be no longer than, when fully fat, would just prevent the animal's belly from trailing upon the ground. The leg is the least profitable portion of the hog, and we therefore require no more of it than is absolutely necessary for the support of the rest. See that the feet be firm and sound; that the toes lie well together, and press straightly upon the ground; as also that the claws are even, upright, and healthy. Many say that the form of the head is of little or no consequence, and that a good pig may have an ugly head, it being no affair of anybody but the animal himself who has to carry it; but I regard the head of all animals as one of the very principal points in which pure or impure breeding will be most obviously indicated. A high-bred animal will invariably be found to arrive more speedily at maturity, to take flesh earlier, and with greater facility, and altogether to turn out more profitably than one of questionable or impure stock; and such being the case, I consider that the head of the hog is by no means a point to be overlooked by the intending purchaser. The description of head most likely to promise, or rather to be the concomitant of, high-breeding, is one not carrying heavy bone, not too flat on the forehead, or possessing a too elongated snout—indeed the snout should, on the other hand, be short, and the forehead rather convex, recurving upwards; and the ear should be, while pendulous, inclining somewhat forward, and at the same time light and thin. Nor would I have the buyer to pass over even the *carriage* of a pig. If this be dull, heavy, and dejected, I would be disposed to reject him, on suspicion of ill health, if not of some concealed disorder actually existing, or just about to break forth; and there cannot be a more unfavourable symptom than a hung-down, slouching head, carried as though it were about to be employed as a fifth leg. Of course, if you are purchasing a fat hog for slaughter, or a sow heavy with young, you are scarcely to look for much sprightliness of deportment; but I am alluding more particularly to the purchase of young stores, the more general, because the more profitable, branch of pig management. Nor is colour to be altogether lost sight of. In the case of pigs, I would, as in reference to any other description of live stock, prefer those colours which are characteristic of our most esteemed breeds. If the hair be scant, I would look for black, as denoting connection with the delicate Neapolitan; but if too bare of hair, I would be disposed to apprehend too intimate alliance with that variety, and a consequent want of hardihood, that, however unimportant, if pork be the object, renders such animals hazardous speculations as stores, from their extreme susceptibility of cold, and consequent liability to disease. If white, and not *too small*, I would like them as exhibiting connection with the Chinese. If light or sandy, or red with black marks, I would recognise our favourite Berkshire; and so on with reference to every possible variety of hue. These observations may appear trivial; but I can assure my readers that they are the most important I have yet made, and that the intending pig-buyer will find his account in attending to them.'

Breeding—Littering.

As in the case of other domesticated animals, so with the pig—a perfect, profitable race cannot be maintained without careful and judicious breeding.—'In selecting the parents of your stock,' says the authority above quoted, 'you must diligently bear in mind the precise objects you may have in view—whether the rearing for pork or bacon; and whether you desire to meet the earliest market, and thus realise a certain profit with the least possible outlay of money, or loss of time; or whether you mean to be contented to await a heavier, although somewhat protracted return. If bacon and the late market be your object, you will do well to select the large and heavy varieties, taking care to ascertain that the breed has the character of being at once possessed of those qualities most likely to insure a heavy return; namely, *growth*, and *facility* of taking fat. If, on the other hand, your object be to produce pork, you will of course find your account in the smaller varieties; such as arrive with greatest rapidity at maturity, and which are likely to produce the most delicate flesh. In producing *pork*, it is not advisable that it be too fat, without a corresponding proportion of lean; and on this account I would recommend that you rather take a cross-bred sow than a pure Chinese stock, from which the over-fattening results might most naturally be expected.

In every case, whether your object be pork or bacon, the points to be looked for are—in the Sow, a small, lively head, a broad and deep chest, round ribs, capacious barrel, a haunch falling almost to the hough, deep and broad loin, ample hips, and considerable *length* of body in proportion to its height. One qualification should ever be kept in view, and perhaps should be the first point to which the attention should be directed; namely, the *smallness of bone*. Let the Boar be less in size than the sow, shorter and more compact in form, with a raised and brawny neck, lively eye, small head, firm, hard flesh, and his neck well furnished with bristles: in other respects, look for the same points as I have described in reference to the sow. Breeding within too close degrees of consanguinity, or, as it is technically termed, *breeding in and in*, is calculated to produce degeneracy in size, and also to impair the animal's fertility; it is therefore to be avoided, although some breeders maintain that a first cross does no harm, but, on the contrary, that it produces offspring which are predisposed to arrive earlier at maturity, and take fat with greater facility. This may in some instances be the case: it is so with horned cattle; but as far as swine are concerned, it is not my own experience, and I still adhere to the recommendation I have given. Differences of opinion also exist as to the precise age at which breeding is most advisable. Pigs, if permitted, breed at the early age of six or seven months; but this is a practice not to be recommended. My advice is, to let the female be *at least* one year old, and the male *at least* eighteen months; but if the former have attained her second year, and the latter his third, a vigorous and numerous offspring are more likely to result.'

The sow is very prolific, compared with other large-sized quadrupeds, and for that end is provided with from twelve to sixteen teats. Her period of gestation is sixteen weeks; the number of young varies considerably, being frequently below ten, and occasionally rising to twenty. The young pig is exceedingly delicate; and the brood sow should not be allowed to farrow in winter, but in spring and autumn, when the weather is less severe and food more abundant. Another peril to the litter arises from the semi-carnivorous habits of the mother, which lead her to forget the dues of nature, and devour her own brood. She ought therefore to be well watched, and fed abundantly at such periods. The male, for the same reason, must be excluded altogether. Not unfrequently, moreover, the young are crushed to death by the mother, in consequence of their nestling unseen below the straw. To prevent this risk, a small quantity only of straw, dry and short, should be placed below them. The young are weaned when six weeks old; and after weaning, it is essentially necessary to feed them with meal and milk, or meal and water.

Many persons labour under the notion that swine, while breeding, should be kept lean; but nothing can be more erroneous; for, after farrowing, great part of those juices which would be converted into milk, were she in good condition, will naturally go towards nourishing her system. When required for the purpose of fattening, the male young pigs are cut, and the females spayed, which is an analogous process. These operations should always be intrusted to a farrier or other properly-qualified person. At weaning time, it is also customary to 'ring' the young pigs; that is, to insert a ring of iron in the cartilage of the nose, to prevent the animal from grubbing and turning up the floor of the piggery. In pigs intended to be turned to the woods or fields, this process is necessary; but where requisite, it is preferable to the barbarous and less effectual plan of cutting off the cartilage altogether.

Pig-houses.

Although swine are found to succeed in all countries, and their constitutions have been accommodated to every climate, yet they are found to degenerate and thrive ill either in the extremes of heat or cold. In a native state we find them, when inhabiting countries towards either extreme, seeking situations most adapted to their constitution. Swine, in a domesticated state, require to be kept very dry and warm, otherwise they will never thrive. It will be noticed that in cold weather they invariably bury themselves among the straw and litter with which they are supplied as bedding, thus pointing out their natural desire for heat. The piggery should therefore be in some well-sheltered spot, and, if possible, with a south or west exposure. If kept in small styes, there should be a small aperture at each end of them, so as to permit the free passage of air through them for ventilation. These may be kept open constantly during the summer months, but only allowed to be open for air once every second day in winter, and that in the forenoon, while they must be carefully shut up in the evening. Pigs will be found to grow notwithstanding the neglect of all these precautions; but we know, from experience, that they will grow and fatten much faster, and will be more healthy under them. When the weather is fine, a few hours' liberty will also serve the health, and consequently the condition, of a growing pig; and if he can obtain a little grazing it will be all the better.

In most cases, pigs are kept in a shamefully filthy condition; their stye ill ventilated, the straw dirty, their small courtyard no better than a wet dunghill, and consequently the skin of the animal begrimmed with scurf and all sorts of impurities. We cannot too strongly reprehend this infamous treatment of the pig, which is not naturally dirty, as some suppose, but loves to be kept dry and clean, as well as warm, as any one may observe by the delight it evidently takes in having its hide scratched and scrubbed. Let us then beseech all pig-keepers under whose eye this sheet may come, to preserve the stye in the driest and cleanest condition possible, to change the straw frequently, and to curry the skin of the pig at least once a week. By doing so, without a particle of additional food, the animal will thrive and fatten in a very superior degree, while the flesh will be more pure and delicate.

To insure comfort to the pig or pigs, let the stye consist of at least two compartments—a sleeping apartment, and an open courtyard, the one opening into the other. The sleeping apartment should be about seven feet square; well built and roofed, for the sake of dryness; and the floor, formed of strong planks, should slope outwards to the door. The outer court should be about ten feet square; paved in a substantial manner with large flag-stones, and sloping in a particular direction, to which the liquid refuse can flow into a gutter. It is advantageous for the erection to be near the dunghill, to which all liquid may run, and solid materials be carried without loss. Keep plenty of straw both in the pig-house and its court, in order to absorb moisture or dung, and let all be raked out regularly, and renewed. The money lost by allowing the dung to go to waste by mere evaporation—flying off into the atmosphere—no one can calculate. The open court of the pig-house should, if possible, lie to the sun, as the inmates are fond of basking in his beams. The feeding utensils placed in the court should consist of two strong troughs, which cannot be easily knocked over. These should be daily washed and scoured.

Feeding.

In rural situations, where extensive woods exist, and where the grass is otherwise of no value, the feeding and breeding of pigs will be found very profitable to the cottager; for, where they have a wide range, they will require little food save what they find for themselves in grazing under the trees, and in digging for worms and roots of various kinds—for which latter task their long and strong snouts peculiarly fit them. Artificial feeding is only resorted to in winter, and when the pigs are to be fattened for the market or table. It is more common, however, for the cottager to keep one or two pigs entirely within a stye, to add to the means of subsistence of his own family; and even when kept with this limited view, the pig is a creature of no little consequence. As Cobbett acutely and pithily observes—'The sight of a flitch or two of bacon on the rack tends more to keep a poor man from poaching and stealing than whole volumes of penal statutes. They are great softeners of the temper, and promoters of domestic harmony.'

When a young pig is to be purchased for feeding and killing, it is advisable to buy one which will be about sixteen months old at Christmas, that or some time in January being the preferable period of slaughtering the animal. Unless for delicate pork, it should not be killed less than a year old. During the summer, the pig may be fed on any refuse from the kitchen or garden, including turnip and potato parings, table-waste, cabbage leaves, &c.; but if barley-dust, or grains from a distillery, can be economically procured, either forms a good article of diet. Let it be kept in remembrance that the finer the feeding, the finer will be the pork. The food should at all events be of a vegetable kind, or principally so; nothing beyond slops from the table being to be tolerated in the shape of animal food. Whatever be given, let it be offered in small quantities, and frequently, it being a matter of importance never to allow the pig to become violently hungry. The half-starving system of feeding is poor policy, and is repaid by a lank poor carcass scarcely worth killing.

Farmers possess great advantages for feeding pigs. The straw-yard of itself affords continual support to them; and many pigs reach the age of one year without having received any food but what they themselves have gathered, yet are in good condition. What with the sweepings of the barn, and the straw, turnips, carrots, and clover, lying about a steading, with the refuse of the kitchen, a farmer, it has been calculated, may sustain swine in the proportion of one to every seven or eight acres of land under crop, without being conscious of the consumption made by them. In few instances are swine reared in such numbers as to have crops specially laid out for them, though some writers assert that they would yield, in such a case, greater and readier profits than other live-stock habitually reared in the same way. Where rearing on the large scale is attempted, a proper plant of sheds, courts, and feeding-troughs is erected; and besides the miscellaneous refuse of the farm, special crops of coarse potatoes, cabbage, carrots, and Swedish turnips, are grown for the piggery.

About the month of September, the process of fattening pigs should commence, whether they be designed for pork or bacon. If for pork, the fattening need not be carried to the same extent. In either case, a nourishing diet must be given, the only precaution being not to commence feeding too rapidly, otherwise surfeit may be produced. The best materials for feeding are barley and peas-meal; and if milk, either skimmed or churned, can be given at the same time, it will greatly facilitate the feeding, and improve the quality of the flesh. Many persons feed their pigs on potatoes; but in that case the flesh is not so solid and good, and the fat is somewhat loose and flabby. Soft meat may do very well for pigs when they are growing, but it is not the food which should be given when they are fed for killing. Those who feed pigs for their own use, generally give them a feed or two of corn daily for fourteen days before they are killed, and give them nothing else but churned or skimmed milk to drink; and for a day before killing, the pig should not get any food. Where people's circumstances will not permit any of the modes of feeding for killing which we have above pointed out, boiled potatoes, mixed with a handful or two of oatmeal, may be resorted to as a substitute. It is undeniable, notwithstanding what has been said above, that the Irish peasantry produce excellent pork by feeding their pigs almost entirely on potatoes. It is not so fat as the pork produced from peas and barley, but it is on that account the better suited to stomachs unaccustomed to very strong food. Swedish turnips, carrots, and broken corn, with a little bean or pease-meal, make an excellent fattening dietary, and can be procured at little more than half the expense of the old potato-and-meal system.

In concluding the subject of feeding, we cannot do better than reiterate the following sound injunctions by Mr Richardson:—'1. Avoid foul feeding. 2. Do not omit adding salt in moderate quantities to the mess given—you will find your account in attending to this. 3. Feed at regular intervals. 4. Cleanse the troughs previous to feeding. 5. Do not overfeed; give only as much as will be consumed at a meal. 6. Vary your bill of fare. Variety will create, or at all events increase appetite, and it is further most conducive to health. Let your variations be guided by the state of the dung cast: this should be of a medium consistence, and of a grayish-brown colour. If hard, increase the quantity of bran and succulent roots; if too liquid, diminish or dispense with bran, and let the mess be firmer: if you can add a portion of corn, that which is spoiled, and thus rendered unfit for other purposes, will be found to answer perfectly well. 7. Feed your stock separately, in classes, according to their relative conditions: keep sows in young by themselves; and bacon pigs and porkers by themselves. It is not advisable to keep your stores too high in flesh, for high feeding, however strange it may seem, is calculated to retard development of form and bulk. It is better to feed pigs intended to be put up for bacon *loosely*, and not too abundantly, until they have attained their full stature; you can then bring them into the highest possible condition in an inconceivably short space of time. It is by such a system of management as this that the monstrous swine, their weight exceeding frequently twelve hundred pounds, or at all events half a ton, are raised. 8. Do not neglect to keep your swine clean, dry, and warm. These are essentials, and not a whit less imperative than feeding; for an inferior description of food will, by their aid, succeed far better than the highest will without them. And while I speak of cleanliness, suffer me to reiterate the benefit derivable from washing your pigs; this will repay your trouble manifold.' To these we may add—when the time arrives for slaughtering, let it be done in a humane and neat style by a butcher, so as to avoid all mangling or injury to the flesh.

[The most approved modes of curing and preparing pork, brawn, bacon, and hams, will be detailed in a subsequent number—47.]

Diseases.

In a state of nature, the pig is a healthy animal, and even when domesticated, is not readily injured, if treated with anything like common humanity. Cribbed and confined, however; compelled to wallow in filth; exposed indiscriminately to all weathers; now surfeited, and now starved; this day receiving stale food, and to-morrow a diet scalding hot—it is not to be wondered at if the animal should be subjected to the attacks of dangerous and often fatal maladies. The principal diseases to which swine, as thus treated, are liable, are—Fever, leprosy, tumours, murrain, measles, foul skin, mange, crackings of the skin, staggers, swelling of the spleen, indigestion or surfeit, lethargy, quincy, heavings or inflammation of the lungs, catarrh, and diarrhoea. A large proportion of these, it will at once be seen, are the direct result of want of cleanliness and injudicious feeding, and might be wholly prevented by attending to the directions already given. In cases of fever and other sudden ailments, bleeding, purgatives, and a spare diet, are the safest and surest remedies. Bleeding may be performed by opening the vein behind the ear, or by cutting off a portion of the ears and tail. Castor or linseed oil, Epsom salts, jalap, and flour of sulphur, are simple purgatives, and can be readily administered in a small mess of enticing food; and when given, should always be followed by a spare and liquid diet. For skin diseases, frequent scrubbings with soap and water, and unguents of tar and sulphur, will be found most effectual. In the case of measles—one of the most common diseases to which pigs are liable—the following recipe has been recommended:—Suffer the animal to fast, in the first instance, for twenty-four hours, and then administer a warm drink containing a drachm of carbonate of soda, and an ounce of bole armeniac; wash the animal, cleanse the stye, and change the bedding; give at every feeding, say thrice a day, thirty grains of flour of sulphur, and ten of nitre. It is to filthiness, combined with a common fault too little thought of, namely, giving the steamed food or wash to the pigs at too high a temperature, that this troublesome malady is generally to be attributed.

RABBITS.

Rabbits belong to the family *Leporidæ*, members of the *Rodentia* or Gnawing Order of animals. Their form and appearance are too well-known to require any special description. In a wild state, rabbits live in holes in the earth; and where the proprietor permits of their accumulation for sport, they collect in great numbers, undermining with their burrows whole plains or tracts of land, and forming what are called *warrens*. Their amazing fecundity renders the keeping of a few of them in a tame state an object of some consequence in cottage economy. The rabbit litters seven times in the year, and generally produces eight young at a time. At the age of five months the animal begins to breed; and, taking an estimate perfectly within bounds, it is supposed that a pair of wild rabbits, which breed no oftener than seven times in a year, would multiply in the course of four years to the amazing amount of a *million and a quarter*, if the young were preserved. Many of them die, however, being injured by cold and damp, or devoured by the male or *buck*.

Experienced rabbit-keepers conceive too frequent breeding to be injurious; but even when proper rules are observed in this respect, three domesticated females (*does*) and a buck will give a family a rabbit for dinner at least twice a week. This is a matter of some consequence. By keeping a few of these pretty little creatures, which wild vegetables will almost entirely supply with food, the poor man may derive ten times the benefit to be gained by violating the laws, and poaching on the game-preserves of his rich neighbours. A stock of rabbits is easily set a-going: they may usually be bought under one shilling, and sometimes even at twopence a pair. It is of importance, in making such a purchase, to attend to the varieties which feed kindly and furnish the best flesh.

The short-legged stout rabbits are generally supposed to be the most healthy, and also the best breeders. The large hair-coloured variety is much esteemed by some people; but the white, or white-mottled with black or yellow, are more delicate in flesh. The gray, and some of the blacks, approach nearer to the flavour of the wild rabbit than any others. With respect to the colours of these animals, gray is considered the worst of all colours; black is the next in gradation; fawn, and white and gray, hold the third place in estimation; pure white, with red eyes, is by some reckoned equal with, and by others superior to these; tortoise-shell (a rich brown and white, and brown, gray, and white) and black and white rank the highest; a uniform mouse-colour, though little noticed by fanciers in general, is much admired by a few.

The most important part of the duty of the rabbit-rearer is to erect his rabbit-house or hutch on proper principles. Two objects are particularly necessary to be attended to. The house or rabbitry must be kept always dry and well-aired; because the animal, in its natural state, prefers a dry and airy habitation. Rabbits are sometimes placed in boxes; but whether kept in these or in regularly-erected houses, the place must be kept quite dry, as too much humidity will cause the stock to rot. Where considerable numbers are housed together, fresh air is of great moment; still, they should not be exposed to cold currents, which may bring on a disease called the snuffles—a dangerous and frequently fatal malady.

Persons who live in large towns will in general find considerable difficulty in keeping rabbits, as it is seldom they have open grounds behind their houses wherein they might construct their rabbitry. In cases of this nature, rabbits might be kept on a small scale in wooden hutches, open in front, with spokes like a cage, and having a division to separate the sleeping apartment from the feeding-place, and a small door betwixt the one place and the other. But it will be found, on trial, that rabbits do not thrive well when put in cages, or confined in this manner. The genuine rabbitry must be a small house constructed on purpose, where the animals will have liberty to feed and amuse themselves. These houses may be built about four feet square, and the same in height, with a sloping roof, covered with thatch, or some other substance that will carry off the rain. This house ought to be paved on the floor, so as to prevent the inmates from burrowing and undermining the walls. It should be well laid with dry straw or meadow-hay, and possess several boxes with the open side downwards, and holes for the rabbits to go in and out. It would also be as well for these holes to be provided with slide-boards, which could be shut when necessary. To this house there ought to be attached a little open court, also paved, and covered completely with open spokes, so as to give air and light, as well as to afford you an opportunity of seeing the creatures when sporting or feeding.

On the subject of feeding, the following extract may be offered from the 'Boys' Own Book'—a pleasing work addressed to the young:—'If too much food be given at once, the animals will get disgusted with, and refuse it, so that a rabbit may be nearly starved by affording it too great a quantity of food. Most persons feed their rabbits twice, but for our own part we feed ours thrice a day. To a full-grown doe, without a litter, in the morning we give a little hay or dry clover, and a few of such vegetables as are in season; in the afternoon we put two handfuls of good corn into her trough; and at night we give her a boiled potato or two, more vegetables, and, if her hutch be clear of what we gave her in the morning, but by no means otherwise, a little more hay or clover. If you give rabbits more hay than they can eat in a few hours, except it be to a doe just about to litter, they will tread it under foot, and waste it; if you give them but a moderate quantity at a time, they will eat and enjoy it. Generally speaking, rabbits prefer green or moist food to corn; but it is necessary to make them eat a sufficient proportion of solid food, to keep them in health; occasionally, instead of corn, we give our rabbits a few split or whole gray peas. When a doe has a litter by her side, and also for rabbits recently weaned, we soak the peas a few hours previously to putting them in the trough. If a rabbit will not eat a proper quantity of corn, we mix a small quantity of squeezed tea-leaves with her portion, and stint her proportionately in green meat. Tea-leaves, in small quantities, well squeezed, may at all times be given, by way of a treat; but it is highly improper to make them a daily substitute for green meat.

Almost all the vegetables and roots used for the table may be given to rabbits: in preference to all others, we choose celery, parsley, and the roots and tops of carrots; and in this choice the animals themselves heartily agree with us; lettuces, the leaves, and, what are much better, the stumps of cabbages and cauliflowers, they eat with avidity, but these must be given to them with a sparing hand; turnips, parsnips, and even potatoes in a raw state, we occasionally afford our stock, on an emergency, when better roots or good greens are scarce. In the spring time, no soft meat is better for them than tares, so that they be not wet; in fact no green meat ought to be given to rabbits when there is much moisture on its surface. We have heard of some country persons feeding their rabbits on marsh-mallows, but we never did so ourselves. Dandelions, milk-thistles, or sow-thistles, we know, by long experience, they take in preference to all other food, except celery, parsley, and carrots; and nothing, as green meat, we are convinced, can be better for them.

It must be remembered that a doe will eat nearly twice as much when suckling as at other times; and when her litter begin to eat, the allowance of food must be gradually increased. In our own rabbitry we never admit chaff, and grains only in a dearth of green food. If we can obtain neither greens, roots, nor grains, at feeding-time, we make it a practice to moisten the corn with water, milk, or, as we before stated, with tea-leaves. Though a rabbit must be restricted from rioting in green or soft meat according to its own appetite, for its own sake, yet it is cruel to afford it only such food as will increase rather than appease its thirst; for this reason, in such a case as we have mentioned, we moisten the grain; and some rabbits will even do well with an occasional tablespoonful of water, beer, or milk; but it is a dangerous experiment to try the effect of a liquid on their stomachs.

If well fed, and kept warm, does will breed all the year; but most fanciers are contented with five litters in one season, and let them rest during the winter. It is a disadvantage, rather than otherwise, to have above six produced in a litter, as the young rabbits, when that is the case, are almost invariably weak and puny; and even if they be reduced to a moderate number, by removing some of them to the care of another doe, or otherwise, they seldom or never become remarkable for their size or beauty.

Diseases may in a great measure be prevented by regularity in feeding, good food, and cleanliness. The refuse of vegetables should always be scrupulously rejected. For the liver complaint, to which rabbits are subject, there is no cure; when they are attacked by it, fatten them, if possible, for the table. The snuffles are occasioned by damp or cold. If there be any cure for this disorder, it must be dryness in their hutches and food. Squeezed tea-leaves generally restore a doe to health, if weak, or otherwise affected after littering. A little bread moistened with warm milk may also be advantageously given to a doe at this critical period. When old rabbits are attacked by a looseness, dry food will in general restore them; but do what you will, it is very difficult, and in most cases impossible, to save young ones from sinking under it; dry food for them, as well as for the old ones, is the only remedy.'

When rabbits are to be used as food, it is commonly deemed beneficial to feed them for a short time on hay, and afterwards on shellings and oats, when the flesh will grow very delicate in flavour. As an example of the ordinary extent to which rabbits may be made productive, with common care, the case of a labouring man in the country may be mentioned, who, in a small wooden house enclosed by a railing, fed a batch of rabbits, and killed annually about twenty dozen, still maintaining his stock unbroken. What with the skins, flesh, and sales of the young, he turned the animals to good account; yet he scarcely expended a penny upon their food, and even the care of them was spared to him, when he had once fairly put his children in the way of management.

POULTRY.

Poultry (from *poule*, French for hen) is a term applied to different kinds of large birds in a state of domestication, as the chicken or barn-door fowl, turkey, duck, goose, pea-fowl, and guinea-fowl. The most numerous and important in every respect are

Chickens.

The chicken is classed by naturalists in the tribe of the *Gallinaceæ*, forming part of the order *Rasores* or Scraping-Birds (ZOOLOGY, p. 149). It is needless to describe minutely the appearance of the barn-door fowl. The most prominent characteristics of the cock, or male bird, are a thin indented comb, with wattles on each side under the beak; a tail rising in an arch, and a great variegation of colours. The female, or hen, is smaller as regards body, comb, and wattles, and her tints are less vivid. The domestication of this useful bird seems to have taken place in the earliest times, and Persia is commonly supposed to have been the country of its origin.

Many varieties of it have been enumerated as existing in Britain; but the differences betwixt these, in the majority of cases, seem to lie as much in colour as in any more important features. The best-marked varieties are the following:—The Dunghill Fowl, Game Fowl, Dorking Fowl, Polish Fowl, Spanish Fowl, and Bantam. The first of these varieties is a mongrel one, arising from crosses with all the other breeds; but it is the common and most useful variety. The best fowls of this sort are of middle-size and dark colour, and have white, clean legs; the pure white dunghill fowls are held to be the weakest in constitution, and to lay fewest eggs. It has been usually agreed to call the game fowl the proper English fowl. The body is erect and slender, and the colours showy, particularly those of the cock. In comparison with other breeds, the game bird is like the race-horse beside that which draws the cart and plough. The flesh, moreover, is peculiarly white and delicate in flavour, while, though small, the eggs are also of a very superior quality. There is a peculiarity of disposition, however, in this variety of the domestic fowl, which, while for ages the source of a cruel species of sport, has always impaired the real utility of the creature to a very great degree. We allude to the pugnacious spirit which has gained for the fowl its peculiar name. So strongly-marked is this propensity, that broods scarcely feathered are found occasionally to have reduced themselves to utter blindness by reciprocal battling. Even when the breed is crossed and recrossed, a tincture of the love of fighting still remains, rendering such admixtures the source of risk and trouble, though in other respects advantageous. Where persons prefer to have a game-cock in their poultry-yard, their choice, according to the best authorities, should be directed to a bird of one or other of the following colours:—dark-red, dark black-breasted red, dark-gray, mealy-gray, and reddish-dun.

The Dorking fowl is named from a town in Surrey, where it has long been bred in great numbers. It is a large bird, well-shaped, with a long capacious body, short legs, and five claws upon each foot instead of four. One spur characterises other breeds of the common fowl, but the Dorking fowl has two spurs on each leg. These distinctive marks seem to be of old standing in peculiar breeds, as both Aristotle and Pliny mention five-toed fowls. Though from repeated crossings the Dorking fowls are now found of all colours, white or yellowish-white is supposed to have been the primitive and genuine tint. They lay large eggs, and in great plenty. The Poland (Polish or Paduan) fowl is much valued by breeders, but is seldom found perfectly pure in Britain. The species was imported principally from Holland, and when unmixed, was uniformly of a black colour, with a white crest or tuft on the heads of both cock and hen. Their form is plump and deep, and the legs of the best sorts not too long. They are called *everlasting* layers, from the number of eggs produced by them, and from their disinclination to sit and hatch, which office is usually done for their eggs by other hens. The Spanish fowl is of large size, and lays large eggs. It is of the Polish family, and is almost uniformly marked by a black body, black legs, and large red combs. In London and its vicinity, the breed is now extremely common, being valued for the size of the eggs; but it is supposed to be inferior in some respects to other breeds, though yielding good food. The bantam fowl is well known for its small size, and its feathered grotesque-looking limbs. It was originally a native of India, and the nankeen-coloured and black birds are the most esteemed. The bantam should have a rose-comb, a full tail, and a lively carriage, and should not weigh above one pound. It has been recently discovered that the characteristic of feathered legs is not an improvement, the birds with clean bright limbs being the best. The flesh of this diminutive breed is said to be peculiarly delicate.

Besides these well-marked varieties of the common domestic fowl, there are a number of others, brought from foreign countries, which have produced mixtures pretty familiar to breeders. The Turkish, Malay, Rumkin, Russian, and Barbary species, may be mentioned as the principal of these. It need only be observed here, that all the crested mixtures or varieties are much esteemed, as possessing the best qualities of the race. All or any of the breeds of the domestic fowl are valuable to the cottager, even one good laying hen being a treasure to a humble family.

Hen-house.—The artificial assistance given by the cottager in housing the birds is usually of the scantiest order. The upper part of the space at the door of the cottage, or the *baulks* (loft), is often the nightly roost of two or three hens, and the roadside is their daily walk. Yet, with the petty scraps of food furnished in addition to their own pickings there, these hens will lay good eggs, and produce fine birds. At farm-steadings, it is common for the hens to roost among the beams of the stables or cattle sheds, and to lay in holes formed by scraping away a portion of lime on the top of the side walls. Very little pains might give to the humblest families much better and ampler accommodation for poultry. We quote on this subject the directions given in a little work by Mr Peter Boswell of Greenlaw:—'Always in the building of a cottage, and sometimes even where there was no intention of the kind when it was built, very ample accommodation for poultry can be provided, almost without a shilling of additional expense. To this purpose a part of the space next the roof, so often unoccupied and useless, might easily be devoted. To accomplish the object, a part of it next the kitchen fire gable end should be partitioned off, floored, and fitted up with baulks and laying-places. This could be done either on a large or a small scale, according to the inclination or the means of the projector. An opening of sufficient width should be made in the wall, at the height of the lower ceiling, through which the fowls could be conducted, by means of a *hen-ladder*, to the enclosure prepared for them below. There must be a hatchway somewhere, to afford access for the purpose of inspection and cleaning. If the attics are sufficiently high, it may be placed anywhere, but evidently with greatest convenience in the passage of the house; but if they are low, the nearer it is to the space portioned off for the reception of the fowls the better. This is a location for poultry possessing many advantages. Having their berth immediately above the cottage kitchen, they are secured in a proper degree of dryness and warmth, which in winter, especially with the spring-hatched pullets, will tell well in the production of eggs. Perhaps this is the best hen-house locality for securing eggs in winter which can be suggested to the frugal and judicious. Besides, the fowls are here free from many dangers, and safe from many enemies, to which they are exposed in a lower and more open situation.'

Another simple poultry-house of small size may be formed by building a shed against the gable of the house, opposite to the part warmed by the kitchen fire, and placing cross-bars in it for roosting, with boxes for laying in, or quantities of fresh straw. There should always be an opening, to allow of the cleaning out, once a week at least, of the poultry-house—a process too often neglected, but very essential to the health of the poultry. They never will thrive long amid uncleanness; and even with the utmost care, a place where poultry have been long kept becomes what the housewives call tainted, and there they will thrive no longer. The surface of the ground becomes saturated with their exuviæ, and is therefore no longer healthy. To avoid this effect, some poulterers in the country frequently change the sites of their poultry-houses, to obtain fresh ground; and to guard against the same misfortune, farmers who cannot change their hen-houses and yards, purify the houses by fumigations of blazing pitch, by washing with hot lime-water, and by strewing large quantities of pure sand both within and without the poultry-houses. Washing the floor of the house every week is necessary; for which purpose it is of advantage that it be paved either with stones, bricks, or tiles. But as these three modes are expensive, a good flooring, which is cheaper, may be formed by using a composition composed of lime and smithy ashes, together with the riddlings of common kitchen ashes; these having been all finely broken, must be mixed together with water, and put on the floor with a mason's trowel, and nicely smoothed on the surface. If this is put on a floor which is in a tolerably dry situation, and allowed to harden before being used, it will become nearly as solid and compact as stone, and is almost as durable. The inside of the laying-boxes requires frequent washing with hot lime-water, to free them from vermin, which greatly torment the sitting hens. For the same purpose poultry should always have a heap of dry sand or fine ashes laid under some covered place, or thick tree, near their yard, for them to dust themselves in; this being their resource for getting rid of the vermin with which they are annoyed.

The office of keeping and managing domestic fowls should be performed by the same individual, as the voice and presence of a stranger scare them, and disturb the operations of the hen-house. To distribute food and drink at regular hours, to visit the nests, to remove eggs as soon as laid, and carry them to a cool place, to examine by candle-light what eggs are fecundated, and to place these under the hen, and mark the time, are among the daily duties to be performed by the keeper. When the hens lay in a secret corner or covert, the keeper may readily discover it by placing a few grains of salt in the oviduct, which hurries on the process of laying, and causes the animal to retire to the spot anew.

Feeding.—Most persons are doubtless aware that fowls swallow food without mastication. That process is rendered unnecessary by the provision of a *crop*, an organ which is somewhat similar to the first stomach of the cow, and in which the food from the gullet is macerated, and partly dissolved by secreted fluids. From the crop, the food passes downwards into a second small cavity, where it is partly acted on by a digestive juice; and finally, it is transferred to the gizzard, or last stomach, which is furnished with muscular and cartilaginous linings of very great strength. In the gizzard, the partially-softened food is triturated, and converted into a thin paste, fit to be received into the chyle-gut, and finally absorbed into the circulation. Such is the power of the gizzard in almost all kinds of poultry, that hollow globes of glass are reduced in it to fine powder in a few hours. The most rough and jagged bodies do no injury to the coats of the gizzard. Spallanzani even introduced a ball of lead, with twelve strong needles so fixed in it that their points projected a fourth of an inch from the surface, and the result was, that all the needles, with the exception of one or two, were ground down in a short time to the surface of the ball, while those left were reduced to mere stumps. It is remarkable that, to add to the triturating powers of the gizzard, fowls are gifted with the instinct of swallowing gravel with their food.

Fowls, when left to roam at large, pick up all sorts of seeds, grains, worms, larvæ of insects, or any other edible substances they can discover, either on the surface of the ground or by scraping. They also pick a little grass as a stomachic. The more that hens can be allowed to run about to gather their own food, the better for their own health and the pockets of their keeper. When secluded, and fed altogether in an artificial manner, their keep becomes expensive, and is, on the whole, seldom compensated by their produce. We have indeed great hesitation in advising any one to keep fowls who cannot unexpensively give them plenty of refuse from the table, or permit them to range in a field or lane in quest of what seems proper for their natural appetite. The very pleasure of ranging and scraping seems advantageous to them.

If kept in a courtyard or pen, and requiring altogether artificial feeding, their natural tastes should be consulted as far as conveniently practicable. They should be fed regularly, and with a miscellaneous kind of diet; allowed at all times access to clean water for drinking, and have earth, sand, or dust, to scrape at pleasure and roll themselves in. A certain quantity of chalk or lime should also be scattered about for them to pick up, as that material is required by them in the production of eggs. Speaking on this subject, Professor Gregory of Aberdeen, in a letter to a friend, published in a newspaper, observes—'As I suppose you keep poultry, I may tell you that it has been ascertained that, if you mix with their food a sufficient quantity of egg-shells or chalk, which they eat greedily, they will lay, other things being equal, twice or thrice as many eggs as before. A well-fed fowl is disposed to lay a vast number of eggs, but cannot do so without the materials for the shells, however nourishing in other respects her food may be; indeed a fowl fed on food and water free from carbonate of lime, and not finding any in the soil, or in the shape of mortar, which they often eat off the walls, would lay no eggs at all, with the best will in the world.'

In a state of domestication, the hard food of which fowls seem most fond are peas and barley (oats they do not like); and besides a proportion of these, they may be given crumbs of bread, lumps of boiled potatoes, not too cold, or any other refuse. They are much pleased to pick a bone; the pickings warm them, and excite their laying propensities. If they can be supplied with caterpillars, worms, or maggots, the same end will be served. Any species of animal food, however, should be administered sparingly; and the staple articles of diet must always be of a vegetable nature. When wanted for the table, the quantity of food may be increased, and be more substantial; they should also be kept more within the coop, and as quiet as possible. A fortnight's feeding in this way will bring a fowl of a good breed up to a plump condition.

Laying.—The ordinary productiveness of the hen is truly astonishing, as it usually lays, in the course of a year, two hundred eggs, provided it be allowed to go at liberty, is well fed, and has a plentiful supply of water. Many instances have been known of hens laying three hundred in a year. This is a singular provision in nature, and it would appear to have been intended peculiarly for the use of man, as the hen usually incubates only once in a year, although she will occasionally bring out two broods. Few hens are capable of hatching more than from twelve to fifteen eggs; so that, allowing they were all to sit twice a year, and bring out fifteen at a time, there would still be at least one hundred and seventy spare eggs for the use of man. It is therefore evident, that in situations where hens can pick up their food, they must prove very profitable; for supposing that the eggs of one fowl during the year were sold, without any of them being hatched, they would bring (if near a large city) on an average ninepence per dozen, or fourteen shillings, and the hen herself would be worth two shillings at least. As the number of eggs which are annually brought out by a hen bear no proportion to the number which she lays, schemes (to be subsequently noticed) have been imagined to hatch all the eggs of a hen, and thus turn her produce to the greatest advantage; so that, in place of twelve or fourteen chickens, upwards of two hundred may be produced from the annual produce of a single fowl.

Hens will lay eggs which have received no impregnation, but from these, as a matter of course, no hatching can take place; they are equally good, however, for eating. When the chief object is to breed chickens, a cock should be allowed to walk with ten or twelve hens; but when eggs are principally required, the number of hens may be from fifteen to twenty. Endeavour to procure a cock of a good breed, not game, and let him be in his prime, which is at eighteen months to two years old. Cocks will last two years, after which they lose their liveliness of colours, and become languid, inactive, and mere consumers of food. It is fit, therefore, that younger cocks should then take their place in the poultry-yard. It is common to make choice of a young cock, by pitting one or two against each other, and selecting the most courageous, which is always sure to be the favourite of the yard.

Some remarks have been made on the colours of the best hens of the different varieties. As to other qualities, M. Parmentier recommends that they should be chosen of a middling size, robust constitution, large head, bright eyes, and pendant comb. Crowers should be rejected, and those that are of quarrelsome tempers, such hens being rarely good hatchers or layers. Old hens, or those above five years old, are of little use when added to a stock; and when the comb and claws are rough, it is a sign that they have ceased to lay.

If left to themselves, hens would produce, like some wild birds, two broods in the year. Early spring, and, after a cessation, the end of summer, are the two seasons in which they begin naturally to lay. In the depth of winter, under ordinary circumstances, hens very rarely lay eggs, though by artificial means they can be made to do so. If the temperature of the place where they are kept be raised by a stove, or otherwise, they will produce eggs. The fowls of the Irish peasantry, which are usually kept in the cabins of the owners, lay often in winter, in consequence of the warmth of their quarters; and there can be no doubt that warmth affords the most effective means of procuring new-laid eggs in winter, though stimulating food may aid in producing the same result. The fecundity of hens varies considerably. Some lay but once in three days, others every second day, and others every day. In order to induce laying, each hen should have its own nest, made with soft straw, and furnished with a piece of chalk as a decoy. The signs which indicate when a hen is about to lay are well known. She cackles frequently, walks restlessly about, and shows a brighter redness in her comb and wattles. After the process of laying is over, she utters a loud and peculiar note, to which the other fowls usually respond. Shortly after the egg is laid, it should be removed, for the heat of the hen soon corrupts it. When the eggs are taken away by the poultry-keeper, they should immediately be laid in a cool and dry place. If allowed to absorb damp, they soon spoil; indeed one drop of water upon the shell quickly taints the whole egg.

Various methods have been tried to prevent the absorption of air through the shell, and preserve the freshness of the eggs. A not uncommon plan is to keep them secluded from the air in bran, rye, or ashes, which may do very well where the eggs are to be kept in this way till eaten, but is utterly useless if quantities of them have to be sent to market. We beg to offer a plain piece of advice to cottagers on this subject, which, if properly acted upon, will give them the means of at all times commanding the highest price for *fresh eggs*, although situated a hundred miles or more from the place of sale. *Smear all your eggs with a bit of fresh butter the moment you get hold of them.* Do not load the shell with grease, but merely give a light varnish. The butter must be good. By this simple process of smearing, which does not taint the interior in the slightest degree, the egg is as fresh at the breakfast-table when three months old as if just newly laid, and possesses all the delicious milkiness which the freshest eggs possess. Scarcely anything is more common than to hear complaints of the difficulty of getting fresh eggs, and all a result of the sheer negligence of fowl-keepers. By the plan we mention, there need never be such a thing as a bad egg heard of. Dipping in lime-water and some other processes, which will be noticed in No. 47, are said to be equally effectual.

Hatching.—When eggs are to be hatched, it is necessary to pay attention to the choice of proper ones for the purpose. The company of the male bird renders the hen productive of fecundated eggs; and, as already noticed, it is only eggs of this kind which are available for producing young. The eggs must also be fresh; from the time they are laid, they should lie aside in a cool place. It is said to be possible to ascertain, from the appearance of the egg, whether the forthcoming progeny is to be male or female; but we greatly doubt the truth of the popular notions on this subject. When eggs are left to be brought forth by the hen, a certain number is placed under her in the nest, when she is in the full inclination to sit. From nine to twelve eggs are placed, according to the extent of the breast and wings; and the time required for hatching is twenty-one days. Sometimes a hen will desert her eggs, a circumstance which may occasionally be traced to an uncomfortable condition of the skin, caused by vermin or want of cleanliness, and this affords a strong reason for keeping the hen-house clean, and giving the animals the means of purifying their feathers. Occasionally the hen is vicious, or, in short, a bad sitter, and experience in pitching on the best hatching hen is the only remedy. Sometimes a hen will break her eggs with her feet; and in such cases the broken eggs must be removed as soon as observed, otherwise she may eat them, and from that be tempted to break and eat the sound ones, and thus spoil the whole.

It has generally been found that hens which are the best layers are the worst sitters. Those best adapted have short legs, a broad body, large wings, well furnished with feathers, their nails and spurs not too long or sharp. The desire to sit is made known by a particular sort of clucking; and a feverish state ensues, in which the natural heat of the hen's body is very much increased. The inclination, or, as physiologists term it, the *storge*, soon becomes a strong and ungovernable passion. The hen flutters about, hangs her wings, bristles up her feathers, searches everywhere for eggs to sit upon; and if she finds any, whether laid by herself or others, she immediately seats herself upon them, and continues the incubation.

With a proper provision of food at hand, warmth, quiet, and dryness, a good hatching hen will give little trouble, and in due time the brood will come forth; one or two eggs may perhaps remain unhatched or addled, but their loss is of little consequence. As soon as the hen hears the chirp of her young, she has a tendency to walk off with them, leaving the unhatched eggs to their fate; it is therefore advisable to watch the birth of the chicks, and to remove each as soon as it becomes dry, which may be in a few hours afterwards. By this means the hen will sit to hatch the whole; yet she should not be wearied by too long sitting. If all the eggs are not hatched at the end of twelve or fifteen hours after the first chick makes its appearance, in all probability they are addled, and may be abandoned. The chicks must be kept in a warm place during the first day, and at night restored to the mother, who now assumes her maternal duties. The food given to the young chicks should be split grits, which they require no teaching to pick up; afterwards the ordinary food of the poultry-yard, or what the mother discovers for their use, is sufficient. Some give the yolks of hard-boiled eggs or curd, when a nourishing diet seems advisable. The extreme solicitude of the hen for her young, or the brood which may be imposed upon her, is well known. She leads them about in quest of food, defends them by violent gesticulations and the weapons which nature has given her, calls them around her by a peculiar clucking cry, and gathers them carefully under her wings to shelter them from danger, or to keep them warm at night. This maternal care is bestowed as long as the chickens require her assistance; as soon as they can shift for themselves, the mutual attachment ceases, and all knowledge of each other is very speedily lost. The young now go to roost, and the mother again begins to lay. Young hens, usually called pullets, begin to lay early in the spring after they are hatched.

Artificial Hatching.—As heat is all that is necessary to incubation, eggs may be hatched artificially, without the intervention of the hen. This practice was common in Egypt in very early times, and has since been adopted in many other quarters, but with indifferent success. In the neighbourhood of London, attempts at artificial hatching have from time to time been made—one of the most successful being that of the *Eccaleobion*, or life-evoker, established several years ago. An oven, consisting of eight floors or compartments, was employed to contain the eggs, while they were subjected to heat from steam-pipes. Each compartment held from 200 to 300 eggs, and the whole exhibited the hatching process in all its various stages. The regularity with which the temperature was maintained, as well as accommodated to each peculiar stage of the process, brought out the chick with much greater certainty than when the incubation was performed by the hen, which sometimes cannot be kept steadily to the work. A visitor to the Eccaleobion gave the following account in 'Chambers's Edinburgh Journal,' No. 400, of the management of the chick after hatching:—'The superintendent of the oven politely exhibited a compartment in which the eggs were chipping. Some had chipped the day before, others that day, and some would not be chipped till the morrow; in a few cases, we observed the beak of the chick boring its way through the shell, and getting itself emancipated. When the little creatures are ushered into the world, they are not immediately removed out of the oven, but are allowed to remain for a few hours till they become dry; they are then removed and put into a glass-case, on the table at the end of the room. This case is very shallow, and the glass cover can be easily pushed aside to permit the superintendent handling them if required. They are here for the first time fed, though not for twenty-four hours after being hatched; the material scattered among them is small bruised grits, or particles little larger than meal; these they eagerly pick up without any teaching, their instinctive desire for food being a sufficient monitor. After the brood has been kept in the glass-case, which is partially open, for two or three days, and been thus gradually accustomed to the atmosphere, they are removed to one of the divisions in the railed enclosure on the floor. Here hundreds are seen running about, uttering peepy cries, picking up grits, or otherwise amusing themselves, all being apparently in as lively and thriving a condition as if trotting about in a barn-yard. At six in the evening they are put to bed for the night in the coops, twelve together in a coop: these coops are small wooden boxes lined with flannel, and furnished with a flannel curtain in front, to seclude and keep the inmates as warm and comfortable as if under the wing of a mother. At six or seven in the morning they are again allowed to come forth into their court-yard, which, being strewed with sand, and provided with food and water, affords them all the advantages of a run in an open ground.

I made some inquiries respecting the failures in hatching, and deaths, and received the following information:—The eggs are usually purchased from Leadenhall market, and consequently, not being altogether fresh, or otherwise suitable, one-half of them fail in hatching. Once hatched, they are safe, for not more than one dies out of fifty which are brought into existence. If good and suitable eggs could be procured in all seasons, the failures in hatching would be comparatively trifling. Bad eggs, therefore, are the weak point in the establishment; and I should recommend the proprietor to complete his arrangements, by adding an egg-laying department to those which he has for hatching. This might be done by keeping a regular poultry-yard, either in connection with the place or in the country. The apparatus for hatching is capable of producing forty thousand chickens in a year; and making allowance for failures, the actual produce cannot fall far short of half of that number. When three weeks old, as I was informed, the chickens are taken to market, and sold for a shilling each. Thus, we should suppose, the Eccaleobion turns out at least a thousand pounds' worth of chickens annually—no bad revenue, it will be said, after paying expenses, but not greater than the ingenious contriver and proprietor, Mr William Bucknell, deserves.' The writer concludes by calling the attention of the public to the case with which similar establishments might be got up in all large towns. The price of poultry, he argues, might be greatly lowered in the market, and the dietary resources of the common people materially improved and extended. He forgets, however, that the rearing or feeding, and not the hatching, is the main difficulty; and that it is not possible for any establishment of this kind to compete with the cottager and farmer's wife, the fattening of whose chickens cost little, or next to nothing. Unless the price can be reduced, the mere creating of greater numbers will never have the effect of causing a greater demand than at present.

Capons.—The best modes of fattening fowls for the table have been adverted to. The process of converting chickens into capons, however, ought also to be noticed here. By removing the reproductive and oviparous organs from the male and hen chickens respectively, a great change is produced in them as regards voice and habits, and they can be made remarkably fat for the table. Capons are chiefly reared in Sussex, Essex, and one or two other counties around London. They can be trained to watch chickens, hatch eggs, and do many useful offices of the poultry-yard. Upon the whole, however, the special benefit derived from rearing capons does not counterbalance the trouble which they give and the danger of the primary operation, for an account of which, as practised in different countries, see Dickson on Poultry.

Diseases.—Chickens are liable to various diseases, demanding attention from the poultry-keeper. The *pip* is the most common; it consists of a catarrhal thickening of the membrane of the tongue, causing a dangerous and obvious obstruction to respiration. It may be cured in most cases by throwing the fowl on its back, holding open the beak, and scraping or peeling off the membrane with a needle or the nail. The part may be wetted with salt or vinegar afterwards, and a little fresh butter pushed over the throat. Dr Bechstein recommends giving a mixture of butter, pepper, garlic, and horse-radish, as an internal remedy. But the operation is most effective. *Thirst* sometimes attacks fowls like a fever, and often arises simply from dry food, though more frequently symptomatic of indigestion or some internal and deep-seated derangement. Careful attention to diet is the first and great point in all such cases. If *constipation* appear to be present, bread soaked in warm milk, boiled carrots or cabbages, earth-worms, chopped suet, or hot potatoes with dripping, will be found useful. A clyster of sweet oil should be tried in severe cases. Where a tonic seems to be required, a little iron rust may be mixed with the food, and will generally relieve atrophy or loss of flesh. Where diarrhoea or scouring is observed, iron or alum may be given in small quantities. There is also a species of influenza, called the *roup*, which is often epidemical in the poultry-yard, and causes much havoc among the young birds. The eyes become swollen, a discharge comes from the nostrils, and the fowl gapes continually, showing much difficulty of breathing. Some observers have ascribed this complaint to worms in the windpipe, and have recommended their extraction by an operation; but warmth, cleanliness, soft food, and such laxatives as sulphur, with frequent ablutions of the eyes and nostrils, are more likely perhaps to do good, and are not attended with danger. Where general fever has been observed in fowls, the use of a little nitre has been found very advantageous. Saffron is another remedy very often employed in relieving the symptoms of sickness in fowls.

Many of these remarks will apply equally well to the diseases of geese and the other species of domestic poultry yet to be noticed; and this subject, therefore, need not again be adverted to in detail.

Turkeys.

The turkey, like the common chicken, has been included by naturalists in the *Gallinaceous* family of birds, and possesses the main characteristics common to the whole. It is a native of the woods of North America, and is certainly one of the most valuable fowls which have been naturalised in this country, but is very difficult to rear. The turkey-hen lays from fifteen to twenty eggs, and then sits upon them. She will bring out two broods in a year. The eggs are of a pale yellowish-white colour, finely streaked and spotted with reddish-yellow. They are a most delicious food, much more delicate in their flavour than those of the common hen. In England or Scotland, however, the eggs are comparatively seldom to be met with for sale, being deemed too valuable to be used as food. In Ireland, they are to be got in the markets in great abundance, especially in the midland counties, where we have bought them at ninepence per dozen. In that country, when the hen has laid about half-a-dozen eggs, they afterwards take away one daily, by which means the hens are induced to produce a greater number of eggs than otherwise. This they assist by means of stimulating food, such as hemp-seed and buck-wheat. There is an interval of a day between the laying of each egg. It is said that the first two eggs which she lays are unfruitful. A turkey-hen can seldom hatch more than from sixteen to eighteen eggs. The time of incubation varies from twenty-seven to twenty-eight days, at which time the young begin to pierce their shelly prison, and emerge from it.

General Treatment.—When turkey chicks first come forth, they are extremely weak, and much assiduous care is necessary to rear them. The first thing to be attended to is, to remove them to a situation where they are not exposed to the sun's rays, which at first are too powerful for them. A woody place is the most suitable to their natural habits. Nothing is so destructive to them as rain, from which they must be protected. When young turkeys accidentally get wet, they should be brought into a house, carefully dried by applying soft towels to them, and then placed near a fire, and fed upon bread which has been mixed with a small proportion of ground pepper or ginger. It should be made up in the form of small peas. If the bread is too dry for this purpose, it may be moistened with a little sweet milk. Should the turkey-poults refuse to eat it, a few of these pellets may be forced down their throats. Even heavy dews prove destructive to them, and frost is no less injurious in its effects. These must therefore be most carefully guarded against when the hens incubate in March or early in April. Dry and sandy situations are most congenial for breeding turkeys, and especially elevated situations where large woods are contiguous. A single male turkey is sufficient for twelve or sixteen females, although the former number is probably the safest, to prevent sterility in the eggs, which is frequently the case with those of turkeys. Eggs should never be intrusted to the care of a female until she is at least two years of age, and they may be kept for the purpose of incubation till they reach their tenth year. The largest and strongest hens should always be kept for this purpose. During the time the hen is sitting, it becomes necessary to place food near her; as otherwise, from her assiduity, she may be starved to death, as turkey-hens seldom move from their nest during the whole time of incubation.

Where farmers rear turkeys in great numbers, they do not indulge the hen by allowing her to sit as soon as she has done laying, but keep them from her until all the other hens have ceased to lay, as it is of consequence that they should all be hatched about one time. When hens are unhappy during this interval, they may be indulged with hens' eggs. When they have all ceased to lay, each of them is provided with a nest ranged close to the wall, in a barn or other convenient place, and each is supplied with from sixteen to twenty of her own eggs. The windows and doors are then closed, and only opened once in the twenty-four hours for the admission of air, and for the purpose of feeding the hens. They are taken off their nests, fed and replaced, and again shut up. On the twenty-sixth day, the person who is intrusted with the management of the birds examines all the eggs, and removes those that are addled; feeds the hens, and does not again disturb them till the poults have emerged from their shells, and have become perfectly dry, from the heat of the parent bird; as to be subjected to cold at this time would certainly kill them. When the young birds are thoroughly dried, two of the broods are joined together, and the care of them intrusted to a single hen; and those which have been deprived of their offspring are again placed on hens' or ducks' eggs, and subjected a second time to the tedious operation of incubation, in which case it is not unusual for them to bring out thirty eggs. We cannot recommend this practice in point of humanity; for the poor hens, when they have accomplished their second sitting, are literally reduced to skin and bone, and frequently so weak as hardly to be able to walk.

As before hinted at, great care should be taken of the young turkey-poults; besides warmth, proper food, and shade, the nearer they are to a pure running stream the better, as they drink a great deal, and nothing is of greater importance to their being successfully reared than fresh drink. They must be also carefully protected from strong gusts of wind, and on the slightest appearance of a thunder-storm, should be immediately taken into a house. They should get no food for twenty-four hours after they leave the egg. Their first food should be hard-boiled eggs finely chopped, and mixed with crumbs of bread. Curd is also an excellent food for them. When they are about a week old, boiled peas and minced scallions are given to them. If eggs are continued, the shells should be minced down with their food, to assist digestion, or some very coarse sand, or minute pebbles. They should be fed thrice a day; and as they get older, a mixture of lettuce-milk will be found beneficial, together with minced nettles. Barley boiled in milk is another excellent food at this period, and then oats boiled in milk. In short, the constitution of young turkeys requires at all ages every kind of stimulating food. When about three weeks old, their meat should consist of a mixture of minced lettuce, nettles, curdled milk, hard-boiled yolks of eggs, bran, and dried camomile; but when all these cannot be readily obtained, part of them must be used. Fennel and wild endive, with all plants which are of a tonic character, may be safely given to them. Too much lettuce, however, has been found to be injurious. When poults are about a month old, they should be turned out, along with the parent bird, into the fields or plantations, where they will find sufficient food for themselves. Grass, worms, all kinds of insects and snails, are their favourite food, and nature dictates to them such vegetables as are conducive to their general health. As their feet are at first very tender, and subject to inflammation from the pricking of nettles and thistles, they ought to be rubbed with spirits, which has the effect of hardening the skin, and fortifying them against these plants.

The glandulous fleshy parts and barbles of their heads begin to develop when they are from six weeks to two months old. This is a critical period with the poults, and unusual care must be bestowed on them, as they now become weak, and often sickly. A little brine mixed with their food will be found very beneficial, or spirits much diluted with water. A paste made of fennel, pepper, hemp-seed, and parsley, has been found an excellent remedy when afflicted with an inflammation in the wattles, to which they are liable when growing. They are very subject to this if the weather happens to be broken and changeable at the time these tubercles are growing. These parts swell and grow very red, which frequently proves fatal to them. If, therefore, such be the state of the weather at this critical period, the paste above recommended should be given although they are perfectly healthy, which will be found an excellent preventive. When the inflammation becomes very great, recourse is often had to bleeding in the axillary vein, which frequently has the effect of recovering them.

Soon after the turkey-poults have acquired their first feathers, they are liable to a disease which is very fatal to them, if not attended to. This distemper produces great debility, and the birds appear languid and drooping, and almost totally neglect their food. Their tail and wing-feathers assume a whitish appearance, and their plumage has a bristled aspect. This is occasioned by a disease in two or three of the rump-feathers. On examination, the tubes of these will be found filled with blood. The only remedy for this disease is to pluck them out, when the bird will speedily acquire its wonted health and spirits.

In fattening turkeys for the table, various methods are resorted to. Some feed them on barley-meal mixed with skim-milk, and confine them to a coop during this time; others merely confine them to a house; while a third class allow them to run quite at liberty; which latter practice, from the experience of those on whose judgment we can most rely, is by far the best method. Care should, however, be taken to feed them abundantly before they are allowed to range about in the morning, and a meal should also be prepared for them at mid-day, to which they will generally repair homewards of their own accord. They should be fed at night, before roosting, with oat-meal and skim-milk; and a day or two previous to their being killed, they should get oats exclusively. We have found from experience that when turkeys are purchased for the table, and cooped up, they will never increase in bulk, however plentifully they may be supplied with food and fresh water, but on the contrary, are very liable to lose flesh. When feeding them for use, a change of food will also be found beneficial. Boiled carrots and Swedish turnips, or potatoes mixed with a little barley or oat-meal, will be greedily taken by them. A cruel method is practised by some to render turkeys very fat, which is termed cramming. This is done by forming a paste of crumbs of bread, flour, minced suet, and sweet milk, or even cream, into small balls about the bulk of a marble, which is passed over the throat after full voluntary meals.

Pea-Fowl.

The peacock, also one of the gallinaceous tribe of birds, came originally, it is said, from India, and was well known to the ancient Greeks and Romans, who introduced it into their mythology. The great beauty of its tail, so ample in extent and so rich in colours, rendered it indeed not unworthy of such preferment.

One peacock is usually kept with three or four hens. The female is extremely fastidious about a spot to lay in, and generally leaves any artificial nest for the grass of some neighbouring coppice, where she lays under the branches of a shrub, in a well concealed situation. One reason for this is the propensity of the cock to break the eggs if he discover them. When the eggs of the pea-hen are gathered in sufficient numbers, whether from a natural or artificial nest, it is a common practice to place them under a common hen, which hatches them in thirty days, and makes an excellent stepmother to the young chicks. These are very tender at first, but soon grow vigorous, even in a chilly climate. Barley-meal paste, mixed with cheese or curd prepared from milk, with alum, ants' eggs, meal-worms, and hard-boiled egg, are among the common articles of diet given to the young. The grown-up pea-fowl feeds on boiled barley or other common grains, and is a dangerous neighbour to corn or wheat fields and gardens. On the other hand, they are voraciously fond of such creatures as frogs, lizards, and the like, and keep grounds clear of such annoyances. In moulting-time, it is requisite to be more careful of these fowls than at other times, and to give them good grain, with a little honey, and fresh water.' Though the tongues and livers of peacocks were ranked among the dainties of the Roman epicures, the bird is rarely killed for table now-a-days. Yet it always bears a high price, being one of the most beautiful of the feathered race, and an object on which the eye ever delights to dwell, though its screaming note by no means gives a corresponding pleasure to the ear.

The Guinea-Fowl.

This stranger is found native in Africa, as its name indicates, and it also exists in an indigenous state in South America. The Guinea-fowl (*Numidia meleagris*) is about the size of the common hen, and the male differs very little in appearance from the female. Three species exist in considerable numbers in Europe—namely, the crested, the mitred, and Egyptian varieties. A very beautiful sort is marked by a pure white tint of body, but the most familiar hues are dark-grey and black. The bird is less tame than other common poultry, and prefers to live in a half-wild condition in its native regions, perching and living on trees like undomesticated birds. It is a spirited creature, and will battle even with the turkey. Guinea-hens require great attention at the time of laying, making their nests by preference in corners of the woods. Their eggs are small, but much esteemed; and the common hen is usually made to rear their broods. In the market, guinea-fowls always bear a high price, both on account of their flesh, which is of a good quality, and because they form a very pretty variety of the poultry stock. Their food is grain, of the various kinds given to ordinary barn-door fowls, with which they assimilate closely in habits. On the whole, they may be said to be kept more from curiosity than for profit.

The Goose.

The goose differs in many respects from the fowls already noticed, being aquatic in its habits. It is marked by a flat bill and webbed feet, characters also possessed by the duck and swan, which, in conjunction with the goose, may be held as forming a distinct family (*Anatidæ*) of the feathered aquatic tribes.

Our common tame goose is the wild species domesticated, known to naturalists by the name of the fen or stubble-goose. Where people have a right of common, or live in the vicinity of marshy heaths, the breeding and rearing of geese will prove very profitable, for in such situations they are kept at a trifling expense; they are very hardy, and live to a great age. If properly kept, and fed regularly, although sparingly, they will lay upwards of a hundred eggs yearly. If these are set under large hens, each having half-a-dozen, with the assistance of the goose herself, they may be nearly all hatched. For the first three or four days, they must be kept warm and dry, and fed on barley-meal or oat-meal mixed with milk, if it is easily procured; if not, let these ingredients be mixed with water. They will begin to grow in about a week. For a week or two the goslings should not be turned out till late in the morning, and should always be taken in early in the evening. In Ireland, the tenantry depend much on the breeding of these birds and turkeys to pay their rent; and with those who are industrious and favourably situated for rearing geese, they even do more in many instances. In the early part of the year they are allowed to feed on grass, on heaths, meadows, commons, and road-sides; and as most of the peasantry have small bits of corn land of their own, the geese are turned out on the stubble to pluck what grass is left; and they also fatten upon it, and improve the flavour of their flesh.

Although water be the natural element of geese, yet it is a curious fact that they feed much faster in situations remote from rivers and streams. To fatten geese, it is necessary to give them a little corn daily, with the addition of some raw Swedish turnips, carrots, mangel-wurzel leaves, lucerne, tares, cabbage leaves, and lettuces. They should not be allowed to run at large when they are fattening, as they do not acquire flesh nearly so fast when allowed to take much exercise. Therefore those who can only afford to bring up a goose or two, should confine them in a crib or some such place about the beginning of July, and feed them upon the ingredients above recommended, with a daily supply of clean water for drink. If, on the contrary, from a dozen to twenty are kept, a large pen of from fifteen to twenty feet square must be made, and well covered with straw in the bottom, and a covered house in a corner for protection against the sun and rain when required, because exposure to either of these is not good. It will be observed that about noon, if geese are at liberty, they will seek some shady spot, to avoid the influence of the sun; and when confined in small places, they have not sufficient room to flap their wings and dry themselves after being wetted; nor have they room to move about so as to keep themselves warm. There should be three troughs in the pen, one for dry oats, another for vegetables—which ought always to be cut down—and a third for clean water, of which they must always have a plentiful supply. It must be remembered that the riper the cabbages and lettuces with which they are supplied, the better. In the neighbourhood of large towns, the most profitable way of disposing of geese is in a dead state; as nearly the same sum can be obtained for them as if they were alive; and then you have the feathers, which are valuable, and may be sold to much advantage by themselves when you have collected a stone weight or more.

Geese are kept in vast quantities in the fens of Lincolnshire, several persons there having as many as a thousand breeders. They are bred for the sake of their quills and feathers, as well as for their carcase; it is therefore customary to strip them partially of the fine downy feathers, and leave them to grow afresh, and also to take quills from their wings—both practices barbarous in the extreme, however they may be attempted to be justified. Geese breed in general only once a year, but if well kept, they sometimes hatch twice in a season. The best method for promoting this is to feed them with corn, barley, malt, fresh grains, and, as a stimulant, they should get a mixture of pollard and ale. During their sitting, each bird has a space allotted to it, in rows of wicker pens placed one above another, and the goose-herd who has the care of them drives the whole flock to water thrice a day, and bringing them back to their habitation, places every bird (without missing one) in its own nest. One gander is generally put to five geese. The time of incubation varies from twenty-seven to thirty days. The goose begins to lay in March, but the time of the month depends upon the state of the atmosphere. When goslings are first allowed to go at large with their dam, every plant of hemlock which grows within the extent of their range should be pulled up, as they are very apt to eat it, and it generally proves fatal to them. Nightshade is also equally pernicious to them, and they have been known to be poisoned by cropping the sprigs of the yew-tree.

Ducks.

Ducks are easily kept, particularly near ponds or streams of water. In such situations, even the poorest families may have half-a-dozen of them running about without the least inconvenience. In keeping them in a domestic state, one drake is usually put to half-a-dozen ducks. The ducks begin to lay in February; their time of laying being either at night or early in the morning. They are extremely apt to deposit their eggs in some sequestered spot, and to conceal them with leaves or straw. From eleven to fifteen eggs is the number which a duck can properly cover. The time of incubation is about thirty-one days. The place where they incubate should be as quiet and retired as possible; and if they have liberty, they will give no trouble whatever in feeding, as the duck, when she feels the call of hunger, covers her eggs carefully up, and seeks food for herself, either by going to the streams or ditches in her neighbourhood, or, if such are not at hand, she will come to the cottage and intimate her wants by her squalling. When the young are hatched, they should be left to the care of the duck, who will lead them forth in due time; and when she does so, prepare a coop for them, which should be placed on short grass, if the weather is mild; and if cold or stormy, they should be kept under cover. The future strength of the brood will depend much upon the care that is taken of them for the first three or four weeks after they have emerged from the shell. Ducklings will begin to wash themselves the first day after they are hatched, if they find water at hand; therefore a flat dish filled with that element should be always within their reach. Many persons are in the practice of clipping the tail, and the down from beneath it, in ducklings, if the weather is wet during the first weeks of their existence. This is to prevent them from draggling themselves, which has a tendency to produce intestinal diseases. From a fortnight to three weeks is all that is necessary to confine them to the coop.

The first thing on which ducklings are fed is a mixture of barley, peas, or oat-meal, and water. They may afterwards be fed upon a mixture of buck-wheat and any of the above-named meals. The greatest attention must be paid to keeping their bed warm and dry; and with young ducks, a frequent change of straw is absolutely necessary, as their beds soon get dirty, wet, and fetid.

Ducks are not such attentive guardians of their young as hens, and therefore it is a common practice to place duck eggs under a sitting hen, and leave her to hatch them as her own progeny. When the young ducks so hatched make their appearance, the hen does not appear aware of the imposition, but takes at once to her duties with all a mother's fondness. The natural desire of the ducklings to plunge into water and swim away from the shore vexes her, but she watches for their return, and does all in her power to provide the means of subsistence. She scrapes for them, which a duck would not; she shelters them under her dry and warm bosom and wings, and altogether makes a better nurse than their own proper parent.

In feeding ducks for use, peas and oat-meal are to be preferred. It is said that barley-meal renders their flesh soft and insipid. Bruised oats should be given to them freely for some weeks before they are killed, which renders their flesh solid and well tasted; and the same general principles recommended in the feeding of geese should be kept in view. It has been found that the offal of butchers' shops feeds ducks quickly, and that this does not impair the flavour of their flesh. In very many instances, ducks are reared in situations where there are no pools of clean water for them to dabble in, and the poor animals are compelled to grub with their bills in all sorts of nauseous puddles, which of course makes their flesh rank and offensive. They should in all cases have a pool of clean water to swim in, and are best reared near a natural meadow, lake, or pond, where they can search for their appropriate food.

Those who have paid much attention to the management of domestic poultry, assert that geese and ducks should be kept apart from other fowls. The former should have their houses ranged along the banks of a piece of water with a fence, and sufficiently extensive for walks in front, with doors for their access to the water, which can be closed at pleasure.

Swans.

Swans are generally kept for ornament rather than use. The flesh, even of the young, is black, hard, and rank, while that of the old is too tough for mastication. The eggs also are not peculiarly palatable; and there is little inducement to rear them; in short, if mere pecuniary advantage be looked to, excepting on the score of the skin, feathers, and down, which are articles of considerable value. At the same time, if the swan be not a productive bird, few animated objects can be compared with it as regards ornament. Its great size, snow-white plumage, and graceful form, render it a most attractive spectacle upon the bosom of a pool or loch. It is a hardy, long-lived fowl, and associates in pairs. The food of the swan consists usually of seeds, roots, and plants, rendered succulent by water. When fed in a barn-yard, it seldom thrives, being more decidedly aquatic in its habits than ducks or geese. From the colour of the European swan being so uniformly white, a black swan used once to be proverbially spoken of as an impossibility; but black swans occur abundantly in Australia, from whence they are now frequently brought, as curiosities for the pleasure-ponds of the wealthy.

Pigeons.

Pigeons are among the most ornamental and useful appendages of a rural dwelling. If permitted to fly abroad to seek their food, little expense will be incurred for their keep, while the value of their young will be of some importance to cottagers. The pigeon has a great power of flight, and will go to a distance of many miles in quest of the means of subsistence; but wherever it may fly, it never fails to return home. The leading features of the district around its habitation appear to be impressed on its memory; and flying at a great height, and with a wonderful power of vision, it sees the well-remembered landmarks, and directs its path homeward. This habit of seeking for the place at which it was reared, makes it difficult to keep pigeons in any new home; the best plan of inducing them to settle in a new abode is to clip one wing, which prevents their flying, and keep them in a cot near the ground till they get accustomed to the place.

Many persons keep their pigeons in the space between the garret and roof of their dwelling-house, with holes at which they go out and in; and this arrangement answers very well, for the animal's lodging must be dry and comfortable. A more regular plan is to furnish them with a properly-constructed dovecot, aloof from any building. The cot should consist of a substantial wooden box, with a sloping roof, and divided interiorly by partitions into as many cells as pairs are to be kept, for each pair requires a distinct cell. Each compartment should be twelve inches deep from front to back, and sixteen inches broad; the entrance hole should not be opposite the centre of the cell, but at a side, so that the pigeons may build their nest a little out of sight. In front of each cell there should be a slip of wood to rest and coo upon; but as different pairs incessantly quarrel about the right of walking on these slips, and are apt to fight for the possession of cells, it is best to separate the slips with upright partitions; and it would be an improvement to have two or three small cots instead of one large one. The cot, of whatever size or form, should be elevated on a wall facing the south-east, or otherwise placed at such a height as will be out of the reach of cats and other vermin. The cot should be painted white, as the pigeon is attracted by that colour. Gravel should be strewed on the ground in front of the dove-cot, the birds being fond of picking it; and a little straw or hay is necessary for the nests. Cleanliness is indispensable to the health of the birds, and a scouring out of the cot should therefore take place regularly. The quantity of dung produced in the nests is very great, and its removal to the compost heap will amply repay the trouble of cleaning.

In commencing to keep pigeons, a pair or two should be procured which have not flown, and they should be shut up for a time, and well fed. Their chief food is grain, and the kind which they prefer to all others is dried tares. Small horse-beans are another favourite article of diet, and very nutritious to them. Wheat, barley, oats, and peas, with rape, hemp, and canary-seeds, are also prized by them, but should not be made constant articles of food under any circumstances.

The house-dove or common pigeon, as is well known, begins to breed about the age of nine months, and breeds every month. During breeding time, they associate in pairs, and pay court to each other with their bills; the female lays two eggs, and the young ones that are produced are for the most part a male and female. When the eggs are laid, the female, in the space of fifteen days, not including the three days during which she is employed in laying, continues to hatch, relieved at intervals by the male. From three or four o'clock in the evening, till nine the next day, the female continues to sit; she is then relieved by the male, who takes his place from ten till three, while his mate is feeding abroad. In this manner they sit alternately till the young come out. Kept with ordinary care, a pair will give to the breeder nine pairs or so in a year, and will continue to do this for four years. The bird lives for eight years, but is useless for breeding long before attaining that age. On the whole, the cottager who keeps a few pairs may have a palatable addition to his diet frequently during the year with very little trouble or expense.

With regard to the best breeds of the common domesticated pigeon, it is difficult to give any useful instructions. They have been cultivated to a great extent, and many distinct varieties have been formed, but the differences rest chiefly in colours, and the special value of each lies in the taste of the *fancier*. The leading varieties of fancy pigeons are known by the names of the English Pouter, the Dutch Cropper, the Horseman, the Uploper, the Dragoon, the Tumbler, the Leghorn and Spanish Runt, the Trumpeter, the Nun, the Fan-tail, and the Capuchin. The peculiarities of some of these breeds are very odd. The tumbler, for instance, derives its name from a practice of tumbling in the air while on the wing. Instead of pursuing a steady straightforward flight, it turns over, or casts somersets backward, whirling round heels over head as expertly as a first-rate rope-dancer does when he makes the back spring. The fan-tail derives its name from the circumstance of its having a remarkably broad tail, which it has the power of spreading out like the tail of a turkey-cock. The prime quality of the bird consists in its ability to make its tail touch its head, and surround it with a wide glory of feathers. If it cannot do this, it is valueless to the fancier, no matter how excellent are its other properties. Amusing as this absurdity is, it is not so laughable as the qualities which recommend the English pouter to public favour. This bird, which is a cross between a horseman and a cropper, possesses the remarkable property of blowing out its breast or crop to such an extent, that it rises to a level with its beak, and the bird appears to look over the top of an inflated bladder.

Carrier-Pigeons.—Pigeons have been put to the remarkable purpose of acting as carriers for letters or other light objects. A particular species, larger than common, is trained for the purpose, and in some countries the rearing of them forms a lucrative employment. The instinct which has rendered the carrier-pigeon so serviceable, is the strong desire manifested by all pigeons to return to the place of its ordinary residence; and man has adopted various precautionary measures in order to make its return on particular occasions more certain. A male and female are usually kept together, and treated well; and one of these, when taken elsewhere, is supposed to have the greater inducement to come back. It is even considered necessary by some that the bird should have left eggs in the process of incubation, or unfledged young ones, at home, in order to make the return certain; but probably these are superfluous precautions. It is obvious that the carrier-pigeon can only be put to use in conformity with some contemplated plan, for which the proper preparations have been made. It must have been taken from a place to which it is wished that it should return, and it must, at the moment when its services are wanted, be temporarily at the place from which the intelligence is to be conveyed. It is usually taken to that place hoodwinked, or in a covered basket; the instinct by which it finds its way back upon its own wings must of course be independent of all knowledge of the intermediate localities. When the moment for employing it has arrived, the individual requiring its services writes a small billet upon thin paper, which is placed lengthwise under the wing, and fastened by a pin to one of the feathers, with some precautions to prevent the pin from pricking, and the paper from filling with air. On being released, the carrier ascends to a great height, takes one or two turns in the air, and then commences its forward career, at the rate of about forty miles an hour.

CAGE-BIRDS.

The birds usually domesticated in cages in Britain are canaries, siskins, goldfinches, bullfinches, larks, linnets, thrushes, blackbirds, starlings, and parrots. The only means by which these or any other species of birds can be reared and preserved in a healthy condition, is to accommodate each as far as possible with the food, space for exercise, and other conveniences which the animal would enjoy in a state of nature. The most difficult thing to afford is space: where a room or aviary can be fitted up with all requisite accommodations—perches to resemble trees and branches, grass, moss, and other plants, patches of gravel or sand, secluded places for nests, a trough of clear water, &c.—the birds will thrive, breed, and be cheerful; but such accommodations can rarely be afforded, unless in the mansions of the great; and the aviary, for the most part, is only a tiny cage, more or less ornamental, formed of wood and wires.

Placed in this state of confinement, no birds can possibly exist unless great care is bestowed in furnishing them with food and fresh water daily, keeping their habitation very clean, and placing them in a cheerful situation in a parlour, where they can enjoy the light. Birds that are produced in confinement are more contented than those who have known freedom; but the latter may be reconciled to this new state, and made to sing with their accustomed gaiety. A good plan of reconciling a newly-caught bird to the cage is said to be as follows:—For two or three hours leave it in tranquillity, and then plunge it into fresh water. This exhausts it; but on recovery, it arranges its feathers, becomes hungry, and takes at once to its food. The wetting, however, should take place only during sunshine, so that the feathers may be speedily dried.

The food of cage-birds is very various. 1. Canaries, goldfinches, and siskins, live only on seeds; 2. quails, larks, chaffinches, and bullfinches, feed on both seeds and insects; 3. nightingales, redbreasts, thrushes, and blackbirds, take berries and insects. Referring to these classes of birds, Bechstein observes—'Experience teaches me that a mixture of crushed canary, hemp, and rape-seed, is the favourite food of canaries; goldfinches and siskins prefer poppy-seed, and sometimes a little crushed hemp-seed; linnets and bullfinches like the rape-seed alone. It is better to soak it for the young chaffinches, bullfinches, and others; in order to do this, as much rape-seed as is wanted should be put into a jar, covered with water, and placed in a moderate heat, in winter near the fire, in summer in the sun. If this is done in the morning, after feeding the birds, the soaked seed will do for the next morning. All of them ought to have green food besides, as chickweed, cabbage-leaves, lettuce, endive, and water-cresses. Sand should be put in the bottom of the cages, as it seems necessary for digestion.

Amongst those of the second class, the quails like cheese and the crumbs of bread; the lark, barley-meal, with cabbage, chopped cress, poppy-seed mixed with bread crumbs, and in winter, oats; the chaffinches, rape-seed, and sometimes, in summer, a little crushed hemp-seed. Too much hemp-seed, however, is hurtful to birds, and should only be given as a delicacy now and then, for when they eat too much of it they become asthmatic, blind, and generally die of consumption. Yellow-hammers like the same food as the larks, without the vegetables; the tits like hemp-seed, pine-seed, bacon, meat, suet, bread, walnuts, almonds, and filberts.' The same author proceeds to describe two kinds of paste, simple and cheap, and which may be termed a universal food for birds.

'To make the first paste, take a white loaf which is well baked and stale, put it into fresh water, and leave it there until quite soaked through, then squeeze out the water and pour boiled milk over the loaf, adding about two-thirds of barley-meal with the bran well sifted out, or what is still better, wheat-meal; but as this is dearer, it may be done without.

For the second paste, grate a carrot very nicely (this root may be kept a whole year if buried in sand), then soak a small white loaf in fresh water, press the water out, and put it and the grated carrot into an earthen pan, add two handfuls of barley or wheat-meal, and mix the whole well together with a pestle.

These pastes should be made fresh every morning, as they soon become sour, particularly the first, and consequently hurtful. For this purpose I have a feeding-trough, round which there is room enough for half my birds. It is better to have it made of earthenware, stone, or delft ware, rather than of wood, as being more easily cleaned, and not so likely to cause the food to become stale.

The first paste agrees so well with all my birds, which are not more than thirty or forty, at liberty in the room, that they are always healthy, and preserve their feathers, so that they have no appearance of being prisoners. Those which live only on seeds or only on insects, eat this food with equal avidity; and chaffinches, linnets, goldfinches, siskins, canaries, fauvettes, redbreasts, all species of larks, quails, yellow-hammers, buntings, blue-breasts, and red-starts, may be seen eating out of the same dish. Sometimes, as a delicacy, they may be given a little hemp, poppy, and rape-seed, crumbs of bread, and ants' eggs. One of these is necessary for the birds of the third and fourth class.

Every morning fresh water must be given to the birds, both for drinking and bathing. When a great many are left at liberty, one dish will do for them all, about eight inches long and two in depth and width, divided into several partitions, by which means they are prevented from plunging entirely into the water, and in consequence making the place always dirty and damp. A vessel of the same size and shape will do for holding the universal paste, but then it must have no partitions. Quails and larks require sand, which does for them instead of water for bathing.

Some birds swallow directly whatever is thrown to them: great care must be taken to avoid giving them anything with pepper on it, or bad meat. This must be a general rule. I shall also remark, that food sufficient for one day only must be given to birds kept in cages, for they are accustomed to scatter it about, picking out the best, and leaving only the worst for the next morning; this makes them pine, and puts them out of humour.'

Canaries—Siskins.

Canaries are the chief pets of the parlour, and the method of treating them requires to be given at some length. Being originally from a warm climate, they are tender, and must be kept in rooms of an agreeable temperature; if exposed to cold either in rooms or the open air, they pine and die. In dry weather in summer, their cage should be hung in the open air, or at least in the sunshine. If the apartment is kept too hot, they will moult at an improper season, and this must be avoided. Only one male should be allowed in a cage. Females for breeding are the better for having a large cage, as it affords them space for exercise. The greatest care must be taken to clean the cage, of whatever dimensions, and to scatter a little fine sand on the bottom of it. Each should be provided with three cross-sticks as perches, a small glass trough for water fixed outside at the extremity of one of the sticks. The water must be changed daily, or even more frequently.

Some persons, from mistaken kindness, offer pieces of rich cake and other inappropriate food to canaries, and the little creatures being fond of these things, they do themselves a great injury by eating of them. A canary in high song will at once be rendered mute by partaking of any improper food of this sort. As already mentioned, the food must be of a simple and natural kind; besides the seeds and other things described, they should be supplied daily with a little green vegetables; such as chickweed in spring, lettuce and radish leaves in summer, endive, water-cress, and slices of sweet apple in winter. As they like to wash their feathers, a cup of fresh water may be placed in the cage daily. In the moulting season, it is recommended to put a nail into the water they drink, in order to strengthen the system by the slight infusion of iron matter.

The breeding of canaries requires additional accommodations. The breeder must have a large cage, into which the pair of birds is put about the middle of April. At the upper part of the cage, at one end, boxes for the nests are placed, with holes to go out and in by; and in the centre of the cage, near a perch, a net-work bag is hung filled with cotton, wool, moss, hair, and other soft materials, for the birds to use for their nests. The female only builds; and in about ten days after pairing, she lays the first egg. She ordinarily lays six eggs, one every day; but each egg is to be taken away as laid, leaving an ivory one only; and when done laying, replace all the six. The period of incubation is thirteen days. When the young are hatched, finely-minced egg and bread should be placed near the feeding-trough, to enable the parents to carry suitable food to their young. Canaries will mate with siskins, linnets, several of the finches, and other allied birds, producing in many instances highly-esteemed mules.

The system of treatment now described is also well adapted for the Siskin, of which there are several varieties, as the black, white, and speckled. This bird, which is somewhat smaller than the canary, is of a handsome shape, lively, and intelligent. In a wild state, it is found throughout Europe, particularly in Germany and the central districts. In the house, whether caged or not, it soon becomes familiar, and may be taught to perform many tricks and amusing operations. It is a sweet and busy songster, with notes fully more varied and less piercing than those of the canary. It pairs readily with the canary, particularly the green variety, the produce being a prettily-spotted mule, partaking of the qualities of both parents. Being naturally very lively, the siskin does not take with too close confinement; it requires also more food (poppy or hemp-seed, and the first universal paste described) than the canary, and not less water, though it is not quite so fond of bathing.

Linnets—Finches—Larks.

The species of these birds which thrive in confinement are too well known to require description. In a wild state, the Linnets are scattered over all Europe; in summer frequenting the skirts of large forests, thickets, hedges, and bushes, particularly furze; but as soon as September arrives, they pass in large flights to the open fields. In confinement, it is best to keep them in square cages, as they are less subject to giddiness in these than in round ones, and sing better. On the whole, it has been found better to keep linnets pretty closely to the cage, as they are not naturally of a very lively or roaming disposition. In the wild state, their food consists of all kinds of seeds which they can shell; and in confinement, summer rape-seed has been found to agree with them well. If allowed the liberty of the room, the common universal paste may be given, along with green vegetables, plenty of water, and sand for dusting. Most of the linnets are naturally slow and indolent, and are therefore apt to become too fat if fed abundantly.—The Finches are also well known, being found in all parts of Europe, frequenting orchards, brambles, thickets, and mountainous districts, interspersed with woods and fields. They are greedy devourers of all kinds of small seeds, and are, on the whole, healthy and hardy birds. The most common cage species are the goldfinch and bullfinch—both, however, more esteemed for their beauty and docility than for the sweetness or variety of their notes. A square cage is recommended by Bechstein as better suited to the habits of the birds; and as to food—poppy, hemp, lettuce, rape, and canary-seed, either pure or in mixture, are found to agree with them. The common paste, chickweed, lettuce leaves, endive, and the like, are occasionally beneficial as alteratives or correctives.—Of the Larks, which are all somewhat delicate, and difficult to rear in confinement, the common field or skylark is that most frequently to be found in the cage of the bird-fancier. In a wild state, the skylark is found all over the world, frequenting fields and meadows, and by preference plains. 'In rooms,' says the authority above quoted, 'it is usual to let it hop about; it is, however, also kept in cages, where it sings best. Whatever form may be given to these cages, they must be at least 18 inches long, 9 wide, and 15 high: the bottom should have a drawer, in which enough of river sand should be kept for this scratching bird to be able to roll and dust itself conveniently. It is also a good plan to have in a corner a little square of fresh turf, which is as beneficial as it is agreeable. The top of the cage must be of linen, since, from its tendency to rise for flight, it would run the risk of wounding its head against a covering of wood or iron wire, especially before it is well tamed. The vessels for food and drink must be outside, or, which I prefer, a drawer for the food may be introduced in the side of the cage: sticks are not necessary, as the lark does not perch. When it is allowed to hop free in a room, the latter must be very clean and neat, otherwise a thread or hair may entangle the feet, and if not removed, it easily cuts the skin, maims the bird, and the entangled toes shrink and fall off. When wild, the food consists of insects, especially ants' eggs, also of all kinds of seeds, and in autumn of oats, which these birds skin by striking them against the ground. In the spring, the sprouting seeds and young buds, also the blades of young grass, are eaten, and grains of sand to help digestion. In the house, if the lark is hopping about, nothing is better than the first universal paste described; but if caged, the second will suit it better. Poppy-seed, bruised hemp, crumbs of bread, and plenty of greens, as lettuce, endive, cabbage, or water-cress, according to the season, must be added. A little lean meat and ants' eggs are favourite delicacies, which make the bird gay, and more inclined to sing.'

Blackbirds—Thrushes—Starlings.

The male Blackbird is a handsome creature, lively in manner, and possessing some sweet 'wood-notes wild,' which sound most agreeably from a garden or the outside of a window. The bird requires a large wicker cage, which, whenever weather permits, ought to be hung in the open air. In a state of nature, the blackbird eats berries, seeds, insects, larvæ, and worms. It loves to run about a grass plot, in the spring mornings, and pick up any stray worm which is straggling from its hole. This habit suggests the propriety of giving it, when in confinement, both vegetable and animal food. The universal paste will answer; but if too heating, which it is liable to be, give bits of bread, flies, cockchaffers, worms; and failing these, chopped raw meat. A rough bone from the table will also not be inappropriate. A short experience will show upon which kinds of food the creature thrives best, and let that be adhered to. Give also plenty of pure water to drink; and once a week, when the sun shines, set a basin of water in the cage for it to bathe in and clean itself. Let the cage be carefully and regularly cleaned.

Belonging to the same family are the Thrushes, of which the song-thrush is the smallest and most attractive. It is found all over Europe, frequenting woods near streams and meadows, and is naturally somewhat shy and timid. In confinement, it may be lodged and treated like the blackbird, though less luxuriously. When wild, it lives on insects and berries; and in the cage, the two common pastes, oatmeal moistened with milk or water, or even bran moistened with water, have been found to answer. It also requires a great deal of water for bathing and drinking; but is much more cleanly than the blackbird. It is an excellent songster, but takes less kindly to the cage than the blackbird, and is not so easily taught any artificial note.—The Starling, another of our cage favourites, is found all over the world, but is not so easily reared as found. It is by no means cleanly, and requires to be kept in the cage, which should be particularly large and roomy. In a wild state, insects, grains, and berries, are devoured indiscriminately; in confinement, starlings eat minced meat, worms, bread, the universal paste, indeed any food, provided it be not sour. If well treated, the starling soon becomes exceedingly familiar, and may be taught to whistle various airs, and pronounce words and short sentences with accuracy. For these ends no cutting or slitting of the tongue is requisite—an operation as stupid and unnecessary, as it is cruel and barbarous.

Parrots.

Under this head may be classed a number of beaked birds of similar character, as parrots, parroquets, cockatoos, and maccaws, all possessing beautiful plumage of green, crimson, yellow, or grayish tints. They are chiefly from South America, and require the warmth of a dwelling-house to keep them alive in this country. All possess harsh voices, and would on that account be considered a positive nuisance by most persons, except for the oddity of their being able to repeat certain words; but this is a quality possessed by some in greater perfection than others. Each species of these birds may be treated much in the same manner. They are allowed a large cage, formed of strong wires, with thick round bars to perch upon, and a ring at top to swing from by their hooked beak. All the parts must be of tin, for they would soon peck wood to pieces. In Zoological Gardens, they are usually seen perched on a cross-bar of tin at the top of a staff, but chained by the leg to prevent their escape; but this method is not so favourable for their climbing, swinging, and grotesque manœuvres as a large roomy cage.

The food offered to parrots, maccaws, &c. is chiefly bread steeped in milk, nuts, or any other simple article. Care must be taken never to give them anything with salt or pepper. On the subject of feeding them, Bechstein makes the following observations:—'In its native country, the fruit of the palm-tree is its principal food; our fruit it also likes, but white bread soaked in milk agrees with it better; biscuit does not hurt it; but meat, sweetmeats, and other niceties, are very injurious; and though at first it does not appear to be injured, it becomes unhealthy, its feathers stand up separate, it pecks and tears them, above all those on the first joint of the pinion, and it even makes holes in different parts of its body. It drinks little; this is perhaps occasioned by its eating nothing dry. Many bird-fanciers say that the best food for parrots is simply the crumbs of white bread, well baked, without salt, soaked in water, and then slightly squeezed in the hand. But though this appears to agree with them pretty well, it is, however, certain that now and then something else ought to be added. I have observed, indeed, that parrots which are thus fed are very thin, have hardly strength to bear moulting, and sometimes even do not moult at all; in that case they become asthmatic, and die of consumption. It is clear that feeding them only on this food, which has very little, if any, moisture in it, is not sufficient to nourish them properly, at least during the moulting season, and while the feathers are growing again. I never saw a parrot in better health than one which belonged to a lady, who fed it on white bread soaked in boiled milk, having more milk than the bread would absorb, which the parrot drank with apparent pleasure; there was also put into the drawer of its cage some sea biscuit, or white bread soaked in boiling water; it was also given fruit when in season. It is necessary to be careful that the milk be not sour.

Some young maccaws are fed on hemp-seed, which must always be of the year before, as the new would be too warm and dangerous. Yet they must not be fed entirely on this food, but there must be added white bread soaked in milk or water, as has already been mentioned, some fruit and nuts, but never bitter almonds, as they will infallibly kill all young animals. In all cases the excrements of the birds will indicate the state of their health, and whether the food ought to be changed or not. Although maccaws rarely want to drink, as their food is very moist, yet they must not be left without water, which is generally placed in one of the divisions of their tin drawer. It is also a good thing to entice them to bathe; nothing is more favourable to their health, or better facilitates the painful operation of moulting, or keeps their feathers in better order. A little attention to these favourites—deprived of their liberty, their natural climate, and food—cannot be too much trouble to amiable persons who are fond of them, and to whom these pretty birds soon become greatly attached.'

The cockatoo is generally esteemed as of milder temper than the parrot. Of this species, Buffon observes—'Cockatoos, which may be known by their tuft, are not easily taught to speak; and there is one species which does not speak at all; but this is in some measure compensated for by the great facility with which they are tamed; in some parts of India they are even so far domesticated that they will build their nests on the roofs of the houses: this facility of education is owing to their intelligence, which is very superior to that of other parrots. They listen, understand, and obey; but it is in vain that they make the same efforts to repeat what is said to them; they seem to wish to make up for it by other expressions of feeling and by affectionate caresses. There is a mildness and grace in all their movements, which greatly add to their beauty. In March 1775, there were two, a male and female, at the fair of St Germain in Paris, which obeyed with great docility the orders given them, either to spread out their tuft, or salute people with a bend of the head, or to touch different objects with their beak and tongue, or to reply to questions from their master with a mark of assent, which clearly expressed a silent *yes*; they also showed by repeated signs the number of persons in the room, the hour of day, the colour of clothes, &c.; they kissed one another by touching their beaks, and even caressed each other; this showed a wish to pair, and the master affirms that they often do so even in our climates. Though the cockatoos, like other parrots, use their bill in ascending and descending, yet they have not their heavy disagreeable step; on the contrary, they are very active, and hop about very nimbly.' For ornamental pets, parroquets—many of which are not much larger than the common house-sparrow—are now very generally preferred; and though not quite so showy in plumage as the maccaws, lories, and cockatoos, yet their tints are often extremely beautiful, and they never become offensive by screaming, which is too often the case with their larger congeners.

THE HONEY-BEE.

The subject of Bees, which is equally extensive and interesting, has for many ages attracted the attention of mankind. The Sacred Writings, the most ancient of which we have any knowledge, show in numerous places how strongly the fathers of the Jewish people had been impressed by the peculiarities in the natural history of the Bee; and we know that Aristotle and other philosophers of old Greece deemed the subject worthy of years of patient investigation. Virgil, also, and many other Roman authors, dwelt on it with enthusiasm in their writings; while, in much later times, Swammerdam and other distinguished cultivators of science have pursued the same track with undiminished ardour. The most zealous of these inquirers was Francis Huber (born at Geneva 1750, died 1831), who, though labouring under the deprivation of sight, by the aid of his wife formed a most valuable collection of observations on the habits of bees, and to whose work —as yet the best of its kind—we shall have frequent occasion to refer. Societies have also been formed for the sole purpose of investigating this portion of natural history. A mere summary of the interesting essays, therefore, which this insect, so universally appreciated, has called forth, would occupy a very large space. On the present occasion, an attempt can only be made to cull from the most approved sources such details as may form a complete history of the Honey-Bee, though at the same time it must necessarily be a concise one, along with directions for the practical management of this most useful insect.

Bees are arranged by zoologists into the family of the *Apidæ* (*apis*, a bee), in the order *Hymenoptera* (having four unequal membranaceous wings) of the insect class. The Social Bees form the principal division of the family, their type being the *Apis mellifica*, the Honey-making, or, in common phrase, the Honey-Bee. It is so called not from an exclusive peculiarity, but because it is the species which has long yielded to man the rich product indicated in its name. As the observations to follow will have reference to the Honey-Bee, it may simply be mentioned that the description of this species involves the leading features in the natural history of its less important congeners, the Wild or Humble Bees. (See Zoology, p. 168.)

ANATOMY AND PHYSIOLOGY.

Of the family of the Social Bees, two species seem to exist in Europe, the one found in the north, and the other in the south; but, making allowance for a slight deepening of tint from brown to red in the rings of the body in the case of the more southerly insect, the description of the common hive-bee of Britain will apply to the other in all important respects. A hive of honey or garden-bees contains three ranks or sexes of inhabitants, the external characters of which differ considerably, while their uses and functions in the community are most obviously distinct. The most important, and by far the most numerous rank, is that of the *workers*, or working-bees, formerly regarded as neuters in respect of sex, but now more properly considered as undeveloped females. The second rank is composed of the males of the hive, termed the *drones*. There is usually but one perfect member of the third sex present at a time in a hive, and this is the *queen*, or mother-bee, the sole female of the community.

Workers.

The working honey-bee has a body about half an inch in length, blackish-brown in hue, and covered with close-set hairs, which are feather-shaped, and assist the creature materially in collecting the farina of flowers. The *head*, which is a flattened triangle in shape, is attached to the chest by a thin ligament; and the chest or *thorax*, which is of a spherical form, is united in a similar way to the *abdomen* (see No. 11). The abdomen is divided into six scaly rings, which shorten the body by slipping over one another to a certain extent. These three external divisions of the insect's body have all of them appendages of peculiar interest and utility. The head is provided with a double visual apparatus. In front are placed two *eyes*, consisting each of numerous hexagonal plates, studded with hairs, to ward off the dust or pollen of flowers; and three small eyes are also to be found on the very top of the head, intended, doubtless, both to heighten the general sense of seeing, which the creature so peculiarly requires, and to give a defensive vision upwards from the cups of flowers. The *antennæ*, however, which are two slender tubes springing from betwixt the front eyes, and curving outwards from each side, most probably fulfil many of the purposes of vision in the dark interior of the hive. These instruments have each of them twelve articulations, and terminate in a knob, gifted with the most delicate sensitiveness. By the flexibility of the antennæ, the bee is enabled to feel and grasp any object in its way; and there can be little doubt that it is chiefly by means of these it builds its combs, feeds the young, fills the honey-cells, and performs the other operations of the hive. Bees also use these appendages for the recognition of one another.

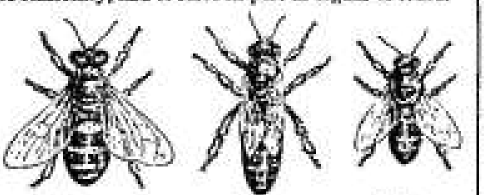
The mouth of the bee is a very complex structure, and one wonderfully fitted for its duties. Its most important parts are the *mandibles*, the *tongue*, the *proboscis*, and *labial feelers*. The mandibles are merely the two sides of the upper jaw, split vertically, and movable to such a degree as to enable the insect to break down food betwixt them, to manipulate wax, and use them otherwise as serviceable tools. They are furnished with teeth at their ends, two in number. The tongue of the bee is extremely small, and indeed is scarcely admitted by some naturalists to exist at all, the proboscis being often signified by that name. Many of the usual functions of such an instrument are indeed performed by the proboscis, a long slender projection, composed of about forty cartilaginous rings, fringed with fine hairs. From the base of this, on each side, rise the labial feelers, instruments also fringed or feathered interiorly; and outside of these are the lower jaws, similarly provided with hairs. When the feelers and jaws close in on the proboscis, they form a sheath or defence to it. Naturalists used to term the proboscis a tube; but they now know that it acts by rolling about and lapping up, by means of the fringes around it, everything to which it is applied. The gathered material is then conveyed into the gullet at its base, whence it passes into the internal organs. Thus we find the mandibles of the upper jaw ready to break and prepare the food for the sweeping-up apparatus of the lower parts. While perfect in action in an expanded state, the whole, moreover, can be so folded or coiled together, as to form one strong well-protected instrument.

To the trunk or thorax of the bee exteriorly are attached the muscles of the wings and legs. The wings consist of two pairs of unequal size, which are hooked to one another, in order to act in concord and steady the movements in flying. The bee has three pairs of legs, of which the anterior pair are the shortest, and the posterior the longest. All of them are formed upon the same principle as the limbs of man, having articulations for the thigh, leg, and foot, with some minor joints in the latter part. The hind-legs are marked by a special and beautiful provision: this is a cup-like cavity on the *tibia* or fore-leg, intended for the important purpose of receiving the kneaded pollen which the bee collects in its wanderings. The legs are all thickly studded with hairs, and more particularly the cavity mentioned, in which the materials require to be retained securely. Another provision of the bee's limbs consists in a pair of hooks attached to each foot, by means of which the animal suspends itself from the roof of the hive or any similar position. Beneath or behind the wings, the *spiracles* or air-openings are found, which admit air for the purpose of permeating the chest, and probably the whole body, for the oxygenation of the circulating system. Huber completely proved both that respiration is essentially necessary to bees, and that the spiracles are the instruments by which it is effected. He found that they die in an exhausted receiver, and become asphyxiated when shut up in numbers in close bottles. They perish in water only if the spiracles are under the surface; and the use of these apertures is then made apparent by the bubbles which escape from them under water. As will be shown, also, bees carefully ventilate their hives. Therefore, though no blood has been detected in bees or other insects, these tiny spiracles are of no slight consequence in the physical economy of the insect, oxygen being apparently not less necessary to the vitality of its circulating fluids than to those of warm-blooded animals.

Besides these appendages and contents of the chest, that region is traversed by the *œsophagus* or gullet, on its way to the digestive and other organs situated in the abdomen. These organs consist of the *honey-bag*, the *stomach*, the *wax-pockets*, and the *intestines*, with the *venom-bag* and *sting*. The honey-bag, sometimes called the first stomach, though digestion never takes place there, is an enlargement of the gullet into a pea-sized bag, pointed in front, with two pouches behind. In this receptacle is lodged the fluid or saccharine portion of the bee's gatherings, and by the muscularity of the coats it can be regurgitated to fill the honey-cells of the hive. A short passage leads to the second or true stomach, which receives the food for the nourishment of the bee, and also the saccharine matter from which the wax is secreted. The small intestines receive the digested food from the stomach, and from them it appears to be absorbed for the purposes of nutrition. Wax, it was once thought, was pollen elaborated in the stomach and ejected by the mouth; but it is entirely derived, it is now known, from the honey or saccharine matter consumed by the insect; and John Hunter discovered two small pouches in the lower part of the abdomen, from vessels on the surface of which it is secreted. After accumulating for a time in these pouches, scales of it appear externally below one or other of the four medial rings of the abdomen, and are withdrawn by the bee itself or those around it. Close to the stomach is found the last important organ of the abdomen, the sting. Much beautiful mechanism is observed on a microscopical examination of this weapon, so powerful in comparison to its bulk. It consists of two long darts, adhering longitudinally, and strongly protected by one principal sheath. This sheath is supposed to be first thrust out in stinging; and its power to pierce may be conjectured from the fact that, when viewed through a glass which magnifies a fine needle-point to the breadth of a quarter of an inch, the extremity of the sheath ends so finely as to be invisible. The sheath once inserted, then the two still finer darts follow, and make a further puncture. The use of this is to receive the poison, which is conducted to the end of the sheath in a groove; and in order that the conjoined darts may not be withdrawn too soon for this purpose, they have each nine or ten barbs at the point to retain them. When the weapon is withdrawn, the poison is thus left with a cavity to enter, causing a deeper festering. The insect ejects the poison by means of a muscle encircling the bag at the base of the sting, in which bag the venom is secreted. The chemical composition of the poison has not been discovered, though it has so far the nature of an acid as to redden the vegetable blues. Altogether, Paley, in his 'Natural Theology,' is fully justified in pointing to the defensive weapon of the bee as a wondrous union of mechanical and chemical perfection.

The manner in which the bee collects the food which forms the various secretions alluded to, is worthy of note. The hairs with which its body and feet are covered, are the main instruments used for this end. By means of the hairs on the feet, the insect usually begins its collection of the pollen in the corolla which it has entered, and after kneading the dust into balls, finally places it in the baskets of the hind-legs. But the creature is not content with the product of this process. Rolling its body round and round, it brushes off the pollen still more cleanly, gathers it into two heaps with its active brushes, and loads its baskets to the brim. Even afterwards, they sometimes fly home like dusty millers, and brush their jackets when unloaded. The pollen is understood to be brought home by the working-bees more peculiarly as food for the young. The fluid secretions contained in the nectaries of flowers, and honey-dew, which is a deposition of certain aphides on plants, serve as other natural varieties of the bee's food. The insect is also at certain periods a liberal drinker of water.

The senses of bees have been in part touched upon already. The means of vision bestowed on them, it was mentioned, consist of the many-lensed eyes in front, and the supplementary organ above. Inquirers have been staggered by the seeming contradictions connected with the vision of the bee. After collecting its store of food, its first movement is to rise aloft in the air, and look for the site of its home. Having determined this in an instant, however distant the hive may be, it goes for the point with the directness of a cannon-ball, and usually alights at its own door, though the whole country be crowded with hives. Yet if the hive, or its door, has been shifted to a slight extent, the insect seems confused, and cannot find its way. The conclusion from this is, that the eyes of the bee have a lengthened focus, suiting them for the main purposes of its existence. But the consequent inability to determine accurately on short distances has been compensated to the creature by the antennæ, which then become a highly serviceable resource. The sense of *taste* in bees has been the subject of much argumentation. Huber was of opinion that it was the most imperfect of their senses, and they have been observed to resort to putrid marshes for water, even when they were not restricted in their choice. Xenophon found his men seriously injured by taking honey produced by bees which had fed on deleterious plants. But, on the other hand, it has been noticed that they reject many substances, and prefer others, when a choice is allowed them; and it has been conjectured that they go to marshes purposely for the salt in their waters. Moreover, what renders the honey deleterious to man, may not be hurtful to bees. Honey formed from a particular flower in the Jerseys, was found unfit for use from its intoxicating qualities; yet the bees throve wonderfully upon it all the while. Their taste in selecting the richest flowers is likewise unquestionable. No doubt the sense of *smell* comes into operation on these occasions, as well as the sense of taste. Betwixt the influence and effects of the two, indeed, it is scarcely possible to discriminate. Even in the case of the human being, it is an established fact, that the powers commonly ascribed to the sense of taste are to a remarkable degree dependent on the sense of smell. If the eyes be bandaged, and the apertures of the nose well shut up, the most experienced judge will be at a loss to determine between any two kinds of ardent spirits, or other pungent substances. The most nauseous medicines, also, much as they may usually seem to affect the taste, will be found almost insipid if the site of the sense of smell be closed up while they are swallowed. In bees, the site of the two senses seems to be almost one and the same. Many experiments of Huber seem to prove that the sense of smell lies in the mouth, and that it is very acute. He found that they hate the odour of turpentine, yet on plugging up the mouth, they showed no disgust when placed beside that liquid. He concealed honey at considerable distances, and they in a very short time detected the hidden treasure. The acuteness of their sense of smell, in truth, is sufficiently proved by their admirable skill in tracking out, over hill and dale, the most fragrant flower-parterres and beds of mountain heath. The sense of *hearing* has been denied to bees by many observers, while others describe the antennæ as their organs of hearing. The probabilities are in favour of the latter position. Noise, produced by the wings, and varied to suit particular purposes, is well known to be used as a mean of inter-communication; and Huber, though doubtful about the faculty, avers that by a particular sound, emitted from the mouth apparently, the queen will render the whole hive silent and motionless in one instant. A certain sound, too, heard in the hive before swarming, is always followed by definite consequences. Such facts as these go far to establish the possession of hearing by bees; as signals by sound, made when the eyes could not detect the movement attending their production, would otherwise be valueless. The antennæ have been mentioned as possessed, if not of hearing, at least of a delicate sense of *touch*. Huber points out a moonlight night as the best time for observing the uses of the antennæ in this respect. The bees, guarding against the intrusion of moths, have not light enough to see fully, and they circumambulate their door with the antennæ stretched right before them. The instant a moth is felt, it is destroyed. When the queen of a hive is lost, the antennæ form a curious means of spreading intelligence. Bee after bee protrudes its antennæ, and crossing them with those of his next neighbour, disseminates in this way the sad news over the hive. Besides the antennæ, the feelers have been shown by experiment to possess a considerable degree of sensibility, and to serve in part as organs of touch.



Drone. Queen. Worker.

Such are the anatomical and physiological characteristics of the common or working-bee. The duties of this order include almost the whole business of the bee community, as will be shown afterwards in detail. Hives differ greatly, of course, in the number of their inmates, taking them even at the same season. Some contain but a few thousands; others from twenty to thirty, forty, and even fifty thousand. Of these the drones compose but a thirtieth part, or little more; all the rest, with the exception of the queen, are workers.

Drones or Males.

The drones differ considerably in outward appearance from the workers. They are bulkier and flatter in body, with a round head, a shorter proboscis, and antennæ with an additional articulation; they have no basket-cavity on their hind-legs, and their abdomen contains the means of secreting neither honey, wax, nor poison, while the reproductive organs are there found instead. They are called drones, from the peculiarly loud noise which they make with their wings. It has been already stated that the drones are the males of the hive. They live but for the reproduction of the race, and when the object of their existence is accomplished, they are doomed to die. The workers, who have their own winter food and that of the coming young to provide, instinctively pass sentence of death at the fitting time; despatch the defenceless males with their stings, and cast them forth from the hives, in which, from their size and voracity, their presence has now become a positive evil. With these exceptions, the description given of the worker-bee applies also to the drone.

Queen-Bees.

The queen-bee is of larger size than either the drone or the worker. She has an elongated body, blackish above, and tinted with yellow inferiorly, while the presence of two ovaries or egg-receptacles in the abdomen, demonstrate her sex. She has also a sting, considerably bent. The Germans call the queen the *mother-bee;* and this is the most appropriate name, since her functions are those of a parent rather than a potentate. Her sole province is to lay the eggs, from which issue those annual multitudes that perpetuate the race in new communities. The progress of all kinds of bees, from the larva state to maturity, will fall to be described in an ensuing section; but it may in the meantime be observed, that the queen usually commences laying eggs on the fifth day after she has assumed the perfect state, and often continues without intermission from early spring to the end of September, laying in the warmest season about two hundred eggs a day. Such are the distinguishing characteristics and functions of the mother-bee.

We propose now to give an account of the natural and regular operations of a colony of bees, from the moment of their introduction to an unfurnished habitation, to the establishment of a perfect hive.

NATURAL ECONOMY OF THE HIVE.

The breeding of young bees commences in February, and a hive, however thinned by the previous winter, becomes, under ordinarily favourable circumstances, crowded to excess in midsummer. Besides the developed bees, it abounds in eggs and young ones not matured. That fine instinct which, in the case of bees, occasionally prompts to acts almost above the power of reason, relieves this crowded state of things. The queen-bee, the proper mother of at least the great body of the hive, resolves upon departure with a swarm. The phenomena attending that departure will be noticed under a separate section; in the meantime, let it be supposed that the queen has led off a colony, and that, by the care of the owner of the bees, the swarm is lodged in a new and empty hive.

The first object of the community is to clean out their new lodging thoroughly, if they find this not done beforehand. The next great object is to block up all the chinks of the hive, smooth its projecting parts, and lay a stable foundation for the future works of the interior. Besides the wax which they use so extensively in their architecture, bees also employ, particularly at first, a remarkable substance called *propolis*, from the Greek words *pro* and *polis* (before the city), as indicating its use on the superficial parts of the hive. Propolis is a grayish-brown resin, of an aromatic odour, and better fitted by its tenacity for cementing than wax. Huber first showed distinctly that the bees gather this from the poplar, alder, birch, and willow trees, but more especially from the first of these trees. The ingenious naturalist alluded to, suspecting Reaumur to be wrong in referring the propolis to the pine, placed near his hives some wild-poplar branches, which the bees soon discovered, and flocked to in great numbers. In the heat of the day, when the viscous matter is ductile, it is thus carried off by the insect. A small thready portion is detached, kneaded with the mandibles, and then, by means of the fore-feet, placed in the basket of the hind-legs, a smart pat or two being given to secure it there. Another portion, similarly kneaded to make it portable, and a little drier, is basketed in the same way, till as much is procured as the insect can carry. Sometimes the patient creature will spend half an hour in the mere kneading of a portion of propolis; and occasionally other bees will come behind and rob the little labourer of its whole load, for a succession of times, without eliciting the slightest symptom of impatience. When a bee reaches the hive with its load, the propolis adheres so firmly, that the insect has to present its limbs to the workers in the hive, who detach it, and immediately use it, while yet ductile, to fill all the crevices of the hive, and smooth the projecting parts, so as to prevent hurts being received in the dark. Another remarkable use is made of the propolis. From the hour of their entrance into the hive, bees are liable to the intrusion of other creatures. A fly they can soon remove, but what are they to do with a snail? They can sting it to death, to be sure, in an instant, but their puny strength is totally insufficient to remove the carcass. In this dilemma, they completely obviate the disagreeable effects of the presence of a large putrefying body, by covering it with propolis, which hardens over the mass, and gives them a pleasant aroma in place of a fetid odour. With the propolis, moreover, they often narrow the entrance to the hive, forming a secure barrier, when they have reason to dread the intrusion of the death's-head moth, their great enemy in some countries.

In the meantime, while some workers are using the propolis for the purposes first stated, others are commencing the preparation of the cells or combs. The propolis is employed to attach these to the edges of the hive, but wax is the component material of the cells themselves. We shall find, in noticing the after-arrangements of the completed hive, that the working-bees are naturally divided into two great classes; but at the outset of their labours, when the cells are being constructed, they form *three* sections, each of which pursues its allotted toil with admirable order and regularity. One section produces the material for the combs, and forms it roughly into cells; the second division follows the first, examines and adjusts the angles, removes all the superfluous wax, and perfects the work; while the third band passes continually out and in, seeking and bringing provisions, chiefly pollen, for the second section, which never quits the hive. The first class flies abroad at intervals, it being necessary that they should have rich saccharine food for the secretion of the wax. As the secretion goes on best in a state of repose, bands of the wax-producers, after feeding fully, suspend themselves in clusters from the roof, each hanging from the hind-legs of the one above, till the wax-scales are formed, and they are prepared to take up the work. This clustering occurs on the very entrance of a swarm into a hive, when a seeming inactivity of several hours takes place, till the production of wax is set a-going. It will be seen that the second section, the architects proper, have the most unremitting toil to perform. They never quit it when once begun, excepting to turn to the little waiters of the third section, and indicate their hunger by holding out their trunk, when the caterer either spirts out a drop or two of honey, or furnishes pollen from the stores brought in.

Cells.

But if the labour of the architect class be severe, their work, when complete, is a marvel of instinctive ingenuity. Bees always begin their work, in ordinary circumstances, at the ceiling, suspending their structures from it. Their combs, or clusters of cells, are arranged in vertical and parallel plates, with a space of about half an inch betwixt contiguous pairs; and each comb is nearly an inch in thickness. At the outset, when one wax-making bee leaves the suspended cluster alluded to, and lays the foundation of a cell, others follow in rapid succession, not only adding their wax to that of the first, but soon commencing new combs, one on each side; and so the work goes on, in most cases, until the whole roof is covered with foundations. The architects proper, also, are meanwhile at their finishing work. They have, says Reaumur, to solve this difficult geometrical problem: 'A quantity of wax being given, to form of it similar and equal cells of a determinate capacity, but of the largest size in proportion to the matter employed, and disposed in such a manner as to occupy the least possible space in the hive.' Wonderful to reflect upon, this problem is solved by bees in all its conditions, in their construction of hexagonal or *six-sided* cells. The square and the equilateral triangle are the only other two figures of cells which could make them all equal and similar without interstices. But cells of those figures would have either consumed more material or have been weaker; and they would also have consumed more space, being less adapted to the form of the bee. In short, the hexagonal form combines all the requisites of economy and capacity. Another wonderful arrangement is seen in the construction of the bottoms of the cells. Each of these is composed of three rhombs, or plates of wax in the shape of card-diamonds, disposed in such a manner as to form a hollow pyramid, the apex of which forms the angles of the bases of three cells on the opposite side, giving to each of them one of the three diamond-shaped plates which is required to form their bases. Now, the three rhombs, composing each cell-bottom, have the two obtuse angles each of 110 degrees, and consequently, each of the two acute angles of 70 degrees. Koenig, on being desired by Reaumur to calculate the exact angle which would give the greatest economy of wax in a cell of such capacity, found that the angle should be 109 degrees 26 minutes, or 110 degrees nearly. Other geometricians have arrived at similar conclusions. The problem is one of great difficulty, yet the bee practically solves it at once, under the guidance of the Great Geometrician who made both the bee and the law on which it proceeds. Attempts have been made to ascribe the form of the cells to the peculiar shape of the head of the bee, and the instruments which it employs; but all such explanations have been found liable to insuperable objections.

The cells of the bee are extremely delicate, two or three plates or sides being of the consistence only of a common leaf of paper. They are made strong, however, by mutual support and other means. Besides a sort of froth which the insect mixes with the wax, the cells, at first of a dull white, soon appear yellow on the interior, the change arising from the plastering over them of a compound varnish of wax and propolis. Each cell is soldered, too, at its mouth by a similar compound of a reddish colour, having in it more propolis; and threads of the same substance are laid around the walls, to bind and strengthen them. It is now to be observed that all cells are not alike. They have four different uses in the economy of the hive, and are constructed variously to suit these. One set of cells is for holding the eggs or embryos of worker-bees; a second for those of males or drones; a third for those of young queens, hence called royal cells; and a fourth set are for the reception of honey and pollen. The first are generally about five lines in depth (or less than half an inch), and two lines and two-fifths in diameter. The cells of the young males are much less numerous, and measure from six to seven lines in depth, by three and a half in diameter. It is worthy of note, that in passing from the construction of worker-cells to those of drones, in the same comb, the architects do not alter the size at once, but gradually, thus disordering in the slightest possible degree the delicate arrangement of the bases of the cells. In shifting from larger to smaller, the same rule is observed. A small number only of royal cells, about ten or twelve, are constructed on ordinary occasions. They are about an inch in depth, and nearly one-third of an inch in width, with walls about an eighth of an inch in thickness. After the breeding season is over, the cells both of worker and male bees are used for holding honey. Those made purposely for that end are chiefly marked by a greater divergence from the horizontal plane, that the honey may be better secured; and it is curious to observe that, in a very warm season, these wise insects give the floor a still greater dip from the mouth inwards. As the store enlarges, they seal up the mouth with a ring of wax, to which they gradually add concentric layers till the cell is filled, when they close it altogether—reserving its treasure for use during winter and spring. Pollen, as brood food, is kept in cells of considerable size.

Laying of Eggs.

A very short time elapses ere a great number of cells are constructed; for, in the height of the honey season, a good swarm has been known to build *four thousand* in a day. The queen-mother very soon begins the task of laying eggs. A thousand conjectures have been hazarded as to the mode in which the fecundation of the female bee takes place. No observer has yet been able to discover any contact with the drones in the hive. It was supposed by Swammerdam that a certain aura or odour from the males was all that was necessary to render the eggs of the queen productive; while M. Debraw imagined that the eggs, as in the case of frogs and fishes, were fecundated by a fluid from the drone after being laid. M. Hattorf thought, again, that the queen was fecundated by herself alone. All these opinions Huber refuted in a satisfactory manner, by separations and confinements of the insects in various ways. He at length came to the belief, founded on experiments which appear almost decisive of the question, that the female bee never becomes fruitful in the hive, but requires to go abroad for that purpose; and it has been also thought probable that the fecundation takes place by contact in the air, as is known to occur in the case of winged ants. The number of drones in a hive has been thought a most unintelligible circumstance. Huber's views explain the matter fully. It is essential that they should be numerous, that the female may have a chance of meeting them abroad; and it is to be observed that she always quits the hive at the hour when the drones leave it, or immediately afterwards. One intercourse is sufficient, according to Huber's experiments, to render the female bee productive for at least two seasons; and if the intercourse takes place at the end of the year, the consequent laying of eggs may be deferred till the ensuing spring. The cold weather has a powerful influence in this respect. These conclusions may be more fully ascertained by reference to Huber's interesting work, a translation of which was published by J. Anderson, Edinburgh, in 1808, and another by Tullis, Cupar-Fife, in 1840.

M. Huber discovered that the queen begins to lay eggs forty-six hours after returning from the flight during which fecundation takes place. For the space of eleven months, under ordinary circumstances, a queen, at her first laying, produces the eggs of worker-bees alone. At the end of the space mentioned, a considerable laying of the eggs of drones commences; and soon after the appearance of these, the workers of the hive, with a strange instinct, begin to prepare royal cells for the queen-eggs that are certain to follow. Altogether, the fruitfulness of the female bee is amazing, from one to two hundred eggs a day being the usual amount of her produce. One hundred thousand is said to be no very uncommon number of young for her to give origin to in a single season. A swarm consisting of 2000 or 3000 in the beginning of the year, will throw off in June swarms amounting to 40,000 or 50,000; in many cases the first swarm, and in some the cast or second swarm, throw off colonies of 10,000 or 12,000; and yet the original stock is left augmented to the number of 18,000 or 20,000. Occasionally, an early and numerous first swarm casts even twice.

Transformation of Worker-Bees.

A fertilised queen is so impatient to begin her laying of worker-eggs, that, in a new hive, she only waits till a few inches of comb are erected. Before depositing the egg, she carefully examines the cell, and, if satisfied, turns and drops into it from the oviduct an egg of an oval shape and bluish-white tint. Here the egg remains for three days attached by a viscous fluid to the corner of the cell; and, on the fourth, the thin outer shell of the egg bursts, exposing a small lively worm. Now come into play the *nurses* or nursing-bees, one of the two great sections into which Huber and others consider the labourers of the hive to be divided. The other class are the *wax-workers*. Both elaborate honey, but the latter class alone make wax and form combs. Again, the nurses, whose figure may be distinguished from its being more ovoidal than the others, are those who alone take care of the young. As soon as the egg is hatched, they watch over the larva or worm with the tenderest and most incessant care, administering copious supplies of mixed pollen, honey, and water, which the nursling devours with avidity. Like other larvæ, it soon grows so as to cast its cuticle; and, five days after chipping the shell, it has become large enough to fill the cell, lying coiled up like a ring. It now ceases to eat, and the bees seal up the cell with wax. Left to itself, the larva begins the process of spinning a cocoon round its body, which it does in thirty-six hours, the material being a fine silken thread from the mouth of the spinner. In three days more it is converted into the state of *pupa* or chrysalis, when all the parts of the future bee become gradually visible through the transparent covering, assuming a darker hue day by day, and progressing to the state of the complete *imago* or insect. On the twentieth day from the deposition of the egg, the young bee begins to cut through its prison-door with its mandibles, and in half an hour makes its escape. Old writers say that the elder bees fondly caress and feed the new-comer; but later observers, of no mean authority, declare that, on the contrary, they seem to think their duty ended with the closing up of the cell, and leave the young stranger to shift for itself in the busy world upon which it has entered. One thing, however, is done by the elder bees. They instantly clean out the vacated cell, and prepare it again for eggs or honey, leaving at the same time the silk cocoon adhering to the walls.

Male Eggs—Royal Eggs.

The passage of male eggs through the larva and pupa state is attended with the very same phenomena as in the case of the eggs of workers, with the exception that the process occupies a little more time, twenty-four days in all being spent in the change. The cause of male eggs being laid, in ordinary circumstances, only after eleven months have been passed in the laying of worker-eggs, was explained by Huber. He conceived eleven months to be necessary to perfect the male eggs, and was of opinion that the arrangement of the eggs in the ovaries was such as to permit, and even compel, the retention of both male and royal eggs until they were fully matured. This idea seems to be confirmed by the ordinary course of things in the hive, but certain anomalous facts startlingly contravene it. Huber himself found, that if a young queen had not the opportunity of proving fertile within twenty days of her birth, all her after-product consisted of drones, and drones alone; and, what is still more curious, he discovered that she began to produce these drones at the time when she should have laid worker-eggs—namely, within forty-six hours after fecundation. The gestation of eleven months seemed totally unnecessary in such cases of retarded fecundation. Huber confessed himself incapable of explaining this remarkable circumstance. Though we do not understand it, however, it only tends to make us marvel more and more at the perfection of order in the bee economy. The queen-bee is never voluntarily guilty of that breach of the laws of her being which produces such remarkable effects; and, if artificially confined till she is twenty days old, her violent agitation shows her instinctive sense of the departure from the order of nature into which she is compelled.

The raising of workers and drones from the egg to the insect state is a simple matter in comparison with the same transition in the case of queen-bees. The royal eggs, which the queen begins to lay twenty days after she has commenced the deposition of male ones, differ in no respect from common eggs. But on the royal larva, when it breaks from its three days' confinement in the shell, the nurses bestow peculiar attentions. They watch it incessantly, and feed it with a rich *jelly*, slightly acescent, and given in such quantities that the royal cell is usually wet with it. In five days the young majesty of the hive has grown, so as to be able to spin her web, and the bees wax up the cell. The cocoon is spun in twenty-four hours; two days and a half of inactivity follow; the larva is then transformed into a pupa, or a *nymph*, as the insect in this state is more frequently termed; and after other four or five days have passed, the royal insect is complete—the whole time occupied in the metamorphosis being about sixteen days.

Young Queens.

We have now arrived at one of the most extraordinary points in the history of the hive. The young queen, or rather queens, do not issue from their cells when perfect, like workers and drones. They are not permitted, unless the old or regnant queen has quitted the hive with a swarm, or the seat of royalty is in any other way vacated. They therefore close the royal cells more firmly, leaving only a small aperture to introduce food; and, acting as if aware that they may need a queen in case of swarming, they at such times will not permit the old queen to approach the cells. Her struggles to do so are often violent, and her dire hostility to her own sex leads her, if she gets near the cells, to destroy them instantly, whether in the state of full insect or nymph. The strength of this instinctive hate is even such, that a young queen no sooner leaves her own cell than she feels its stirrings.

According to Huber, there can only be a single queen in a hive. The mere offspring of two could scarcely co-exist in the same hive; and it is wonderful to observe by how many accessory circumstances nature has insured the death of one or other of any two placed in the same community. The first thought of a young queen, it has been seen, is to kill her yet undeveloped rivals. Nature has given her the chance, for, as more queen-eggs than one are seldom laid daily, one is usually the oldest. If, however, two do quit the cell at the same instant, they rush into combat with the most headlong fury. If a stranger enters a hive, its queen-regnant flies to the field without a moment's hesitation. In short, in all ordinary circumstances, two queens brought into contact, fight. But they might *both* die in the contest, and the community be left without a queen. Nature demands but one victim, and she has arranged that but one victim shall fall. Bees are only vulnerable in the belly; and Huber observed that, whenever two royal combatants were so locked together that they could mutually plant their stings in the fatal part, their instinct caused them to separate precipitately, without harm on either side. The combat only closes when one can get an advantage of position, and kill its rival with safety. Again, the worker-bees might interpose to prevent these mortal combats. On the contrary, their instinct is to prevent the queens from parting, and force on a fatal issue. Alluding to one battle, Huber says that it seemed as if 'the bees anticipated the combat in which these queens were about to engage, and were impatient to behold the issue of it, for they retained their prisoners only when they appeared to withdraw from each other; and if one less restrained seemed desirous of approaching her rival, all the bees forming the clusters gave way, to allow her full liberty for the attack; then if the queens testified a disposition to fly, they returned to enclose them.'

Another remarkable provision for insuring the existence of but one queen in a hive, is beheld in the peculiar mode in which the royal larvæ spin their cocoons. Other bees spin perfectly close cases; the queen-larvæ spin cocoons which envelop only the head, thorax, and first ring of the abdomen, leaving a part open behind. Huber thus explains this minute but important peculiarity:—'Of several royal nymphs in a hive, the first transformed attacks the rest, and stings them to death. But were these nymphs enveloped in a complete cocoon, she could not accomplish it. Why? Because the silk is of so close a texture, that the sting could not penetrate, or if it did, the barbs would be retained by the meshes of the cocoon, and the queen, unable to retract it, would become the victim of her own fury. Thus, that the queen might destroy her rivals, it was necessary the last rings of the body should remain uncovered; therefore, the royal nymphs must only form imperfect cocoons. You will observe that the last rings alone should be exposed, for the sting can penetrate no other part: the head and thorax are protected by connected shelly plates, which it cannot pierce. Hitherto philosophers have claimed our admiration of nature in her care of preserving and multiplying the species. But from the facts I relate, we must now admire her precautions in exposing certain individuals to a mortal hazard.' Examining further into the causes of the open cocoon of the royal nymphs, Huber came to the conclusion that it arose from the figure of their cells, and was designed for the purpose of exposing them to the certainty of destruction.

Loss of a Queen.

If bees, by death or artificial means, are deprived of their queen, the event has a marked influence in the hive. We do not allude to the case in which a stranger kills the queen-regnant; for if such a thing happens, as naturalists conceive it scarcely ever can do under natural circumstances, on account of the wariness of the bees to prevent intrusion, the victorious stranger mounts the vacant throne, and reigns in peace. We refer, however, to the removal of a queen without the introduction of any other. In such a case, the following results ensue, according to Huber:—'Bees do not immediately observe the removal of their queen; their labours are uninterrupted; they watch over the young, and perform all their ordinary occupations. But in a few hours agitation ensues; all appears a scene of tumult in the hive. A singular humming is heard; the bees desert their young, and rush over the surface of the combs with a delirious impetuosity. Then they discover their queen is no longer among them. But how do they become sensible of it? How do the bees on the surface of the comb discover that the queen is not on the next comb?' It is supposed that the alarming intelligence of the loss is communicated by the strokes on the antennæ, which bees are uniformly observed to give to each other at these times. The insects then appear to seek for their lost queen, some rushing hurriedly out to make the search abroad. At the end of five hours, the commotion greatly ceases, and an instinctive recourse to the means of supplying the vacancy takes place. If they have royal larvæ, they turn their whole attention to them. If they have only the larvæ of working-bees, they immediately select two or three of them, pull down the neighbouring cells, at the cost of the lives of the young within them, and construct a royal cell around each of the selected larvæ—the consequence of which proceeding will be immediately explained. If they have no larvæ at all on the loss of their queen, still they build several royal cells, as if so far at least to supply the emergency. If a stranger queen be introduced in such a state of things, within twelve hours after the loss of their own sovereign, the new-comer is treated as an intruder, and the bees surround her so closely that she commonly dies from privation of air, suffocation being the resource of bees in such cases. If the stranger be introduced within eighteen hours, they also surround her, but leave her sooner. To show that they possess memory, it is only necessary, now to re-introduce their own queen, when they will show every symptom of recognition and joy. But their memory is short-lived; for, if the stranger be not introduced till twenty-four hours elapse, she receives a treatment very different from that experienced at an earlier period. 'I introduced,' continues the ingenious naturalist, 'a fertile queen, eleven months old, into a glass hive. The bees were twenty-four hours deprived of their queen, and had already begun the construction of twelve royal cells. Immediately on placing this female stranger on the comb, the workers near her touched her with their antennæ, and passing their trunks over every part of her body, they gave her honey. Then these gave place to others that treated her exactly in the same manner. All vibrated their wings at once, and ranged themselves in a circle around their sovereign. Hence resulted a kind of agitation, which gradually communicated to the workers situated on the same surface of the comb, and induced them to come and reconnoitre, in their turn, what was going on. They soon arrived; and having broke through the circle formed by the first, approached the queen, touched her with the antennæ, and gave her honey. After this little ceremony they retired, and, placing themselves behind the others, enlarged the circle. There they vibrated their wings, and buzzed without tumult or disorder, and as if experiencing some very agreeable sensation. The queen had not yet left the place where I had put her, but in a quarter of an hour she began to move. The bees, far from opposing her, opened the circle at that part to which she turned, followed her, and formed a guard around. She was oppressed with the necessity of laying, and dropped her eggs. Finally, after an abode of four hours, she began to deposit male eggs in the cells she met with.

While these events passed on the surface of the comb where the queen stood, all was quiet on the other side. There the workers were apparently ignorant of a queen's arrival in the hive. They laboured with great activity at the royal cells, as if ignorant that they no longer stood in need of them: they watched over the royal worms, supplied them with jelly, and the like. But the queen having at length come to this side, she was received with the same respect that she had experienced from their companions on the other side of the comb. They encompassed her, gave her honey, and touched her with their antennæ; and, what proved more satisfactorily that they treated her as a mother, was their immediately desisting from work at the royal cells: they removed the worms, and devoured the food collected around them. From this moment the queen was recognised by all her people, and conducted herself in this new habitation as if it had been her native hive.'

Making of a Queen.

If one queen is not so introduced to supply the loss of another, and no royal larvæ exist, one of the most wonderful phenomena of the hive takes place. It has been stated that bees, on losing their queen, build a royal cell around an ordinary worker-bee larva, or several of them, if the larvæ are abundant. These, by peculiar feeding, are formed and developed into *queens*, thus proving that the worker-bees, commonly viewed at one time as neuters, are in reality undeveloped females. This remarkable discovery was made by Schirach. Having used smoke about a hive, he so annoyed the queen that she flew away, and the circumstance of the bees immediately building royal cells around common larvæ, when they had no royal larvæ, revealed to him the truth. Huber proved the same thing by the succeeding experiment:—'I put some pieces of comb, containing workers' eggs in the cells, of the same kind as those already hatched, into a hive deprived of the queen. The same day several cells were enlarged by the bees, and converted into royal cells, and the worms supplied with a thick bed of jelly. Five were then removed from these cells, and five common worms, which, forty-eight hours before, we had seen come from the egg, substituted for them. The bees did not seem aware of the change; they watched over the new worms the same as over those chosen by themselves; they continued enlarging the cells, and closed them at the usual time. When they had hatched on them seven days, we removed the cells, to see the queens that were to be produced. Two were excluded, almost at the same moment, of the largest size, and well formed in every respect. The term of the other cells having elapsed, and no queen appearing, we opened them. In one was a dead queen, but still a nymph; the other two were empty. The worms had spun their silk cocoons, but died before passing into their nymphine state, and presented only a dry skin. I can conceive nothing more conclusive than this experiment. It demonstrates that bees have the power of converting the worms of workers into queens, since they succeeded in procuring queens by operating on the worms which we ourselves had selected.' This curious provision seems intended to preserve the communities of bees, in any emergency, from the danger of wanting that all-important member, the queen; and it is reasonably conjectured that the evolution of a queen from a worker-larva is dependent on the effects of the royal food upon the ovarian system.

Fertile Worker-Bees.

Another most remarkable fact observable in the economy of the hive was discovered by M. Riem. Common worker-bees, that naturalist proved, sometimes lay fertile eggs. It was reserved for Huber to determine this, and also to explain the cause. He in the first place found that, in a hive deprived of its queen, the eggs of drones were laid. Though he did not put faith in what had been said by some naturalists respecting the existence of *small* queens, he nevertheless satisfied himself, by directing a careful examination to be made of each individual bee in the hive, that no queen was amongst them, every one having the little basket on the hind-leg, and a straight sting. Thus convinced of the reality of Schirach's discovery, Huber, having detected several workers laying eggs, examined them, and found the ovaries partially developed. He now bethought him that the only known cause of such development is the use of the food or jelly given to the royal larvæ. Led into this strain of thought, he speedily discovered that all the fruitful worker-bees are born in hives where no queen exists, and where worker-larvæ are transformed to queens; and he further found that they are always born in cells adjacent to those of these larva-queens. Continued investigations brought him to the belief, finally, 'that when bees give the *royal treatment* to certain worms, they either by accident or by a particular instinct, the principle of which is unknown to me, drop some particles of royal jelly into cells contiguous to those containing the worms destined for queens;' whence the expansion of the ovaries to a certain degree. That expansion is imperfect. As in the case of retarded fecundation in queens, the fruitful worker-bees produce nothing but drones. In this fact, it seems to us, may possibly be found the principle of the unexplained instinct in question. May the instinct which leads them to create queens from worker-larvæ, not also prompt them so to dispense the royal food to common larvæ, as to supply the hive with new drones for the new queens? This end is at least gained by the mode in which the worker-bees become productive. Ovaries, in a rudimental or undeveloped state, have been found by late observers in all working-bees.

Mutilations of Queens.

Before leaving the particular subject of queens, the remarkable effects of mutilations upon them may be mentioned. Huber cut off one antenna from a queen without any marked effects; but when he cut off both, the case was different. 'From this moment there was a great alteration in her conduct. She traversed the combs with extraordinary vivacity. Scarcely had the workers time to separate and recede before her: she dropped her eggs without taking care to deposit them in any cell. The hive not being very populous, part was without combs. Hither she seemed particularly earnest to repair, and long remained motionless. She appeared to avoid the bees; however, several workers followed her into this solitude, and treated her with the most evident respect. She seldom required honey from them; but when that occurred, she directed her trunk with an uncertain kind of feeling, sometimes on the head, and sometimes on the limbs of the workers, and if it did reach their mouths, it was by chance. At other times she returned upon the combs, then quitted them, to traverse the glass sides of the hive; and always dropped eggs during her various motions. Sometimes she appeared tormented with the desire of leaving her habitation. She rushed towards the opening, and entered the glass tube adapted there; but the external orifice being too small, after fruitless exertion, she returned. Notwithstanding these symptoms of delirium, the bees did not cease to render her the same attention as they ever pay to their queens; but this one received it with indifference. All that I describe appeared to me the consequence of amputating the antennæ.' Another similarly mutilated queen was placed beside her; they had both lost their natural combativeness. Finally, on being again left alone, the poor mutilated queen quitted the hive, unheeded, and abandoned to her fate. This evidence of the indispensable utility of the antennæ was gained, on the whole, in a manner for which even a Huber's ardour for science can scarcely form an excuse.

Massacre of the Drones.

Another of the great natural phenomena of the hive is the massacring of the drones. It was at one time asserted that the worker-bees did not use their stings against the stingless males, but merely pushed them out to die. This idea, however, resulted from the massacre being always committed at the bottom of the hive, whither the poor drones retire in clusters in July and August, as if aware of the doom impending over them. As usual, by one of his ingenious expedients, Huber discovered the truth. Six swarms were put on glass tables, beneath which the watchers placed themselves. 'This contrivance succeeded to admiration. On the 4th of July, we saw the workers actually massacre the males, in the whole six swarms, at the same hour, and with the same peculiarities. The glass table was covered with bees full of animation, which flew upon the drones as they came from the bottom of the hive; seized them by the antennæ, the limbs, and the wings, and after having dragged them about, or, so to speak, after quartering them, they killed them by repeated stings directed between the rings of the belly. The moment that this formidable weapon reached them, was the last of their existence; they stretched their wings and expired. At the same time, as if the workers did not consider them as dead, as they appeared to us, they still struck the sting so deep, that it could hardly be withdrawn; and these bees were obliged to turn round upon themselves, with a screw-like motion, before the stings could be disengaged.

Next day, having resumed our former position, we witnessed new scenes of carnage. During three hours, the bees furiously destroyed the males. They had massacred all their own on the preceding evening, but now attacked those which, driven from the neighbouring hives, had taken refuge amongst them. We saw them also tear some remaining nymphs from the combs; they greedily sucked all the fluid from the abdomen, and then carried them away. The following days no drones remained in the hives.

These two observations seem to me decisive. It is incontestable that nature has charged the workers with the destruction of the males at certain seasons of the year. But what means does she use to excite their fury against them! This is a question that I cannot pretend to answer. However, an observation that I have made may one day lead to a solution of the problem. The males are never destroyed in hives deprived of queens; on the contrary, while a savage massacre prevails in other places, they there find an asylum. They are tolerated and fed, and many are seen even in the middle of January. They are also preserved in hives which, without a queen, properly so called, have some individuals of that species that lay the eggs of males, and in those whose half-fecundated queens, if I may use the expression, propagate only drones. Therefore the massacre takes place in none but hives where the queens are completely fertile, and it never begins until the season of swarming is past.'

Swarming.

We have now only another of the great natural operations of the hive to advert to, before coming to the consideration of the artificial provisions which have been discovered and employed by man for augmenting the usefulness of this interesting insect. Swarming is the operation referred to, which usually takes place, in temperate climes, in May and June, though additional swarms, and swarms from swarms, are commonly later. In noticing the proceedings of a community from its first settlement, it was mentioned that the old queen led off the first swarm, and did so as if under alarm at the number of royal embryos, usually from twelve to twenty, which were in progress to maturity, and which the worker-bees would not allow her to approach. Other causes also operate, beyond doubt, in a certain degree. The increased heat of the hive from crowding, for example, in all likelihood influences the movement. Bees cannot do without freedom of respiration and fresh air, and it has surprised many observers to find the air usually pure, and below 80 degrees, in a hive ordinarily filled. The insects, however, have been discovered to manage this by active ventilation in their own way. A number of them are always to be seen near the inner, and sometimes the outer side of the opening of the hive, vibrating their wings with great rapidity, and sending the entering air backwards in a smart current. One band relieves another at this task. These means of ventilation, however, seem to become comparatively ineffective when the hive gets overcrowded. The heat often rises to about 100 degrees; the bees are driven to the door in clusters, while the warmth makes the hive visibly moist. At the same time, the old queen's alarm at the growth of the royal young seems to have its influence. She would fain kill them, but the worker-bees lose all respect for her, biting and beating her off with violence. The way in which they defend the royal young at swarming time is indeed most remarkable. If, at any other season, they bring up queens from worker-larvæ, the first queen that leaves the cell is allowed to kill the rest at pleasure. But when casting colonies, the workers, as if from the sense that various swarms may be cast off, and various queens required, will not permit the old queen to touch the young, whom nature has given them the strange power of keeping alive, for better security, in their cells. Nor will they allow the first young one to whom they grant freedom to touch the rest. Huber illustrates this subject beautifully. Suppose an old queen to have left a very populous hive, as described, with a swarm—'After the departure of the colony, the remaining workers set another queen at liberty, and treat her with equal indifference as the first. They drive her from the royal cells; she also, perpetually harassed, becomes agitated, departs, and carries a new swarm along with her. In a populous hive, this scene is repeated three or four times during spring. The number of bees being then so much reduced, they are no longer capable of preserving a strict watch over the royal cells; several females are therefore enabled to leave their confinement at once; they seek each other, fight, and the queen at last victorious reigns peaceably over the republic.

The longest intervals we have observed between the departure of each natural swarm, have been from seven to nine days. This is the time that usually elapses from the period of the first colony being led out by the old queen until the next swarm is conducted by the first young queen set at liberty. The interval between the second and third is still shorter; and the fourth sometimes departs on the day after the third. In hives left to themselves, fifteen or eighteen days are usually sufficient for the throwing of the four swarms, if the weather continues favourable, as I shall explain.

A swarm is never seen except in a fine day, or, to speak more correctly, at a time of the day when the sun shines and the air is calm. Sometimes we have observed all the precursors of swarming—disorder and agitation—but a cloud passed before the sun, and tranquillity was restored: the bees thought no more of swarming. An hour afterwards, the sun having again appeared, the tumult was renewed: it rapidly augmented, and the swarm departed.

Bees generally seem much alarmed at the prospect of bad weather. While ranging in the fields, the passing of a cloud before the sun induces them precipitately to return. I am led to think that they are disquieted by the sudden diminution of light. For if the sky is uniformly obscured, and there is no sudden alteration in clearness, or in the clouds dispelling, they proceed to the fields for their ordinary collections, and the first drops of a gentle shower do not make them return with much precipitation.

I am persuaded that the necessity of a fine day for swarming is one reason that has induced nature to admit of bees protracting the captivity of their young queens in the royal cells. I will not deny that they sometimes seem to use this right in an arbitrary manner. However, the confinement of the queens is always longer when bad weather lasts several days together. Here the final object cannot be mistaken. If the young females were at liberty to leave their cradles during those bad days, there would be a plurality of queens in the hive, consequently combats; and victims would fall. Bad weather might continue so long, that all the queens might at once have undergone their last metamorphosis, or attained their liberty. One victorious over the whole would enjoy the throne; and the hive, which should naturally produce several swarms, could give only one. Thus the multiplication of the species would have been left to the chance of rain or fine weather, instead of which, it is rendered independent of either by the wise dispositions of nature. By allowing only a single female to escape at once, a regular and successive formation of swarms is secured. This explanation appears so simple, that it is superfluous to insist further on it.'

Our author adds, that another important circumstance resulting from the captivity of queens is, that they are in a better condition to fly when the bees have given them liberty, and are therefore capable of profiting by the first moment of sunshine to depart at the head of a new colony.

Dangers during Swarming.

The capture of the queen, when a swarm has settled on some bush or tree, is, it should be added, the first step towards lodging a swarm in a new hive. If she be placed in it, with two or three bees, the rest will soon follow. A strong glove will enable any one to handle the bees without risk, as they are less disposed to sting when they are swarming than at other times. It sometimes happens, however, that a swarm may settle on the person of any individual who may be near, in which case presence of mind is absolutely necessary for the preservation of life. The following anecdote, related by Thorley, is strikingly illustrative of what has now been advanced:—

'One of my swarms settled among the close-twisted branches of a codling-tree; and not to be got into a hive without help, my maid-servant, being in the garden, offered her assistance to hold the hive while I dislodged the bees. Having never been acquainted with bees, she put a linen cloth over her head and shoulders to guard and secure her from their swords. A few of the bees fell into the hive, some upon the ground, but the main body upon the cloth which covered her upper garments. I took the hive out of her hands, when she said that the bees had got under the covering, and were crowding up towards her breast and face, which put her in a trembling posture. When I perceived the veil was of no farther service, she gave me leave to remove it. This done, a most affecting spectacle was presented, filling me with the deepest distress and concern, as I thought myself the unhappy instrument of drawing her into so imminent hazard of her life. Had she enraged them, all resistance had been vain, and nothing less than her life would have atoned for the offence. I used all the arguments I could think of, begging her, with all the earnestness in my power, to stand her ground, and keep her present posture. The bees had now got in a great body upon her breast, about her neck, and up to her chin, and I began to search among them for their queen. I immediately seized her, taking her from among the crowd, along with some of the commoners, and put them together into the hive. Here I watched her for some time; and as I did not observe that she came out, I conceived that the whole body would quickly abandon their settlement; but instead of that, I soon observed them gathering closer together, without the least signal for departing. Upon this I immediately reflected that either there must be another sovereign, or that the same was returned. I directly commenced a second search, and in a short time, with a most agreeable surprise, found a second, or the same. She strove, by entering farther into the crowd, to escape me; but I reconducted her, with a great number of the populace, into the hive. And now the perilous scene began to change to one infinitely more pleasing and agreeable. The bees, missing their queen, began to dislodge and repair to the hive, crowding into it in multitudes, and in the greatest hurry imaginable; and in the space of two or three minutes, the maid had not one single bee about her, neither had she received so much as one sting, a small number of which would quickly have stopped her breath.'

ARTIFICIAL MANAGEMENT—THE APIARY.

The artificial management of the hive forms, in some measure, a branch of the present subject perfectly distinct from the consideration of the natural operations of bees, of their various classes, of the phenomena attending their transformation, and of their social economy in general. Many able writers of recent date have given to the public their experience of the best modes of preserving these insect communities, and rendering them most productive. And, in the first place, the local situation of an apiary, or accumulation of beehives, has been held of especial consequence.

Site of Apiaries.

The hives must be sheltered in a particular manner from the action of high winds. A wall or hedge is not sufficient to yield the requisite protection; houses or lofty trees are necessary to insure it. The reason of this is, that the bees, returning homewards, require a calm air at a considerable height above their dwellings, otherwise, when they attempt to alight, they are dashed to the ground and killed, their exhausted strength disabling them from coping with a wind of any force. A low position, enclosed with woods, suits them best. Bees drink much, and a fountain or brook is essential to them; deep pools or cisterns very often cause their death by drowning. Shallow troughs, filled with moss or floating wood, are recommended as a substitute for shallow rills. It is an error, according to the experienced bee-keeper De Gelieu, to suppose that hives should be placed full in the sun. Bees, he says, live and thrive in shady places of moderate and uniform temperature; hence their partiality for forests. Besides, exposure to all the extremes of the solar heat melts and spoils the honey. In fine, if exposure to the sun be beneficial at all, that exposure should last only for a comparatively short time, or from about ten o'clock till noon. Hives should not be placed on upper floors, on account of the increased danger from wind. At the same time, a bee-house ought to be so made as to cause a free passage of air, though not of strong currents, at all periods, with openings both anteriorly and posteriorly. A covered shed or veranda is perhaps the best form of a bee-house, yielding both a shade from the heat and shelter from the wet. Where hives are simply placed on open stands, these should be about sixteen inches from the ground, and each three or four feet apart. Shifting is condemned by almost all observers as very hurtful to the bees. Quiet is also necessary to their successful operations; and it has been found that they do not thrive well in the neighbourhood of smithies, mills, steam-engines, and the like, partly, we believe, on account of the noise, and partly owing to the smells emitted from such works.

As to the district of country, that of course will always be preferable which yields such vegetable productions as the insect can turn to account. 'Large heaths, sheltered with woods,' says the Naturalists' Library, 'are extremely productive of honey, as the wild thyme and other flowering plants with which they abound are not cut down by the scythe; and the heath itself remains in bloom till late in the season. The plane-tree, the whole willow tribe, the furze or whin, the broom, especially the Spanish kind, furnish a rich store both of honey and farina. Bees do not feed indiscriminately on every species of flowers; several of the most splendid and odoriferous are wholly neglected by them, while they select others, the flowers of which are extremely small, and not apparently possessed of any valuable qualities. Moreover, they give a decided preference to those spots where a *great quantity* of their favourite flowers grow together. On the continent, fields of buck-wheat afford a copious supply, though the honey extracted from it is of a coarser kind; and in our own country, the white clover will, in fine weather, be found thronged with them, while scattered plants that afford more honey are neglected. When a variety of bee-flowers flourish in the same field, it is said they will first collect from those which furnish the best honey; if, for example, several kinds of thyme grow together, they prefer the lemon variety, which is of a sweeter and richer fragrance.

But while mainly depending, as they must always do, on the natural products of the country, the bee-master will do well to supply his favourites with such flowers, &c. as are not found growing spontaneously in his neighbourhood. In addition to the gooseberry, currant, and raspberry bushes, and the several orchard trees, the flower-borders in his garden should be well stocked with snowdrops, crocuses, wallflower, and, above all, the mignionette, which affords honey of the richest flavour, and which continues flowering till the near approach of winter. The rich melliferous blossoms of the *Buddlea globosa*, too, the bees are very fond of; and some of the *Cacalia* tribe afford an ample store. "The *Cacalea suaveolens*," says Darwin, "produces so much honey, that on some days it may be smelt at a great distance from the plant. I remember once counting on one of these plants above two hundred painted butterflies, which gave it the additional appearance of being covered with additional flowers." Besides these, the plants of borage and viper's bugloss yield a very considerable quantity of the rich liquid. The former is eagerly resorted to by the bees; it is an annual, and blossoms during the whole season, till destroyed by the frost. In cold and showery weather, the bees feed on it in preference to every other plant, owing to its flowers being pendulous. The bugloss appears as a troublesome weed among corn, and grows on dry soils in great profusion: it is a biennial plant. Turnips, particularly the early garden kind, should be sown, and allowed to remain in their beds during the winter; and they will in consequence, by their early flowering, afford a seasonable supply of farina, and also a small portion of honey early in spring. The whole cabbage tribe also may be made to contribute their share; and mustard, when sown in successive crops, will continue to blossom for many weeks together.'

Hives.

The important question of the size, form, and materials of the hive, or artificial habitation, has of course received much attention. Whatever be the form adopted, it is found that bees accommodate their labours to it, and fashion their combs of honey accordingly.

Straw hives, of which a sketch is given in the preceding page, are those most commonly used in cottage gardens; and being easily and cheaply constructed, they still maintain their place, though much better habitations could be suggested. They are of a roundish form, ordinarily measuring about twelve inches deep and nine inches wide in the lower part. Made of unbroken rye straw, or any other straw of a strong and elastic fibre, and well bound, they will, if tolerably well sheltered, last many years. It is customary to place sticks across the interior, from an idea that such are necessary for supporting the combs; but Mr Taylor, in his 'Bee-Keeper's Manual,' combats this opinion. 'The sticks,' observes that intelligent writer, 'are only an annoyance to the bees; and there is little fear of the combs falling, except in very deep hives; at anyrate it may be prevented by contracting the lower part a little. The best way of doing this is by working a wooden hoop inside the bottom band of the hive, as recommended by Dr Bevan, who says, "It should be perforated through its whole course, and the perforations made in an oblique direction, so distant from each other as to cause all the stitches of the hive to range in a uniform manner." The hoop gives greater stability to the hive, preserves the lower edge from decay, and affords facility in moving it. I advise a circular piece of wood (turned with a groove at the edge, to retain it in its place) to be worked into the crown, having through it an inch and a half hole. With a little ingenuity, the bees may be fed through this opening—a better method than the ordinary one at the bottom of a hive. A piece of wood or tin will commonly cover the hole; but at times, and especially in winter, it may be used for the purpose of ventilation, and allowing escape to the impure air of the hive. In this case, a bit of perforated tin or zinc should be placed over it, which, when stopped up by the bees, can be replaced by a clean one. An earthen pan is a common cover to a straw hive, and this may be slightly raised by wedges on the four sides, to permit a small space underneath. Of whatever material the outer covering consists, it must project so far on all sides as to protect the hive from moisture. This cannot be too much guarded against; and whether of wood or straw, hives ought to be well painted at the beginning, and periodically afterwards.'

Wooden hives are superior to those made of straw, the square shape being better adapted for the deposit of combs than the round form. Mr Taylor's observations may be likewise quoted on this important point. 'It matters not much of what wood the boxes are made, provided it is sound, thoroughly seasoned, and well put together. Different opinions are entertained as to the best size of bee-boxes, but I think that much must depend on the number of bees they are to contain, and on the honey locality; there must also be a reference to the proposed mode of working them; for where no swarming is permitted, a larger hive may be advantageously used. A good size is twelve inches square and nine inches deep within; the thickness throughout being not less than an inch. The top of the box ought to project on all sides nearly three-quarters of an inch, for better protection and appearance, and as affording convenience for lifting. On the top a two-inch hole should be cut in the centre, for placing a bell-glass, and for the purpose of feeding; and another hole, to receive a ventilator, may be made near the back window, that position being better for inspection, and less in the way of the bees, than the centre of the hive, which is, or ought to be, the seat of breeding, and should not be disturbed. A window may be placed at the back and front, five inches high, and six or seven inches wide. The best and neatest way of securing the windows that I have seen, is by a sliding shutter of zinc. Round the window there must be a projecting moulding, mitred at the corners. On one side the piece of moulding is movable, and to the back of this is screwed a plate of sheet zinc. This passes into a rabbet to receive it, cut, on the remaining three sides, at the back of the lower edge of the moulding. To prevent any wet from lodging at the bottom moulding, an opening or two may easily be cut through on the under side to allow its escape. For the sake of uniformity of appearance, blank windows may be made opposite to the real ones. Hives of this construction require to be placed under some cover or shed, as a protection from wet and a hot sun.'

To these explanations it should be added, that the hive of either form must be placed on a clean wooden floor or board; and if there be several hives together, each should have its own separate floor. Do not cement the hives to the board, that being a duty which the bees will themselves perform; all that may be given is a slight luting of clay, or any easily removable material. The entrance to the hive requires to be small, a little larger than a shilling, but rather wider than deep, and ought to be at the lower edge of the hive, on the side which is exposed. Numberless have been the plans invented to enlarge hives as may be required, both to permit of the greater accumulation of honey, and to render swarming unnecessary. Capes or hoods are the simplest of these inventions. In order to use capes, hives must have a stoppered hole at the top. A small additional hive, of light structure, is placed over this at the proper time, the stopper being removed. This serves as a second magazine for honey. Storeyed hives are merely hives made originally with one or two storeys, for the same end. Wildman's hive, the Grecian hive, and Lombard's hive, are specimens of hives made on this principle. Collateral hives, again, such as Nutt's, effect the same ends by being placed side by side, and giving increased accommodation, when necessary, either for swarms or stores. But of all such hives, our readers will probably prefer to know the one used by Huber.

Huber's Leaf hive, as he called it, 'consists of eight frames, each 18 inches high [a height of 14 inches is preferable] and 10 inches wide inside, having the uprights and top cross pieces one and a-half inch broad, and one thick, so that the eight frames, when placed close together, constitute a hive 18 inches high, 12 inches between end and end, and 10 inches between back and front, all inside measure. The frames are held together by a flat sliding-bar on each side, secured by wedges and pins. To the first and eighth of these frames is attached a frame with glass, and covered with a shutter. The body of the hive is protected by a sloping roof, and the entrance is made through the thickness of the floor-board. We (Naturalist's Library) dislike the sliding-bars, with their pins and wedges, which are so far inconvenient, that in drawing them out, all the frames are liable to open, and the observer is exposed to some hazard of annoyance, from the bees issuing out at every joint; and we have substituted for them hinges on one side, and a hook-and-eye on each frame on the other; we can thus open any particular leaf without meddling with the rest. In taking honey from this hive, the bee-master has the whole interior completely under his eye and at his disposal, and can choose what combs best suit his purpose, both as to quantity and quality; taking care, however, to do so only at such periods as will leave the bees time to replenish the vacancy before the termination of the honey season. It is also well adapted for artificial swarming. By separating the hive into halves, the honey, brood-combs, and bees, will, generally speaking, be equally divided; and by supplying each half with four empty frames, we shall have two hives, one half empty, equal in number of bees, of brood, and even of stores. One of the new hives will possess the queen; and if the operation has been performed at the proper time—that is to say, a week or ten days before the period of natural swarming—the probability is, there will be royal broods coming forward in the other; at all events, there will be plenty of eggs and larvæ of the proper age for the production of another queen.'

Use of Capes.—It will be observed from these quotations, that experienced apiarians, who work on a large scale, now employ for the most part hives so contrived as to remedy all the inconveniences resulting from the straggling of swarms and the old custom of killing by brimstone. As the use of single straw hives, however, formed upon the simplest plan, still prevails among those who have but one or two hives in all, the cape may be regarded as the easiest means of affording enlarged accommodation in such cases, and the mode of taking away the honey from it is very plain and easy. It is only necessary to remove the cape, invert it, and cover it with a handkerchief, leaving a little opening on one side. A few taps will cause the bees to quit the cape and return to the hive, after which the honey can of course be readily removed. This may be done frequently in the same season. De Gelieu mentions, that in one season he drew from one of his straw hives that did not swarm 72 lbs. of fine honeycomb, by merely emptying the capes as they were filled.

Union of Swarms.

It is strongly recommended by experienced men that swarms should be more often united than they are. Five thousand bees are estimated to weigh a pound; and, according to most bee-keepers, a swarm ought to weigh nearly four pounds. As a hive often casts off successive colonies, each far below this weight, it then becomes proper to unite two or more of them; seeing that one strong population supports itself better, and is incomparably more profitable, than several feeble colonies, which must be frequently in want of assistance. To those who keep bees on a small and cheap scale, convenience also dictates the junction of swarms in such cases. De Gelieu thus describes his mode of practice:—'When two small swarms come off the same day, I gather them separately, and leave them at the foot of the tree or bush on which they have alighted. Towards evening I spread a tablecloth on the ground, on which, by a smart and sudden movement, I shake all the bees out of one of the hives, and immediately take the other and place it gently over the bees that are heaped together on the cloth, and they instantly ascend into it, flapping their wings, and join those which, not having been disturbed, are quiet in their new abode. Early next morning I remove this newly-united hive to the place it is destined to occupy. This doubled population works with double success, and in the most perfect harmony; and generally becomes a powerful colony, from which a great profit is derived. Two feeble swarms may be united after the same manner, although one of them may have come off some days later than the other, and the first may have constructed combs; taking care, however, not to make the first one enter the second, but the second the first, as the bees will ascend more readily to join those that have already begun to make honey and to hatch brood; and next day they will proceed together with increased ardour with the work which the first had already begun, and which will now advance more rapidly from the increase of the labourers. It is to be understood that, after this union, the hive should be placed early next morning in the same place where the oldest of the swarms has already passed some days.' On many occasions, the circumstance of two queens passing out at once is the cause of a colony going off in two halves, and the removal of one of the queens is necessary, to facilitate their cordial junction into one community.

Besides the union of young swarms, it is often advisable to reunite weak swarms with their parent stocks, to unite weak stocks with each other, or even to add to some weak community a portion of one more numerous and healthy. In either case the object is the same—namely, to obtain well-filled, strong, and consequently more active hives. The three usual modes—we abridge partly from Bagster—by which union has been attempted, and indeed, their advocates say accomplished, are—fuming them, immersing them in water, and aspersing them with sugared or honied ale. To these we may add a fourth—namely, operating upon their fears, by confining them for a time, and then alarming them by drumming smartly upon the outside of their domicile. It was operating on their fears that enabled Wildman to perform such extraordinary feats with bees. When under a strong impression of fear, says he, they are rendered subservient to our wills to such a degree as to remain long attached to any place they afterwards settle upon, and will become so mild and tractable, as to bear any handling which does not hurt them without the least show of resentment.

The neatest and most scientific mode with which we are acquainted of uniting weak families together in harmony, was invented by the Rev. Richard Walond, whose experience in the management of bees, for nearly half a century, entitle his opinions concerning them to great respect. His theory and practice upon this subject are as follow:—'Bees,' says he, 'emit a peculiar odour, and it is by no means improbable that every family of bees emits an odour peculiar to itself; if so, as their vision seems to be imperfect, and their smell acute, it may be by this distinctive and peculiar odour that they are enabled to discriminate betwixt the individuals of their own family and those of a stranger hive. Upon this supposition, if the odours of two separate stocks or swarms can be so blended as to make them completely merge into each other, there will then probably be no difficulty in effecting the union of any two families that it may be desirable to unite.' To accomplish this end, therefore, Mr Walond had recourse to a very ingenious contrivance: he procured a plate of tin, the size of a divider, and thickly perforated with holes, about the size of those in a coarse nutmeg-grater. Having confined, in their respective hives or boxes, the two families to be united, and placed over each other, with only a divider between them, he introduced his perforated tin plate upon the divider, which was then withdrawn. Immediately the bees began to cluster with hostile intentions, one family clinging to the upper, the other to the under side of the perforated plate; when, after remaining in this state for about twenty-four hours, they had so far communicated to each other their respective effluvia, and so completely commixed were the odours in both hives, that on withdrawing the perforated plate, the bees mingled together as one family: no disturbance was excited, but such as arose from the presence of two queens, the custom being always in such case to dethrone one of them. According to Huber, this is effected by single combat between the queens. Keys has observed that these incorporations seldom turn to account unless they be effected in summer; and when it is considered that the principal gathering months are May and June (excepting in those neighbourhoods that abound in lime, sycamore, and other trees that are apt to be affected with honey-dew), we cannot of course expect them to be very successful.

This plan of the Rev. Richard Walond is very ingenious, and unquestionably, on his authority, proves our position—that smell is one of the senses used by the bees to detect a stranger—and lead us to doubt the authenticity of accounts which state that the system of union by means of driving has been uniformly successful. Our aim, however, is not to condemn, but to show that fumigation is the easiest and surest operation. The plan is as follows:—In autumn, three or four fuzz-balls or puff-balls (a kind of fungus growing in the meadows, and commonly called the 'Devil's Snuff-box') must be pulled before they are fully ripe. These must be thoroughly dried in an oven, and kept dry till wanted. A round box, made of thick tin, without any solder, must be provided. This box must be about two inches in diameter, and an inch and a-half deep, with a conical movable top, about an inch and a-half high, perforated with holes. The latter must also have three holes in it. With this box, and a piece of a fuzz-ball about the size of a hen's egg, in readiness, the operator commences by fixing an empty hive, of the same size as that from which he intends to take the bees, securely, in an inverted position, in a pail or some other convenient utensil. A sharp pointed stick having been stuck into the empty hive, so as to stand upright within it, the box is fixed thereupon, by inserting the stick into one of the holes in its bottom. The piece of fuzz-ball is then lighted and put in the box, over which the conical lid is placed. The hive from which the bees are to be taken is then placed over the empty hive and the burning fungus. To keep all close, a wet cloth is put round the place where the two hives join. In a minute or two the bees may be heard dropping heavily into the empty hive, where they lie stupified. After a short lapse of time, the full hive may be tapped, to cause the bees to fall faster. On removing the upper hive, the bees from it will all be found lying quiet at the bottom of the lower one. The queen may be taken from them and placed under a glass with a little honey on a small piece of comb. The stupified bees must then be sprinkled freely with a thick syrup made of sugar and ale boiled together. The hive containing the bees with which it is intended to unite the stupified bees must now be placed on the top of that containing the latter, just as the hive was from which they have dropped. A cloth must be closely fastened round the two hives, so as to prevent any of the bees from escaping. The hives in this position must be put aside, where they will not be likely to be thrown down or disturbed. The bees in the upper hive, attracted by the scent of the syrup, go down and begin to lick the sprinkled bees clean. The latter gradually revive, and all get mingled together, and ascend quietly in company to the upper hive, where they dwell as if they had always been one family. The two hives should be left undisturbed for twenty-four or thirty hours, at the end of which the upper hive is to be removed and placed immediately on the spot from whence it was taken. The object of taking the queen away is to avoid all risk of disagreement. It is, however, recommended to preserve her as long as she will live, lest any accident should happen to the sovereign of the other community.

Summer Management of Bees.

The feeding of bees at different seasons is an important point to the bee-keeper. In summer they feed themselves, and of course a good supply of the requisite material is then essential to their well-doing. The most highly-cultivated districts are not so favourable to bees as those in which wild heaths, commons, and woods prevail; or where white clover, saint-foin, buckwheat, mustard, and cole-seed, are produced in abundance. Bee-keepers, however, may do something to further the supply of summer food, by growing near their apiaries a selection of such plants as we have recommended under a previous section. But on the natural products of the country, generally speaking, bees must rely for summer food, if the weather be such as to permit of their gathering it. Should a succession of coarse bad weather occur, however, at the beginning of summer, and particularly after a swarm has entered a new hive, most apiarians think it essentially necessary to give honey, or a syrup of sugar and water, to the newly-hived stock. If no proper brook or fount be at hand, water should always form a part of the summer provision. The bees being at full work in this season, the door of the hive should be opened to its whole extent, and not closed, as is more or less requisite at other times. In the hives formed upon improved plans, ventilators constitute a part of the apparatus, and thermometers are introduced to regulate their use. Though these are valuable adjuncts certainly, they are not indispensable; seeing that the bees, as already mentioned, contrive to ventilate to some extent for themselves. Where artificial ventilation can be effected, it is recommended that the temperature should be maintained at from

65 to 80 degrees of Fahrenheit. It is recommended, on evenings when the moths are numerous, to place a small grating before the hive; and it will also be advisable to destroy any wasps, spiders, earwigs, or other insects which may settle near the hives.

Autumnal Management.

The autumnal period has long been the most calamitous for bees, not through the injuries of enemies or weather, but from the improper management of bee-keepers. After the carcasses of the drones, strewn in multitudes before the hive, have indicated that, with the beginning of August, has come the close of the rich honey season, the bee-keeper deems it time to take from the hive the reward of his care and attention. The use of storeyed hives or extra boxes renders it easy to take away a portion of honey early in the season, and this is called *virgin honey*. Even with a common straw hive, it has been found possible to take away the honey, and retain the bees in the hive. Wildman, the famous experimenter on bees, recommended that the hive should be taken into a dark room, and there struck repeatedly till the bees are forced to ascend into an empty hive. The combs are then cut out with a thin knife, and the bees finally returned to the old hive. But this plan is seldom pursued, being at once dangerous and destructive to the brood combs.

It is generally reckoned advantageous to change the pasturage for a week or two before taking the honey-harvest. About mid-autumn, the ordinary food of bees begins to fail, and their stock of honey to decrease daily. By a removal of three weeks to a heathy district, a hive not only loses nothing, but frequently gains as much as ten or twelve pounds of honey in ordinarily favourable circumstances. So well is this known by bee-keepers near Edinburgh, that one shepherd on the heathy Pentland hills receives in charge several scores of hives annually, for the heath-feeding.

Honey-Harvest.

After the autumnal accession of honey has been obtained, and the bees have been brought home again, the question comes to be, in what manner the harvest should be reaped. By partially depriving each of a portion of comb, and leaving some for food? By suffocating one-half the communities, taking their entire honey, and leaving the other hives with their honey untouched, to serve as stock? Or, finally, by removing the bees from one-half the hives to the other half, forming united stocks, and acquiring all the honey of the evacuated ones? These three plans are known by the several names of *partial deprivation* (commonly and most easily practised with improved hives, as already described), *suffocation*, and *union of stocks*. 'Partial deprivation,' says the Naturalist's Library, 'consists in appropriating early in the season a portion of the stores. In preparing prospectively for thus sharing in the products of the hive, the cultivator who pursues the storifying system, immediately after the swarming season is over, adds another storey or box to the two of which his hive consists, placing it undermost, or, as it is called by some bee masters, *nadiring*. The brood combs contained in the uppermost storey will, as the young bees are hatched, be quickly filled with honey, and may be removed about the beginning of August. The top cover is then replaced on the next storey in position, which was originally the lower, and is *now* the upper. In ordinary seasons, the bees will have ample time to lay in sufficient food for winter and spring use, after the abstraction of this portion of their stores. As the combs of the upper box are frequently found adhering by their lower extremities to the bars of the next, it will be necessary before removal to separate them by means of a very thin long-bladed knife, or a fine wire drawn through the hive at the point of junction. The operator will next expel the bees from this box or storey, by lifting the top cover, and blowing in a little smoke, which will cause the inhabitants to retreat quickly to the lower regions. The box may be then taken away, without the operator running the risk of the slightest annoyance. The honey found in this removed box will not be all honey of the current season, and consequently is not so delicately fine. It is also sometimes found mixed with, or rather deposited above a layer of farina. Should it be wished, therefore, to obtain a supply free from these impurities, the empty storey which is added may be placed *above*, instead of *below*, the original stock, and the honey will thus be of a superior kind. This mode of operating is called *super-ing*, in contradistinction to *nadir-ing*; and we understand that Dr Bevan practises the latter only with young swarms, and the former with those of preceding years.

Partial deprivation has never yet become general, because it is liable to frequent failure, even in improved hives, and because the full benefit is not derived from it at the very commencement of the system. The liability to failure, the first of the objections stated, is owing in most instances not to the *mode*, but to the *period* of the operation. According to the too common practice of those who are friendly to deprivation, a portion of honey is abstracted from the hives about the beginning or middle of September; and the owner compliments himself on his moderation in being content with a part instead of the whole, and on his humanity in saving the lives of his industrious favourites; while in nine instances out of ten he finds, on the arrival of March, that his moderation and humanity have been altogether unavailing, and that he has saved them from a violent death by suffocation, only to expose them to the more tardy, but not less cruel, death by starvation. Whereas if deprivation take place soon after the swarming season, as already recommended, and is managed with discretion, the issue will be very different, and ultimately more profitable to the owner, than the almost universally practised mode by suffocation, which is too well known to need description. The latter system may yield a greater return in proportion to the hives operated upon; but in the former there is a much greater number of hives available. For example, suppose two apiaries, each containing five stock hives at the end of July, exclusive of as many swarms recently thrown. The owner of the one, practising the depriving system, takes from each of his stocks 10 lbs. of honey, making an amount of 50 lbs. as his honey-harvest. The owner of the other, an abettor of suffocation, proceeds in September to smoke his five old hives, and receives from each 25 lbs. of honey, making an amount of 125 lbs. as his honey-harvest—between two and three times the quantity of the other. In the following year, the depriver has his five old stock hives, and the five swarms now become stocks also; from the whole ten he now takes 100 lbs. of honey, while at the same time his apiary is augmented by the addition of ten new swarms, making twenty for the following year; while his rival possesses only his former number of five, yielding 125 lbs. In the next year—that is, two years from the commencement of the comparative trial—the depriver has twenty stock hives, yielding 200 lbs., and so on by a geometrical ratio; while the other remains at his original 125 lbs. This calculation is made on the supposition that each owner takes but one swarm from each stock, and without making any allowance for losses and failures which will affect the produce of both in honey and bees, but to which both are liable.'

The writer of the treatise now quoted from, proceeds to point out the advantages of the humane principle of sparing the lives of these useful insects. 'It is pitiable to reflect, that the small degree of additional trouble required in uniting them, should prove so effectual an obstacle to this conservative practice. Yet the operation with each hive so treated need not occupy more than fifteen or twenty minutes. In the evening, when all are quiet, turn up the hive which is to be operated upon, fixing it in a chair from which the stuffed bottom has been removed; place an empty hive above it, wrap a cloth round the point of junction, to prevent the bees from coming out and annoying the operator; then, with a short stick or stone in each hand, beat round the sides, but *gently*, for fear of loosening the combs. In five minutes, the panic-struck insects will hastily mount into the empty hive, with a loud humming noise, expressive of their trepidation. The hives are then separated—that containing the bees is placed on its usual pedestal, and the other containing the honey is carried off. The union is next to be effected. Turn up the stock hive, which is to receive the addition to its population; with a bunch of feathers, or a small watering-pan, such as is used for watering flower-beds, drench them with a solution of ale and sugar, or water and sugar, made a little warm. Do the same to the expelled bees; and then, placing these last over the stock, mouth to mouth, a smart rap on the top of the hive will drive them down among the bees and combs of the undermost hive. Place this last on its pedestal, and the operation is completed. The strong flavour of the solution will prevent them from distinguishing between friend and stranger; and their first movement, after recovering from their panic, will be to lick the liquid from one another's bodies. This mode of operating is applicable to all kinds of hives.' (See previous section on the Union of Swarms.) With regard to the two queens, one would assuredly kill the other in a very short time; but the best way is to remove one of them before union.

One argument employed by advocates of the plan of suffocation by introducing the fumes of brimstone or other noxious effluvia is, that by the union of stocks you have an immense number of mouths to feed, of which the killing plan relieves you. Only inexperienced bee-keepers, however, could use this reasoning, De Gelieu having discovered the remarkable fact, that the increase of numbers in the winter hives is far from producing a proportionate increase of consumption. From fifteen to twenty pounds of honey, or from three to four pots, are requisite for the winter maintenance of a single hive of ordinary strength, with which the plan of union has not been practised. De Gelieu placed such a hive, with such a store, beside one into which three full communities had been introduced; and he found, on weighing the latter in the spring, that its inhabitants had scarcely used one pound of honey more than those of the single-stocked hive. The experimenter even went further. To a hive already amply stocked, he added the swarms of *four* other hives, and found, on weighing it in the spring, that 'the total diminution of honey did not exceed three pounds more than took place in ordinary single hives.' Had they not been thus united, he says, each of these stocks would have cost him much more honey than they were worth, and indeed the most of them 'would to a certainty have perished.' The cause of this strange fact, by which nature seems to point to the plan of autumnal unions as the best possible for both bees and bee-keepers, is yet unknown.

The combs, by whatever process procured, should be deprived of the honey at once, while a natural warmth remains in them. Various kinds of drainers have been used for separating the honey, and keeping it as much as possible from the external air. The honey which runs off naturally without breaking down the combs, and passes through muslin, is held to be the finest. A second kind is procured by cutting the combs in pieces, and letting the honey pass through a drainer, under exposure to a gentle heat. A third quality is procured by subsequently putting the combs in a vessel placed on a fire; the product, strained through canvas, is used in feeding bees. The separated wax of the combs is introduced into a woollen bag, firmly tied at the mouth, and put into boiling water. The pure wax oozes through, and is skimmed off the surface, where it floats. It is then to be allowed to cool slowly. The best honey is supposed to be that formed from heath. The famous bees of Hymettus were nourished by that plant.

Honey is used as a condiment at the table, and is also employed in medicine. In Britain alone, about £120,000 is annually spent for foreign supply; and if we add to this a large home production, and consider that in other countries the article is even more liberally made use of, we shall arrive at some conception of the economical value of the bee. But it is not the honey alone; we import 10,000 hundredweights of wax each year; and when we state that the price varies from £5 to £10, 10s. a hundredweight, it will be seen that its value is all but equivalent to that of honey.

In ancient times, honey formed the basis of a beverage called *Mead*, and from the practice of drinking it for a month after a wedding, came the expression *honeymoon*. In course of time mead was superseded by beer, wine, and other liquors, but is still allowed by writers on diet to be wholesome as a drink, and certainly less pernicious than the ordinary kinds of intoxicating fluids. As some bee-keepers, to whom our sheets are addressed, may wish to attempt the manufacture of mead for domestic use, we offer the following as one of the best methods for its preparation, from the Encyclopædia Britannica:—'Into twelve gallons of water put the albumen [or white] of six eggs, mixing these well together, and to the mixture adding twenty pounds of honey. Let the liquor boil an hour; and when boiled, add cinnamon, ginger, cloves, mace, and rosemary. As soon as it is cold, put a spoonful of yeast to it, and barrel it, keeping the vessel filled as it works; when it has done working, stop it up close; and when fine, bottle it off for use.'

Winter and Spring Management.

In winter and early spring, bees require to be tended with great care. In the case of those hives which have been entirely deprived of their honey, systematic feeding is of course indispensable in winter; but few bee-keepers of any experience ever willingly follow any other plan than that of leaving to bees a winter supply of their own produce. Some bee-keepers remove their hives into the house in winter; but this seems an unwise practice, as the bees must then be kept continually in confinement. Though the door of the hive should be carefully narrowed or shut up in very cold weather, at which time every bee that issues perishes, yet advantage should be taken of every fine day to let them abroad. On this point, however, great difference of opinion exists: many contending that the bee naturally becomes torpid in winter, object to their exposure to sunshine altogether, and for that purpose recommend screens and coverings. One thing is certain, that a moderate degree of warmth is necessary, and that this warmth should be as equable as possible; while at the same time there should be the most thorough precautions against damp. It is damp more than cold which kills our hives in winter; and he who protects them from cold and wet by a thorough covering of straw, fern, flax refuse, or the like, plastered over with Roman cement, is sure to have the healthiest apiary.

Proceeding on the 'dormancy' theory, a singular device for winter preservation has been recently resorted to by some bee-masters—namely, *burying the hives*. When this is to be attempted, the hive should be buried in a cool, dry, shady place, among leaves about a foot deep, and the interment should be performed during the first or second week of November. Mr Briggs, who first made public this device, records the following experiments:—'A friend in the vicinity of Hitchin buried a hive of bees in the first week of November, about a foot deep among dry leaves, &c. and disinterred it in the last week of February, when it was just *two pounds lighter than it was in November, and the bees in a lively and healthy state*. Another person, residing in Leicester, immured a hive of bees in the earth, four feet deep, in the second week in November, and at the end of January it was removed, and weighed *only three ounces less than it did before it was buried*. The above experiments,' adds Mr Briggs, 'are worthy of further attention; and I would recommend that a shed, having a northern aspect, and which is as dry as possible, would be a suitable place for further trials. The principal points by which there might be cause for fear of failure, would, as in other cases, be from dampness, disease for want of fresh air, and attacks from vermin. To prevent the former, I would recommend that the hives be placed on a long frame of wood, covered by a web of closely-worked wire, and raised a few inches from the ground, the ends of which should communicate with, and be occasionally opened to, the fresh air. A long tube should also be placed from the hole at the top of each hive to the open air of the shed, from the upper end of which any dampness might be condensed by bell-glasses, and conveyed away, as already directed. The materials with which the hives are covered and surrounded should consist of dry leaves pressed closely together, or dry and powdered charcoal or cinders, and may be several feet in thickness, to preserve the bees in a cool and torpid state, and at a regular temperature, in which state they should be kept as *dry*, *dark*, and *quiet* as circumstances will permit. As the spring approaches, the winter coverings should be gradually removed, and the hives placed in their summer situations. Small quantities of food should then be supplied as occasion requires, until the gooseberry and currant bushes are in bloom, at which time it may in general be considered that their winter is past.'

Where feeding is necessary, the following rules have been laid down for the management of common hives in winter and early spring:—Bees must be fed only when the weather is fine and warm, to prevent the temperature of the hive from being injured; and a large quantity should never be given at once; for the bees are so greedy of food, that they will rather fill the broad cells with it than relinquish their treasure. The quantity of food which ought to be given to a hive may be calculated in the proportion of two pounds a month; but if the weather be very cold, a less quantity will suffice. When a hive is fed in the spring, it should always be after sunset, when the bees have returned from the fields; otherwise the most disastrous consequences may ensue, from the robberies committed by the bees of other hives. If fed in the morning, it must be before sunrise, and the entrance instantly stopped, to keep out depredators; for as bees leave the hive on the very first appearance of daylight, a later period would prevent the return of those which had left the hive previous to the entrance being secured.

Relative to the substances which are proper for the feeding of bees, many different opinions exist; but the following may be considered among the most beneficial as well as economical articles of diet:—To two quarts of good ale put one pound of moist sugar; boil them until the sugar is wholly dissolved, carefully skimming it; when it is cold, it will be found of the consistency of honey, and it may be given to the bees in the following manner:—If the bees are in the plain cottage hive, an eek of the same diameter as the hive must be provided, and from three to four hands in height. When the sun is set, and the bees have retired, let the hive be gently raised, and the eek placed on the stool; then, having filled a soup-plate with the food, place it on the eek, and put down the hive. To prevent the bees being drowned in the liquid, it is necessary to place some straws over the plate, and over the straws a piece of paper, either thickly perforated or cut into nicks; these nicks, however, must not run parallel with the straws, but either across or diagonally; the entrance must then be closed, and the plate removed on the following morning, when the whole of the liquid will have been transferred to the combs.

Diseases and Enemies of Bees.

Bees, according to the conclusions of De Gelieu, after sixty-four years' experience, have 'no real disease; they are always in good health as long as they are at liberty, and when they are warm enough, and have plenty of food.' In early spring, however, they are found liable to an affection called dysentery, which is known by the marks on the board of dark-coloured evacuations, by the offensive smell, and by the frequent deaths. This disease certainly results, in most cases, from long confinement in a damp and impure air. By lifting the hive to expel the vitiated air, scraping, washing, and drying the board, and removing the dead bodies, the complaint, says Mr Taylor, may soon be remedied even in the most extreme cases. Rosemary, mixed with honey and water, has been recommended as a cure; but the experienced apiarian mentioned conceives all dietetic remedies to do more harm than good. A little chloride of lime, he suggests, may be used beneficially in washing the board. One point should be noticed here, that exposure to the sun is held decidedly injurious to the hives in winter. This caution is necessary, as bee-keepers, when they suspect dampness, might fall into an error on this score. While on this subject we may also mention a new remedy, which is said to have been adopted on the continent with success. When dysentery begins to show itself in the apiary, the bee-keeper prepares a syrup composed of an equal quantity of good wine and sugar, which is administered to the bees in every hive, either by pouring it into the cells, or placing it within the hive in a saucer, or any other shallow vessel.

About the end of spring another disorder sometimes makes its appearance, which Du Carne de Blangy calls vertigo. This is supposed to be occasioned by the poisonous properties of certain plants on which they feed. The symptoms are manifested by a dizzy manner of flight, by their involuntary startings, falls and other gestures in attempting to perform their usual operations, or in approaching the hive, and by the lassitude that succeeds these symptoms. This distemper has been hitherto found incurable. Bees, according to the same authority, are liable to a third distemper, the symptoms of which are swelling at the extremities of the antennæ, which becomes also much inflamed, and of a yellow colour; the head assuming shortly after the same tint, the bees lose their vivacity, and languish till they die, unless a proper remedy be applied. In France, they give them Spanish wine for this disorder. There is still another distemper which sometimes makes its appearance among bees, for which the continental agriculturalists administer Spanish wine, as in the former case. This is a kind of pestilence by which many of the insects are cut off. It happens when the queen bee has placed the eggs carelessly in the comb so that the larvæ perish in the cells, or that they are killed by the cold or otherwise, when numbers die and infect the rest. The only attention requisite in this case is to remove the infected combs, perfume the hive with aromatic plants, and give them the wine to sip, as already mentioned, in order to strengthen and restore them from their sickness.

A few hints from Gelieu and others, respecting the chief foes of the bee-tribe, may be useful to bee-keepers:—The former authority after observing that the possessors of bees, often from an ignorant excess of care, are among their greatest enemies, says—'Ants are their least dangerous enemies; true, the bees cannot sting them to death, because they are small and well defended with armour, but they seize hold of them with their teeth, and carry them to a distance. Had they not this means of getting rid of them, their colonies could not exist in the vast forests full of ants' nests, and where they thrive so well, in spite of the horrible massacres that annually take place.

Moths are little known, and never injurious, in the high valleys, nor on the mountains; but they attack and destroy a vast number of hives in the plains or in the vineyards, where they are a great scourge. Huber discovered that the *Sphinx atropos* or Death's-head moth was one of the most destructive of this tribe. As soon as a moth has penetrated a weak hive, it establishes itself in a comb, envelopes itself in a silken web, multiplies rapidly, consuming the wax, and spreading its destructive galleries from side to side, until, arriving at a certain point, the evil has scarcely a remedy. The only means of saving the colony is to imitate the surgeon, who cuts off a diseased limb to save the other

—every bit of infected comb must be cut out, leaving only those occupied by the bees. The bees must then be liberally fed, by giving them every evening as much honey as will maintain them, until such time as the field-flowers shall again yield a sufficient quantity. Thus, concludes Gelieu, I have preserved hives whose circumstances seemed to be desperate.

Spiders annoy the hive much. The bees get entangled in their webs, and are not able to extricate themselves. Here cleanliness is the best protection; therefore care should be taken to sweep the webs away from the hive and its avenues as fast as they appear.

Birds, such as the sparrow, house-lark, and swallow, eat a prodigious quantity of bees, especially in spring, when the trees are in blossom. Poultry, also, that roam about or near the water where the bees go to quench their thirst, gobble up a great many. Fowls should never be permitted in any apiary.

Mice, especially the red mouse, or *Sorex araneus*, sometimes penetrate a hive in the winter-time, either from the entrance being left too wide, or by gnawing a hole for themselves in the straw. They eat the honey, and even the bees, when clustered together on the side of the hive, in which position they are unable to defend themselves, and scarcely even see the enemy. The most effectual preventive against rats and mice is to place the hive on stands with projecting ledges, and in such a position that they cannot reach it.

Wasps are also reckoned among the numerous enemies of bees. I have, however, seldom seen a hive destroyed by wasps; although they are larger, stronger, and armed with a formidable sting, and an impenetrable cuirass, they seldom dare enter a well-stocked hive. Once attacked, they soon fall beneath the united efforts of these brave citizens, who sacrifice themselves to defend the place of their nativity. Wasps only appear in great numbers when the fruit is ripening, and then they range unceasingly round the hives, and enter the weak ones, or those of which the too spacious lodging bears no proportion to the number of its inhabitants. There are three ways of providing against the attacks of wasps. The first is, to unite weak hives by doubling or tripling the population, thereby enabling them to defend themselves. The second is, to contract the entrances, as soon as swarming time is over, after the massacre of the drones; and the third is, to destroy with assiduity all the nests of wasps that can be discovered in the neighbourhood.

Bees are subject also to a peculiar species of *pediculus*, called the bee-louse. Hives that have swarmed more than once, and such as contain but little honey, are most exposed to these troublesome vermin. The hives in this case should be cleared at the farthest once every week, and the stools on which they stand every morning; for the latter are likely to harbour the larvæ and moths, or other insects, as well as the hive. But these obnoxious creatures cannot be entirely extirpated without taking away the infected hive, removing the bees, and cleaning it, before it is restored to the former station. The lice are of a slender shape, or filiform, and of a ferruginous colour, and may be destroyed by strewing tobacco over the bees.

The bees are continually fighting between themselves, and robbing each other; avarice, not necessity, leads them to do so, it being almost always the strongest and best-provisioned hives that pillage the weak ones. When once a bee has been able to introduce itself into a hive, and carry away a load of honey without being arrested, it will return a hundred times the same day; and, making it known to its companions, they will then come in hordes, nor cease their pillage until there is nothing left to take. In one day the whole of the honey will be carried off, and with a determination which one can scarcely have an idea of without seeing it. This kind of pillage is most frequent in the spring and autumn, and it is easier to prevent than to stop it; and, for this purpose, the entrance of the hives ought to be straitened in proportion to the population.'

BRITISH WILD BEES.

Besides the garden or hive-bee, as already mentioned, there are various species of bees, which have never been domesticated by man, though many of them construct hives and produce honey. Of such of these wanderers of the wilds as are indigenous to Britain, the most common is the *humble* bee (*bombus*), an insect at least double the size of the hive-bee, with a black head and body, having yellow rings crossing the latter anteriorly and superiorly, and white and black rings alternating at the posterior extremity.

Both on account of their peculiar habits and selected places of residence, this and the other wild species are unfitted for domestication. Few of them survive the rigours of winter; but one, a female, that does escape, manages for a season the resuscitation of the breed. Abroad, it flies in early, and, alone and unaided, sets laboriously to work in constructing its nest, piercing the earth or moss, as its instinct may be, and excavating a small chamber wherein to lay its eggs. It does not make wax and cells for the young. These come to maturity in the cocoons which they spin for themselves in the larva state; and when they emerge, these cocoons form stores for food. The solitary bee feeds alone its earliest progeny, but these soon multiply around it, enlarge the cells, gather honey, and feed the increasing young. The wants of the young go on increasing for a great part of the summer, and the quantity of honey they consume is very large; towards the middle or latter part of September, however, the energies of the bees begin to wax fainter, and little further progress is made in adding to the colony, or in collecting honey. Cold and showery days begin, even by this time, to thin the number of the insect population, who are now seen creeping slowly, with damp and heavy wings, upon the stalks and petals of flowers, where they were formerly seen actively buzzing about in search of honey. The stores of the honey-cups have not outlasted the wants of the young unfledged bees, of which they were the proper food; and if the nests be examined now, these cups are found quite empty. The bees which survive the accidents of rain, cold, and frost, by degrees forsake the nest and its furniture, leaving the latter as a prey to mice, beetles, or other animals. To shelter themselves for the winter, they seek out some dry bank, where they penetrate to the depth of eighteen inches or two feet, pushing up the soil behind them, and leaving no visible track by which they have descended. In these situations they are often found by labourers and others while digging; and such people are often greatly puzzled to imagine how the insect can have reached such a depth. Those who have attended to the habits of wild bees, can readily fix on the spots where they take refuge.

The experiment of domesticating wild bees has been tried; and it was found that, by removing their nest cautiously in an evening, and placing it in a quiet situation, in a garden or other place where they could be observed, they went on with their works without apparent alarm or interruption. During the whole summer, they continued to prosecute their occupations with the same industry as other bees; but about September, as we have mentioned, the hive began to turn languid, and the numbers which appeared going and coming about the entrance became daily smaller. It was imagined they had taken refuge within the hive; but when this was opened, after all seemed to have ceased their labours, everything was found empty and deserted; there were neither bees nor honey; the stronger and younger insects, no doubt, having gone to make burrows for themselves in the earth, and the older ones having gradually fallen victims to the accidents of approaching winter. Our wild bees, therefore, appear to possess their brief lives but for self-enjoyment, or rather to form one of that order of beings created by the great Author of all as if for the purpose of leaving no corner of the universe without its utmost allotment of sentient and enjoying existence.

THE DOG—FIELD-SPORTS.

THE dog is an animal which seems to have been destined by the Creator to be the friend and assistant of man. Throughout the dangers and difficulties which beset the human being, particularly in an inartificial state of society, the dog has ever proved himself the kindly defender of his life and property, as well as a powerful and essential auxiliary in subduing other animals to his purpose. Without such assistance, man would not even yet have obtained a beneficial dominion over the various races of wild animals, or been able to watch with sufficient care those creatures which he domesticates for his sustenance and comfort.

According to naturalists, the dog belongs to the family *Canidæ* (from *canis*, Latin for dog), in the order *Carnivora*, class Mammalia. In the same family are united the wolf, fox, and jackal, and these so nearly approach the dog in physical construction, and certain habits and qualities, that some authorities are inclined to consider them of the same species. Be this as it may, the resemblance in some respects, and great dissimilarity in others, between dogs, wolves, foxes, and jackals, is not more remarkable than the general similarity of dogs to each other, as far as an apparent unity of species is concerned; while at the same time there is a striking difference of form and character between opposite breeds. One dog is large, another small; one is smooth in the skin, another rough; one has a long head, in another the head is short; one has an exquisite sense of smell, another has comparatively little of that power; and so on. We have an animal which watches our flocks; another which tracks and hunts down noxious wild beasts; another which destroys and digs out vermin from the earth; another which guards our houses and lives while we are asleep; another which seeks out for game in our field-sports; another which will plunge into the deepest waters, and save us from being drowned; besides many other varieties, all less or more distinct in character. The difference is so very remarkable, that the *varieties* would be entitled to be classed as of different *species* of animals, unless for the fact that they all breed together, and perpetuate mixed or mongrel crosses. This circumstance led Buffon and other naturalists to infer that all dogs whatsoever are but of one species; the physiological theory being, that no two different species can produce fertile descendants. Buffon further concluded, from a course of observations, that the numerous varieties have sprung from one common root—the shepherd's dog; and that climate, food, and peculiar training, have been the causes of the departure from the primeval stock.

The line of argument adopted in support of this theory is, that in the animal, as in the vegetable kingdom (see Nos. 3 and 35), improved or very remarkable varieties can be produced by selecting kinds, and breeding from them alone; as, for example, taking the two largest dogs of a breed, and breeding from them; then taking the two largest which this pair produces, and breeding from them also; and so on, till a large variety of dogs is ultimately formed. And further, that if each generation be trained in a particular way, the variety will come to possess properties agreeable to the kind of cultivation bestowed upon it. Such, there is reason to believe, is the true explanation of the extraordinary differences of size and character in the canine species. We must view these dissimilarities as a result of a course of treatment from the earliest period of civilisation till modern times. The ancient Egyptians, and after them the Greeks, are recorded to have paid considerable attention to the training of dogs, and, as is well known, this formed a favourite study in connection with the field-sports of later ages. Doubts may very naturally be entertained respecting the power of transmitting acquired qualities from one generation to another of any species of animals; but investigations into the subject afford some remarkable proofs of what can be accomplished by means of careful training or teaching.

EFFECTS OF TRAINING.

The ordinary training conferred on horses, dogs, and other domesticated animals, seems to be sufficient to establish the general fact of animal educability. We have no more forcible illustrations of the principle than in the uses which are now made of certain of the canine species in rural sports. The pointer, setter, springing spaniel, and all that section of dogs, are understood to be descended from one stock—the Spanish pointer—with a slight crossing from the foxhound, for the sake of improving the speed. The original animal may be considered as a record of the primary powers, to which everything else must be regarded as an addition made by human training. Now the original animal is only gifted by nature with a fine scent for game, and a disposition to make a momentary pause on seeing it, for the purpose of springing upon it. Man has converted this inclination to a temporary pause into a habit of making a full stop, or point as it is termed; and the animal, instead of gratifying his destructive tendency by springing upon the game, has been trained to be contented with witnessing a vicarious execution by the gun of his master.

It is a mistake to suppose that only the spaniel tribe is capable of serving sportsmen in the capacity of pointers and setters. There are other classes of dogs which perseverance would enable, to a certain extent, to act in the same way. Gervase Markham, who wrote on sports in the sixteenth century, speaks of having seen dogs of the bastard tumbler kind adapted to act as setters, though not so well as those of the spaniel kind. Mr Blaine ('Encyclopædia of Rural Sports') is of opinion that this power can be cultivated in most dogs. It has even been elicited in another and very different class of animals—the hog. Some years ago Mr Toomer, gamekeeper to Sir Henry Mildmay, bethought him of teaching a pig to act as a pointer, having been struck by the scenting powers of the animal in its search for palatable roots under ground. He began by allowing a young female pig to accompany his pointers, in their breaking lessons, to the field. Within a fortnight, to his own surprise, she was able to hunt and point partridges and rabbits. There being an abundance of these creatures near the keeper's lodge, her education advanced rapidly by frequent exercise, and in a few weeks she was able to retrieve game as well as the best pointer. *Slut*, as this extraordinary animal was called, was considered to have a more acute scent than any pointer in the charge of the keeper; and it was a kennel of the highest character. They hunted her principally on moors and heaths; and it often happened, that when left behind, she would come of her own accord and join the pointers. 'She has often stood,' says Daniel, 'a jack snipe when all the pointers had passed it: she would back the dogs when they pointed, but the dogs refused to back her until spoke to—Toomer's dogs being all trained to make a general halt when the word was given, whether any dog pointed or not, so that she has been frequently standing in the midst of a field of pointers. In consequence of the dogs being not much inclined to hunt when she was with them (for they dropped their sterns, and showed symptoms of jealousy), she did not very often accompany them, except for the novelty. Her pace was mostly a trot; she was seldom known to gallop, except when called to go out shooting;

she would then come home off the forest at full stretch, and be as much elated as a dog at being shown the gun. She always expressed great pleasure when game, either dead or living, was placed before her. She has frequently stood a single partridge at forty yards' distance, her nose in a direct line to the bird; after standing some considerable time, she would drop like a setter, still keeping her nose in the right direction, and would continue in that position until the game moved: if it took wing, she would come up to the place, and draw slowly after it; and when the bird dropped, she would stand it as before.'

These facts, together with what common observation presents to us in domesticated parrots, blackbirds, ravens, magpies, monkeys, &c. place the educability of animals upon a basis, in our opinion, not to be shaken. But the most wonderful thing, and the most convincing part of the proof, remains in the fact of the transmission of *acquired qualities* by animals to progeny. The habit which education has conferred upon the pointer appears in his puppy, which may be seen earnestly standing at swallows and pigeons in a farmyard, before he has ever once seen such a thing done by his seniors, or received the least instruction. Here only the object is amiss; the act itself is perfect. As may be readily supposed, the puppy of a race of English pointers can be trained to the whole business of the field in one-tenth of the time which the most experienced breaker would require to effect any improvement upon the simple instinct of *the pause* in an original Spanish spaniel. On the subject of the hereditary transmission of acquired qualities by animals, we have some curious information from the venerable naturalist, Mr T. A. Knight, in a communication to the Royal Society in 1807:—'In all animals,' he says, 'this is observable; but in the dog it exists to a wonderful extent; and the offspring appears to inherit not only the passions and propensities, but even the resentments of the family from which it springs. I ascertained that a terrier, whose parents had been in the habit of fighting with polecats, will instantly show every mark of anger when he first perceives the scent of that animal, though the animal itself be wholly concealed from his sight. A young spaniel brought up with the terriers showed no marks of emotion at the scent of the polecat, but it pursued a woodcock, the first time it saw one, with clamour and exultation: and a young pointer, which I am certain had never seen a partridge, stood trembling with anxiety, its eyes fixed and its muscles rigid when conducted into the midst of a covey of these birds. Yet each of these dogs are mere varieties of the same species, and to that species none of these habits are given by nature. The peculiarities of character can therefore be traced to no other source than the acquired habits of the parents, which are inherited by the offspring, and become what I call *instinctive hereditary propensities*.'

It appears from another communication made by Mr Knight to the same society in 1837, that he had then been pursuing investigations on this subject for nearly sixty years. He proceeds in that communication to give a general account of his investigations:—'At the period,' he says, 'at which my experiments commenced, well-bred and well-taught springing spaniels were abundant, and I readily obtained possession of as many as I wanted. I had at first no other object than that of obtaining dogs of great excellence; but within a very short time, some facts came under my observation which very strongly arrested my attention. In several instances, young and wholly inexperienced dogs appeared very nearly as expert in finding woodcocks as their experienced parents. The woods in which I was accustomed to shoot did not contain pheasants, nor much game of any other kind, and I therefore resolved never to shoot at anything except woodcocks, conceiving that by so doing the hereditary propensities above-mentioned would become more obvious and decided in the young and untaught animals; and I had the satisfaction, in more than one instance, to see some of these find as many woodcocks, and give tongue as correctly, as the best of my older dogs.

Woodcocks are driven in frosty weather, as is well known, to seek their food in springs and rills of unfrozen water, and I found that my old dogs knew about as well as I did the degree of frost which would drive the woodcocks to such places; and this knowledge proved very troublesome to me, for I could not sufficiently restrain them. I therefore left the old experienced dogs at home, and took only the wholly inexperienced young dogs; but, to my astonishment, some of these, in several instances, confined themselves as closely to the unfrozen grounds as their parents would have done. When I first observed this, I suspected that woodcocks might have been upon the unfrozen ground during the preceding night; but I could not discover (as I think I should have done had this been the case) any traces of their having been there; and as I could not do so, I was led to conclude that the young dogs were guided by feelings and propensities similar to those of their parents.

The subjects of my observation in these cases were all the offspring of well-instructed parents, of five or six years old or more; and I thought it not improbable that instinctive hereditary propensities might be stronger in these than in the offspring of very young and inexperienced parents. Experience proved this opinion to be well-founded, and led me to believe that these propensities might be made to cease to exist, and others to be given; and that the same breed of dogs which displayed so strongly an hereditary disposition to hunt after woodcocks, might be made ultimately to display a similar propensity to hunt after truffles; and it may, I think, be reasonably doubted whether any dog, having the habits and propensities of the springing spaniel, would ever have been known, if the art of shooting birds on the wing had not been acquired.

I possessed one young spaniel, of which the male parent, apparently a well-bred springing spaniel, had been taught to do a great number of extraordinary tricks, and of which the female parent was a well-bred springing spaniel; the puppy had been taught, before it came into my possession, a part of the accomplishments of its male parent. In one instance I had walked out with my gun and a servant, without any dog; and having seen a woodcock, I sent for the dog above-mentioned, which the servant brought to me. A month afterwards I sent my servant for it again, under similar circumstances, when it acted as if it had inferred that the track by which the servant had come from me would lead it to me. It left my servant within twenty yards of my house, and was with me in a very few minutes, though the distance which it had to run exceeded a mile. I repeated this experiment at different times, and after considerable intervals, and uniformly with the same results, the dog always coming to me without the servant. I could mention several other instances, nearly as singular, of the sagacity of this animal, which I imagined to have derived its extraordinary powers in some degree from the highly-cultivated intellect of its male parent.'

To conclude these preliminary observations on dogs. A gentleman of our acquaintance, and of scientific acquirements, obtained some years ago a pup which had been produced in London by a female of the celebrated St Bernard's breed. The young animal was brought to Scotland, where it was never observed to give any particular tokens of a power of tracking footsteps until winter, when the ground became covered with snow. It *then* showed the most active inclination to follow footsteps; and so great was its power of doing so under these circumstances, that when its master had crossed a field in the most curvilinear way, and caused other persons to cross his path in all directions, it nevertheless followed his course with the greatest precision. Here was a perfect revival of the habit of its Alpine fathers, with a degree of specialty as to external conditions at which, it seems to us, we cannot sufficiently wonder. We thus see that not only does what meta-physicians call the *law of habit* exercise a sway in the intellects of animals, but that modification which takes place in human communities, and passes under the comprehensive name of civilisation, also affects the lower tribes of creation. A race of animals, like a race of men, is civilisable; and we cannot doubt that the same softening influences which have produced the advanced nations of Europe, have operated upon the animals existing in the same countries, and made them very different from what they were in early times. It cannot escape remark, that the whole principle of civilisation acquires strength from having its basis thus widened. We become the more confident in the improvability of our own species, when we find that even the lower animals are capable of being improved, through a succession of generations, by the constant presence of a meliorating agency.

GENERAL CHARACTERISTICS OF THE DOG.

The general form and aspect of the dog is too well known to require any description. He has six incisory or cutting teeth in both jaws; beyond which there are, on each side, both above and below, a canine tooth; and still further into the mouth are six cheek-teeth, or molars, in each side of the upper jaw. The three first are sharp and cutting, which Cuvier calls false molars. The next tooth on each side is a carnivorous tooth, furnished with two cutting lobes, beyond which the other two teeth on each side are flat. There are seven cheek teeth, on both sides, in the under jaw; four of these are false molars, a carnivorous tooth, with the posterior part flat, and behind it two tuberculous teeth. The muzzle is elongated, subject to great variety of length in different varieties. The tongue is smooth and soft; the ears erect in the wild varieties, and in some of the tame ones, but, in the latter kinds, for the most part pendulous. The fore-feet are provided with five toes, and the hind-feet with four toes, furnished with rather longish nails, obtuse at their points, and not retractile. Occasionally a fifth toe occurs on the hind-feet, termed the *dew claw;* this is generally removed by the sportsman when the animal is young, as its presence is calculated to impede the animal's movements. The dew claw is regarded as a sign of degeneracy. The females are provided with both inguinal and ventral teats. The pupils of the eyes are circular.

The female goes with young sixty-three days, and generally produces from three to five at a birth, and sometimes even twelve, which are at first blind, in which state they continue for from nine days to a fortnight. About the end of two months their faculties begin to develop themselves. They shed their first teeth at the end of six months, which are replaced by others that do not exfoliate. At twenty months, or two years, dogs arrive at their full vigour. The males continue to propagate for nearly their whole lives, while the female discontinues having young ones at about the age of eight or nine years.

The average age to which dogs live is about fourteen years; they frequently, however, live to sixteen, and even have been known to attain the age of twenty years. In their latter days, dogs frequently suffer greatly from decay, and various diseases. They are extremely subject to rheumatism, from their liability to exposure to rain and damp beds. Until dogs have attained seven or eight years, their teeth are white, smooth, and acutely pointed; but after this age they become yellow-spotted, and their points assume an uneven and jagged appearance. At this time, also, the hair of the muzzle and around the eyes assumes a hoary appearance, and becomes whiter as they increase in years.

The dog is naturally carnivorous, but when domesticated, he does not refuse farinaceous food. He uses grass as a vomit; and drinks by lapping with his long flexible tongue. He does not sensibly perspire by the skin; the superfluous moisture of the body escapes at the mouth by panting, when heated, and by the extraordinary diuretic habits of the animal. The sense of smell is different in different varieties, but in all is sufficiently strong and refined to enable the dog to seek out and follow his master even among a crowd. His sense of hearing is also quick. He expresses anger by growling or barking, but also barks when joyful; and shows delight by the wagging of his tail. He exhibits fear by crouching and whining; howls when pained; and droops his tail under reproof. He sleeps very lightly, so as to be awakened by the slightest noise; and during his slumbers he is apt to dream, as is indicated by starting, whining, and short barks.

The most remarkable feature in the character of the dog is his attachment to man. In wild unpeopled countries, dogs are known to live in hordes, and seek their prey like other untamed animals; but brought into connection with human society, the dog leaves his own species without regret, and is only happy when belonging to a master to whom he can be faithful as a friend, servant, or companion. In this condition of domestication his ambition seems to be the desire to please; he is seen to come crouching along, to lay his force, his courage, and all his useful talents, at the feet of his master: he waits his orders, to which he pays implicit obedience: he consults his looks, and a single glance is sufficient to put him in motion: he is more faithful than even the most boasted among men: he is constant in his affections, friendly without interest, and grateful for the slightest favours: much more mindful of benefits received than injuries offered, he is not driven off by unkindness: he still continues humble, submissive, and imploring; his only hope to be serviceable, his only terror to displease: he licks the hand that has just been lifted to strike him, and at last disarms resentment by submissive perseverance.

More docile than man, as Buffon observes, more obedient than any other animal, he is not only instructed in a short time, but he also conforms to the dispositions and manners of those who command him. He takes his tone from the house he inhabits: like the rest of the domestics, he is disdainful among the great, and churlish among clowns. He knows a beggar by his clothes, by his voice, or his gestures, and forbids his approach. When at night the protection of the house is committed to his care, he seems proud of his charge; he continues a watchful sentinel; he goes his rounds, scents strangers at a distance, and gives them a warning of his being upon duty. If they attempt to break in upon his territories, he becomes more fierce, flies at them, threatens, fights, and either conquers alone, or alarms those who have most interest in coming to his assistance; however, when he has conquered, he quietly reposes upon his spoil, and abstains from abusing—thus giving at once a lesson of courage, temperance, and fidelity.

CLASSIFICATION OF VARIETIES.

Cuvier, the eminent French naturalist, formed a classification of dogs, founded on the shape of the head, and length of the jaws and muzzle. These he has separated into three great groups, as follows:—

I. Matins.—These have a head more or less elongated; the parietal bones insensibly approaching each other, and the condyles of the lower jaw placed in a horizontal line with the upper cheek teeth.

II. Spaniels.—The head moderately elongated; the parietal bones do not approach each other above the temples, but diverge and swell out, so as to enlarge the forehead and cavity of the brain. In this group are included all the varieties of dogs which are of the greatest utility to man, and also the most intelligent.

III. Dogues.—The muzzle more or less shortened; the skull high; the frontal sinuses considerable; the condyle of the lower jaw extending above the line of the upper cheek teeth. The cranium is smaller in this group than in the two previous, owing to the peculiar formation of the head.

These three groups have, for convenience, been further subdivided into nine sections, which we shall now treat *seriatim*—noticing the different breeds or varieties which have been ranked under each:—

I.—Dogs with Lengthened Heads.

SECTION 1. Half-reclaimed dogs, which hunt in packs.

The *Dingo*, or *Australian Dog*.—The head of this dog is not unlike that of a wolf, on which account Bewick calls it the New South Wales wolf. The muzzle is long and pointed, with short erect ears. He is two feet six inches in length, and about two feet in height. His fur is composed of a mixture of silky and woolly hairs, and is of a deep yellowish-brown colour; and his tail is long and bushy, resembling that of a fox, but generally carried curled over his haunch, and not pendent. The dingo, though naturally ferocious, is easily rendered tolerably tame; and in this state many specimens are now brought to this country. They are not to be trusted, however; and the moment they escape from confinement, all their natural bloodthirsty propensities return. We knew one which, after two years domestication, happened to slip the chain, and in less than a week, upwards of a score of sheep were destroyed by him in the neighbourhood.

The *Dhole* is the native wild dog of India, and bears a strong resemblance to the dingo, but without the bushy tail of that species; he is of a uniform bright-red colour. Differently from other dogs which hunt in packs, according to the account given by Captain Williamson, this species always hunts mute, and only utters a soft whispering sound when in high chase, and near his prey. The dhole is exceedingly swift of foot, and soon overtakes most animals which are the objects of his pursuit. It is said they are exceedingly fond of the flesh of the tiger, and that, in consequence, this animal is prevented from propagating to that extent which would soon overrun and lay waste all the countries which it inhabits. This predilection is confirmed by Bishop Heber, who states, upon the authority of the peasants of Khayra, which borders the frontiers of China, that a tiger is often killed and torn to pieces by the wild dogs, which give tongue like foxhounds or harriers. It is in the unfrequented wilds of the western frontiers of India that the dhole takes up his abode, lurking amongst the extensive jungles which cover mighty tracts of that territory.

The *Pariah* is the common village dog of India. He has a small sharp head, with short pricked ears, a slender body, and particularly drawn up about the abdominal region; his chest is deep, his limbs light, and his colour is of a reddish-brown. The native Indians use the pariahs in hunting the tiger and wild boar. They are very fierce, and follow their game with much avidity and determination.

The *Ekia* is the native dog of Africa, and in all likelihood sprung from the same stock as the dhole. They are said to be of various colours—as black, brown, white, and yellowish. They are eaten by the negroes, who relish them greatly. The African wild dogs, like those of India, hunt in packs.

The *South American Dog* is not unlike the dingo, and is about the size of the springer, with short and pricked ears, like most other wild dogs. The hair on his tail is long and bristly; he is of a brownish-gray colour on the back, with sandy-coloured spots on the legs and flanks. In general aspect he greatly resembles the wolf, but is much smaller in size. There is another South American dog called the Alco, of which there are two varieties. The head of the alco is very small, and the ears pendulous, thus differing from almost all other wild dogs. The back is somewhat curved, and the tail rather short. It is said that the Spaniards found this dog among the natives on the first discovery of America. Herrere says that Columbus found in America many dogs which did not bark. But there is reason to suppose that whatever may have been the original types of the South American dogs, they have been greatly altered by intermixture with the descendants of those introduced at the conquest by the Spaniards.

The *North American Dog*.—We have no very distinct account of this variety, but it is said to resemble the dingo in its pricked ears and general conformation. It is remarkable for the acuteness of its scent, and very expert in the detection of its prey, or animals which it may be trained to pursue.

SECTION 2. Domesticated dogs, which hunt in packs or singly, principally by the eye, although sometimes by the scent.

The *Irish Greyhound* ranks among the noblest of the canine race; his mien is striking, full of dignity, and his conformation beautiful. In his general shape he bears a strong resemblance to the common greyhound, but is much taller, and more robust. His use in early times was to free the country of wolves and wild boars, which abounded in England and Ireland; hence he is sometimes termed the 'Irish wolf-dog.' The hair is rough and shaggy, and the colour of these dogs is fawn or pale cinnamon. The Marquis of Sligo is said to have had some of this breed (!), which were of various colours: some were brown and white, and others black and white. The ordinary height of the Irish greyhound is about three feet, although they have been known to reach four feet. Goldsmith, who had seen several of this breed, says they were about four feet high, and as tall as a calf of a year old. The *true* Irish wolf-dog is now extremely rare, if not altogether extinct.

The *Albanian Dog* is about the size of a full-sized mastiff. His hair is very fine and close set, and of a silky texture, variously clouded with brown; his tail is long and bushy, and carried like that of a Newfoundland dog; his muzzle is pointed, and rather long; his legs are strong and muscular, which fit him well for hunting the wild boar, in which sport he was much used in ancient times; he was also used in hunting wolves, and in protecting sheepfolds from thieves.

The *French Matin* has an elongated head, and flat above; his ears are erect, and slightly pendulous towards the tips; the hair of a yellowish fawn-colour, with darker, oblique, and, parallel indistinct rays traversing the whole of his fur. His height is about two feet, and his length three feet. He is strong, muscular, and active, and very courageous. He evinces great eagerness in hunting the wild boar and wolf, in which sport he is frequently employed. Pennant thinks this variety is a descendant of the Irish greyhound.

The *Scottish Highland Greyhound* will either hunt in packs or singly. He is an animal of great size and strength, and at the same time very swift of foot. In size he equals, if not excels, the Irish greyhound. His head is long, and the nose sharp; his ears short, somewhat pendulous at the tips; his eyes are brilliant and very penetrating, and half concealed by the long crisped hairs which cover his face and whole body. He is remarkable for the depth of his chest, and tapers gradually towards the loins, which are of great strength, and very muscular; his back is slightly arched; his hind-quarters are powerfully formed, and his limbs strong and straight. The possession of these combined qualities particularly fit him for long endurance in the chase. His usual colour is a reddish sand-colour, mixed with white; his tail is long and shaggy, which he carries high, like the staghound, although not quite so erect. It is this noble dog which was used by the Scottish Highland chieftains in their great hunting parties, and is supposed to have descended in regular succession from the dogs of Ossian.

The *Russian Greyhound* is nearly as large as the Irish greyhound, resembling him in shape as nearly as possible, but covered with long bushy hair. His general colour is a dark reddish-brown. He is sometimes hunted in small packs, and as frequently single, in which case he not unfrequently will kill a wolf, deer, or wild boar, without any aid whatever. When used in coursing, he is taken to the field in slips, in the same manner as is practised with greyhounds.

SECTION 3. Domesticated dogs, which hunt singly, and always by the eye.

The *Gazehound* is a dog, the breed of which is now lost. It was hunted in the same manner as the greyhound, and took foxes and hares by running them down. It is said by Bewick that it was employed in stag-hunting, which we think is rather doubtful, as although the stag is an animal of great speed, yet the contest between it and a dog possessing the swiftness of a greyhound would be but very unequal.

The *Greyhound* is the fleetest of all dogs, which is in consequence of his peculiar conformation. His head is long, tapered, and shaped like that of a snake; his neck long and slender; his ears somewhat erect and pricked, slightly pendulous at their tips: the tail ought to be very fine, pointed, and the hair on it very short; the chest should be wide and deep; the belly drawn up, with strong loins, and with large and prominent hip-muscles. This dog is by no means so intelligent as many other varieties, and he is, in consequence, much less susceptible of education. He has, however, very fine feelings, and seems to be much alive to caresses, which excite him to such a degree, as to produce a quick pulsation of the heart. This may be felt beating against his side with much vigour. He is one of the most elegantly-formed of all the canine species.

The *Scotch Greyhound* is formed exactly like the common greyhound, and differs from it merely by being of a larger size, and in the hair being longer and wiry. The general colour is reddish-brown or sandy.

Shepherd's Dog—Scotch and Irish Greyhounds.

The *Italian Greyhound* is merely a miniature of the common greyhound, being only about half the size of that dog. It has a very fine coat of a silky texture, and is so tender, as to be easily injured by cold or wet. It is used only as a *pet*, being altogether valueless in other respects.

The *Turkish Greyhound* is still smaller than the Italian greyhound, being little more than half its bulk, and is entirely divested of hair, except on the tail, where it is few and scattered. Its usual colour is a blackish lead colour. It abounds in Turkish towns, where it forms a dreadful nuisance to travellers.

II.—Head less elongated than former division.

SECTION 4. Pastoral dogs, or such as are employed in domestic purposes.

The *Shepherd's Dog* is covered with long flowing, and somewhat woolly, hair; his muzzle is long and pointed, and his ears erect, and slightly bent downwards at the tips; his tail is long and bushy; and the usual colour of his fur black and white, or varied with black and gray; the backs of his fore-legs have also long hairs. The peculiar and highly useful qualities of this dog seem to be rather intuitive than acquired; indeed nothing can hardly exceed the quickness with which he can be taught any lesson; and certainly no other dog has the same patient perseverance and courageous fidelity, and at the same time possessed of the greatest discrimination. The labour of a shepherd, with the assistance of this faithful and intelligent animal, is comparatively an easy task; and it is hardly possible to fancy a more arduous employment than it would be, if divested of the services of the dog: for without him, how could he collect extensive flocks scattered over high and widely-spread mountain ranges! The shepherd's dog is possessed of great sagacity, gratitude, and self-denial, as is well known from innumerable anecdotes.

The *Cur*, or *Watch-Dog*, differs from the shepherd's dog in being nearly smooth; he is stronger in his make, and has half-pricked ears, and his tail is rather short, and slightly feathered beneath. He is a trusty and useful servant to the farmer and grazier, and is chiefly employed in driving cattle; and being larger and stronger than the shepherd's dog, from which he is sprung, he is better qualified for the grazier and farmer. He bites with great keenness, and always makes his attack at the heels. His sagacity is very great, and he soon knows his master's fields, and watches with great assiduity the cattle which are in them. A cross between this and the true shepherd's dog has been found to be extremely useful on the sheep-runs of Australia.

The *German Dog* is a small-sized animal, with bushy turned-up tail, bushy neck, small muzzle, and is generally of a cream colour, but also sometimes black. His manner is brisk, and his character that of great fidelity. He is seen all over central Germany, where he appears to be employed chiefly as a merry companion to man, and also for watching. A few specimens are beginning to be seen in England.

SECTION 5. Water-dogs, which delight in swimming, having their feet in general semi-webbed.

The *Pomeranian*, or *Wolf-Dog* has the hair on the head short, as is also that on the feet and ears; but it is long and silky on the body and tail, which last is curled up in a spiral form. His colour is white, black, gray, or sometimes yellowish; his head is long, and his muzzle pointed; his ears are short and pricked. He is possessed of intelligence nearly equal to that of the shepherd's dog, but is much less to be trusted.

The *Siberian Dog* has much the appearance of the Pomeranian dog, and is very nearly allied to him, except that he is covered with long hair, even on the head and paws. In their native country, four of these dogs are attached by pairs to a sledge, and in front of them is placed a leader, on the proper training of which much of the useful services of the others depend. These sledges are just large enough to contain one person, who directs them with his voice, and in which he is partially assisted by a stick. The reins are fastened to the dogs' necks by a collar. These dogs, thus yoked, have been known to drag a sledge from seventy to eighty miles in a day; and so powerful is their scent, that they contrive to keep on the beaten track by that means alone, even although it be obliterated by showers of snow.

The *Greenland Dog* is of a large size, strong in the bone, and its fur consists of long, thick-set, wool-like hair; his muzzle is sharp, and his ears short and pricked; his tail is thick, bushy, and spirally twisted. He is closely allied to the preceding variety.

The *Iceland Dog* is shorter in the hair than the above variety; his ears are pricked, but slightly bent downwards on the tips. His general colour is white, with patches of black differently disposed.

The *Esquimaux Dog.*—This highly useful variety is described by M. Desmarest as having the head shaped like that of the wolf-dog; the tail is spreading and curved, and the ears erect. The hair is thinly scattered, and consists of two sorts, the one silky, the other thick and fine, and somewhat curled, and so detached from the other that it may be pulled off in flakes from the animal. The dogs of the Esquimaux are very good-tempered and intelligent; active, swift, and enduring. (For their utility as beasts of draught, see INLAND CONVEYANCE, p. 103.)

The *Hare-Indian Dog* has a narrow, elongated, and pointed muzzle; his ears are broad at the base, and pointed towards the tips, and perfectly erect; his legs are long and slender, and his tail thick, bushy, and curved slightly upwards, but by no means so decidedly curved as that of the Esquimaux dog. His body is covered with long straight hairs, the ground colour of which is white, marked with large irregular patches of grayish-black, intermingled with various shades of brown. Dr Richardson says it has neither courage nor strength for pulling down any of the larger animals. The feet of this variety are unusually large, spread, and thickly clothed with fur, in consequence of which he can run upon the snow with rapidity and ease without sinking.

The *Newfoundland Dog*.—This beautiful and intelligent dog is remarkable for the symmetry of his form and the acuteness of his understanding. He measures, from the tip of the nose to the point of the tail, six feet and a-half, the length of the tail itself being two feet; from the one fore-foot to the other, over the shoulders, five feet eight inches; the girth behind the shoulders three feet four inches; the length of his head is fourteen inches. He has webbed feet, in consequence of which he is a dexterous swimmer. His hair is long, flowing, and slightly curled, and his tail very bushy, particularly in the lower side, and he carries it in a very graceful manner. The docility of the Newfoundland dog is very great; there are innumerable most striking anecdotes of his sagacity and benevolence of disposition, particularly with reference to his saving persons from drowning. During the gale on Thursday, June 11, 1829, a vessel was driven on the beach at Lydd; no boats could get off to the assistance of the crew, who were, however, all saved and brought ashore through the activity of a fine Newfoundland dog. The surf was rolling furiously, and eight poor fellows were crying for aid, which the spectators could not afford them, when one man directed the attention of his dog to the vessel, and the intelligent animal at once swam towards it, and the crew joyfully made fast a rope to a piece of wood, which the dog seized and swam with to his master on shore; a line of communication was thus formed, and the eight mariners rescued from a watery grave. Intelligent and sagacious as the Newfoundland dog undoubtedly is, there are certain occasions on which he is not to be trusted; and if sharply reproved or punished, is apt to resist the lash even of his master.

The *Russian Dog* is somewhat larger and stronger than the Newfoundland dog; he is a cross between that variety and the Siberian dog, and has now become a distinct race. His head is large, with his ears pendulous and rather full-sized; his tail is curled over his back; his hair is very long and shaggy, consisting of black and white patches.

The *Great Rough Water-Dog* is web-footed, swims with great ease, and dives with much courage and dexterity; his hair is long and curly, and he is of various colours; his legs and feet are also thickly covered with thick and bushy hair.

The *Large Water-Spaniel* is about the size of the English setter, but of a stronger make. His face is smooth, as also the front of his legs; while the rest of his body is covered with small crisped curls, usually of a dark liver-brown colour. This dog is very valuable in the sport of shooting wild-fowl.

The *Small Water-Spaniel*, or *Poodle*, is a breed between the large water-dog and the springer; he is thickly covered with fine hair, all of which is in distinct small curls, more like an effort of art than of nature. It is one of the most active of dogs. Its general colour is white, and sometimes it has various black patches. It dives with much dexterity, and will leap from a very great height into the water; we have seen one leap over Old Tyne Bridge at Newcastle—a height of nearly fifty feet.

The *Shock Dog* is the smallest of the water-dog varieties, and is probably bred between the smaller spaniel or King Charles's dog and the poodle. Its hair is extremely long and flowing, so much so, that its ears and eyes are nearly concealed from view by it. It is kept only as a lapdog.

SECTION 6. Fowlers, or dogs whose inclination is to chase and point birds, and hunt singly by the scent.

The *Springer* is shaped much like the English setter, but shorter in the body and legs in proportion to his size, being about two-fifths less than that dog; the hair is long and shaggy, and the ears very long and pendulous, and covered with long waved hairs. He is usually of a white colour, with patches of liver-colour or chestnut. He is, however, sometimes black, and at other times entirely of a liver-coloured brown.

The *Cocker* is about a third less than the springer, and like it in all respects. It is used as well as that variety for raising woodcocks and snipes, in which exercise they are both very expert and hardy.

The *King Charles's Spaniel* is still less than the cocker, and distinguished by the very great length of his ears. Its hair is silky; and this, with its gentleness and small size, has rendered it a favourite pet of ladies of fashion. It is fashionable for ladies to carry these little creatures in their arms while walking in the streets—an exhibition so absurd that it is even beneath reprobation. They are sold at a high price.

The *Comforter* is another diminutive variety of this race, chiefly used as a lapdog. It is supposed to be a cross between the Maltese and King Charles's dog.

The *Maltese* and *Lion Dogs* are descendants from nearly the same stock. They are also favourites with the ladies; and are rare, but useless.

The *Alpine Spaniel*, or *Great St Bernard Dog*, exceeds other varieties of the spaniel for size and beauty. Its usual height is two feet at the shoulders; and he is six feet in length from the nose to the tip of the tail. Two of these dogs are sent out from the monastery of the Great St Bernard, situated among the Alps of Switzerland, to scour the mountains during snow-storms, in search of lost or wearied travellers—the one with a warm cloak fastened to his back, and the other with a basket tied round his neck, containing a bottle with some cordial, and bread. In this employment they manifest great judgment, and seem to understand perfectly the import of their mission. They are frequently of the greatest use in meeting the travellers, who in those stormy and dangerous regions often fall victims to the inclemency of the weather. It is said that if they meet with a traveller who has sunk under the fatigue and inclemency of the blast, that they will lie close to him, until by their warmth they restore heat and energy to the animation which is nearly suspended, and thus frequently will save the life of the sufferer. Should they discover a traveller to have fallen into some deep pit or fissure, whence he is unable to ascend, and if they are unable to render him any assistance, they will return to the convent and give the alarm to the monks, and then conduct them to the place where the unfortunate traveller is immured.

The *Old English Setter* is supposed to have been produced between the large water-spaniel and the Spanish pointer. They were much more curled than the present breed of setters, and were very steady in the field, but not so rapid in their movements.

The *English Setter* is a mixed breed between the water-spaniel, Spanish pointer, and the springer, which has attained a very high degree of perfection as a sporting dog. He is one of the most beautiful, lively, active, and hardy of dogs.

The *Spanish Pointer* is the stock from which the English pointer has sprung. He is one of the most stanch of all dogs used in the sports of the field, although he is considered too heavy for the present improved mode of sporting, and has now nearly become extinct in Great Britain.

The *English Pointer* was obtained by a cross of the Spanish pointer and foxhound, and is unrivalled for the rapidity of his movements in the field, and the beauty and symmetry of his form. Since his first production, he has been improved by being re-crossed with the harrier. He is subject to considerable variety in point of size as well as of colour. When well trained, and of a pure breed, he is exceedingly staunch—instances having been known where he has remained above an hour in the act of pointing.

Newfoundland—Scotch Terrier—English Pointer—Cocker.

The *Small Pointer* is a diminutive breed, being only about two feet from the point of the nose to the tip of the tail, and scarcely a foot in height, and is a complete and beautiful miniature of the large pointer. They have proved themselves excellent sporting dogs, but their small size renders them unfit for use in rough land.

The Russian Pointer is much like the Spanish pointer in shape, but his hair is long and wiry. He is valuable if well trained; but is rather obstinate and unyielding in temper.

The *Dalmatian* is a handsome animal, beautifully spotted black on a white skin. In his native country he is employed as a pointer; but imported into England, he has there lost all qualities for sporting, and is kept merely as an attendant on carriages—hence the common term 'coach-dog.' While most other dogs attach themselves to man, this one seems to care for nothing but horses. He lives by choice in the stable, and is happiest when running at the heels of the horses; even his own species he abandons in following this prevailing taste. He barks little, and is docile.

SECTION 7. Hounds which hunt in packs by the scent.

The *English Terrier* is too well known to require any description. He is possessed of great courage, and is famous for killing all kinds of vermin, and at one time formed a useful attendant upon a pack of foxhounds, for getting into the earth when the fox has taken to his hole, and driving him out. His hair is smooth. His general colour is black, with tanned cheeks, and the insides of his legs are of the same colour. They are now to be met with of a brown, and even white colour, but these have unquestionably an admixture of some other breed in them.

The *Scotch Terrier* has short wiry hair, very rough, and is much shorter in the legs than the English terrier. His usual colour is sandy, but he is to be found black, and also gray. He bites with great keenness, and is a bold and determined dog. He will attack dogs of any size; and when he fixes on an animal, he maintains his hold with great pertinacity. He was at one time much used as an attendant upon packs of foxhounds, and forms an excellent killer of vermin. The *Skye terriers*, or terriers of the Western Isles, are longer in the body, lower in the legs, and decidedly rougher and shaggier than those of the Lowlands. Indeed they form altogether a distinct variety.

The *Talbot* is one of the primitive breeds of British dogs, and is the same which was used by the ancient Britons in the chase of the deer and other wild animals. It is now, we believe, extinct, or at least not in common use. He had a broad mouth, very deep chops, large pendulous ears, was fine-coated, and usually of a white colour. He was formerly known as 'St Hubert's breed,' and was distinct from the bloodhound, though by some confounded with that dog.

The *Bloodhound* is a powerful and sagacious animal, generally of a dark colour, with brown markings, and is endowed with a keen scent. On being led upon the footsteps of any animal or man, he will follow them up with unerring precision. This has led to the breed being employed for tracking criminals, or the unhappy victims of oppression. By the Spaniards a breed was taken to Cuba to track the natives, and this race of animals still exists in that island. A correspondent in a newspaper thus speaks of them:—'At a period not very remote, the unfortunate negroes in the Spanish settlements were frequently torn to pieces by the Cuba bloodhounds. In fact, under the title of Chasseurs, the Spaniards maintained regular regiments of these dogs and their attendants. In pursuing or hunting the runaway negroes, the chasseur is generally accompanied by two dogs, and armed with a *couteau de chasse*, or straight sword; and we are informed that these bloodhounds, when well and properly trained, on coming up with the object of pursuit, will not kill him unless resistance is offered, but bark at and terrify him till he stops, when they crouch near him, and, by barking, give their keepers notice, who approach accordingly, and secure their prisoner.

Dallas, in his account of the Maroon War in Jamaica, mentions an importation of these Cuba bloodhounds, in order to assist the regular troops in reducing the refractory Maroons. It may seem strange that dogs were called to the assistance of well-disciplined soldiers; but in order to elucidate the subject, it must be observed that the armed Maroons, under the conduct of various cunning leaders, particularly of Cudjoe, Smith, and Johnson, aware of their own inferiority in point of that organisation which constitutes the strength and essence of a regular army, cautiously avoided meeting their opponents on the plain; on the contrary, they retired to the impenetrable fastnesses of the woods and mountains, and by means of ambuscades, contrived so to harass the troops, that the governor of Jamaica ultimately procured a company of these dogs and their attendants from Cuba, which arrived at Jamaica under the command of Don Manuel de Sejas; and a tolerable idea of these dogs may be formed from a review which took place immediately after their arrival. General Walpole, who conducted the war against the Maroons, being anxious to review these chasseurs, left headquarters the morning after they landed, accompanied by Colonel Skinner, and arrived in a postchaise at Seven Rivers. Notice of the general's approach having been given, the chasseurs were taken to a distance from the house, in order to advance when he arrived. The Spaniards were drawn up in a line at the end of a gentle declivity, and consisted of upwards of forty men, with their dogs in front unmuzzled, and held by cotton ropes, as it was intended to ascertain what effect would be produced on the dogs if actually engaged under a fire of the Maroons. The Spaniards, upon the word being given, fired their fusees, when the dogs pressed forward with almost ungovernable fury, amidst the shouts of their keepers, whom they dragged along with irresistible impetuosity. Some of these ferocious animals, maddened by the shout of attack, and held in check by the ropes, actually seized upon the gun-stocks in the hands of the chasseurs, and tore pieces out of them. The unfortunate Maroons, who had successfully opposed all the efforts of regular troops, were panic-struck on the arrival of the bloodhounds, and surrendered without once daring to come in contact with animals which at best could oppose but a feeble resistance to firearms.'

The *Staghound* is the largest of all the British dogs of the chase; he has a noble and dignified aspect, and possesses great sagacity and endurance in the chase; this dog is also supposed to be a direct descendant of one of our original British dogs.

The *Foxhound* has a much larger muzzle than the staghound, and his head is small in proportion to the size of his body; his ears are very long and pendulous, although less so than those of the staghound and bloodhound. Though a determined enemy of the fox, this active hound is by no means destitute of warm affections. A foxhound bitch, belonging to the Kivington Hunt, near Bolton, on the 8th November 1792, during the chase, pupped four whelps, which she carefully covered in a rush aisle, and immediately afterwards joined the pack. In a short time after, she pupped another, which she carried in her mouth during the remainder of a hard chase of several miles, to the great astonishment of a number of spectators, after which she returned to the place where she had originally dropped the four.

The *Harrier* is used in hare-hunting, and was originally obtained by a double cross between the small beagle and southern hound. He is very eager in the pursuit of the hare. There are few instances of any of the deer tribe being hunted with success by dogs of so small a description as harriers.

The *Beagle* is the smallest of the dogs of the chase. He is possessed of a very acute sense of smelling, and pursues the hare with unwearied steadiness; and what he wants in speed and strength he makes up by his perseverance.

The *Otter-Hound* is a cross between the large southern hound and the large rough terrier. He has a large head, with pendulous ears, and his whole fur is of a wiry texture, and rather long; his colour is either sandy or black. Otter-hunting was a favourite sport in ancient times, but is now seldom pursued.

The *Bull-Terrier* is a cross between the bull-dog and the terrier, as its name implies, and has now assumed the character of a distinct breed. It is much used by gentlemen of the fancy as a fighting dog; it forms likewise a first-rate animal for the chain.

SECTION 8. Mongrel hounds, which hunt singly either by the scent or by the eye.

The *Lurcher* is a cross between the greyhound and harrier, and re-crossed with the terrier. His limbs are strong; his head less sharp than that of a greyhound; his ears are short, erect, and half pricked; and his hair coarse and wiry. He is much used by poachers, and is famous for killing rabbits, as he has a fine scent, and runs his game without giving tongue.

The *Leyemer* and the *Tumbler* are imperfectly known dogs, which are now nearly if not entirely extinct. They hunted both by the scent and eye.

The *Turnspit* is a small dog with a long body and short crooked limbs, and was much used in turning the spit before the invention of jacks. Breeds between this now useless variety of dogs and mongrel terriers and hounds, appear to form the nondescript and ugly races of animals which haunt the streets of our large towns, but whose numbers are now diminishing by the proper interference of the police.

III.—With Short Heads.

SECTION 9. Watch-dogs, which have no propensity for hunting.

The *Mastiff* has a large flat head, and a short and blunted muzzle; his lips are full, and hanging considerably over the lower jaw; his ears, although rather small, are pendulous. He has a sullen and grave aspect, and is excellent as a watch-dog; his voice is loud and deep-toned. He is a dog of large size, and is supposed to have been produced betwixt the Irish greyhound and English bull-dog. Like the dog next mentioned, he is ferocious in disposition, and of little use when out of the chain.

The *Bull-Dog* is remarkable for the depth of his chest and the strength of the whole muscles of his body. His head is large, flattened above, and his muzzle much blunted, with the under jaw projecting considerably beyond the upper one; his eyes are set far apart, and project considerably from his head; his power of smelling is less acute than any other of the canine race, on which account he is a dangerous dog, for he has frequently been known to lay hold of his master without discriminating the difference between him and a stranger. He is the boldest and most obstinate of all dogs, and has been known to hold his adversary so determinedly that his legs have been cut off without making him desist.

Many instances have been recorded of the invincible courage of the English bull-dog, but we scarcely recollect one in which so much unconquerable spirit and tenacity of life have ever been displayed as on the following occasion:—A short time since, a large dog of this species, from some cause that was not observed, suddenly flew at a fine cart-horse that was standing at the end of the Salthouse Dock, Liverpool, and fixing his lacerating teeth in his shoulder, defied every effort to get him off. At first he was beaten with cartwhips and sticks, with such fury as seemed to break his bones; but this being unavailing, a carpenter with an adze in his hand came up and beat him with the blunt iron head of the instrument, till it was thought he had pounded him to a jelly; but the dog never moved a tooth. A man then took out a large pointed clasp-knife, with which he stabbed him repeatedly in the back, loins, and ribs, but with no better success. At length one of the spectators, who appeared to have more strength of sinew and arm than the rest, squeezed the ferocious beast so tightly about the throat, that at length he turned up the white of his eyes and relaxed his jaws. The man threw him off to a distance, but the dog immediately went round the crowd, got behind the horse, and again seized him by the under part of the thigh. As no terms could now be kept with this untameable brute, he was again loosened, and thrown into the dock to drown. He instantly, however, rose to the surface, when a sailor struck him a supposed deadly blow on the head with a handspike, which again sent him to the bottom. He arose once more, and was again sent down in the same manner, and this process was repeated five or six times. At length one of the bystanders, who either possessed or assumed some right of property in the dog, overcome by his amazing tenacity of life, and weary of persecution, got him out, and walked off with this prodigy of English courage, to all appearance very little the worse for the horrible punishment he had undergone. Since the very proper disuse of bull-baiting, this ferocious variety of the dog has fortunately diminished in number.

The *Pug Dog* is descended from the bull-dog, by a cross with the small Danish dog, and resembles the former so much in appearance that he may be considered as a miniature of that variety. He is a useless dog, and with generally a bad temper, has no good quality to recommend him.

GENERAL MANAGEMENT.

As formerly mentioned, dogs are very susceptible of education, and will fall into such habits as are impressed upon them by a course of training. Whatever be the peculiar variety kept in or about a dwelling-house, it is important that he be at least taught good manners; as, for example, to be silent and lie down when bidden, to refrain from leaping on the knees of persons visiting the family, and not to sit staring at meals, watching every bit that is put in the mouth. To make a dog behave properly in these and other points, he must be carefully taught when young, and for this purpose his master requires to employ a judicious mixture of severity and gentleness. He must be made fully aware that he must do as he is bid; that if he do not he will be punished, but that if he obey he will be rewarded. As all dogs are very tractable in such matters, they will soon learn to comprehend the meaning of a look, a sign, or a word, and will act accordingly. As very few persons take the trouble to teach domestic dogs either one line of conduct or another, we see on all occasions instances of the natural consequences of such neglect.

Breeding.

The best dogs are produced from parents not less than two years old, to which period a valuable bitch should be reserved. During her heats before this time she should be locked up, and be treated with a little cooling medicine. All who are interested in preserving the breed of their dogs should on no account suffer a cross. In every instance let the male and female be of the true breed designed, not mixed or deteriorated. If a slight alteration of character be desirable, breed from the nearest varieties. Breed always from the healthiest and best-shaped animals. Mongrel breeds are good for nothing.

Breeders of sporting dogs require to pay marked attention to these principles. According to the author of the 'Oakleigh Shooting Guide,' the theory respecting pointers is, 'that the farther any dog is removed from the original Spanish pointer, the worse the dog is; and consequently that all attempts to cross the pointer with any other blood must necessarily deteriorate the breed. The greyhound is seldom or never crossed to give him additional fleetness, nor the hound to improve his nose; why, then, should the pointer be crossed with dogs which, in so far as the sports of the field are concerned, scarcely inherit one quality in common with him! Attempts, however, are constantly made to improve the pointer by a cross with the bloodhound, fox-hound, Newfoundland dog, or mastiff, sometimes with a view of improving his appearance, and bringing him to some fancied standard of perfection, but in reality inducing a deformity. The best pointer is the offspring of a pointer-bitch by a pointer-dog; such a one is nearly broken or trained by nature. The Spanish [or true] pointer seldom requires the whip; the hound-pointer has never enough of it.' The same writer continues—'Dogs should be constantly shot over during the season by a successful shot, and exercised during the shooting recess by some person who understands well the management of them, otherwise they will fall off in value—the half-bred ones will become unmanageable, and even the thorough-bred ones will acquire disorderly habits.'

It appears that the females, before or during a state of heat, are liable to receive mental impressions of the appearance of the males with which they have been in company, and that these remembrances will affect their progeny even for years afterwards. We beg to refer to 'Blaine's Encyclopædia of Rural Sports,' p. 412, for some interesting information on this subject.

Whelps, at a month old, are generally deprived of their dew-claws. With some varieties it is also the custom to shorten the ears and tail, with a view of improving their appearance; but it is questionable if any breed can be improved in aspect by such treatment, and certainly no pure and well-formed variety can benefit by such mutilations. It is not customary to emasculate males, except those which are intended for pets; the operation renders the animal a much more docile and agreeable companion. There is a prejudice of very old standing, that dogs have a worm beneath their tongue, and that the removal of this, called *worming*, deprives the animal of the power of biting should it become rabid. No worm exists; and it is doubtful if the process is of any use. That which is called a worm is merely a minute ligament or fibrous cord in the bridle beneath the tongue; and when the bridle is cut, the ligament may be drawn forward and separated at both extremities; the contraction of the ligament, on extraction, resembles the movement of a worm, and hence the origin of the term.

Feeding.

Some of the most troublesome traits in the dog's behaviour arise from mismanagement in feeding. If a dog be half-hungered, he cannot be blamed for watching the breakfast or dinner table. We advise all who indulge themselves with keeping dogs, not to leave their feeding to the chance scraps of either the kitchen or the parlour. Give the dog his own regular meals, and with food suitable to his wants or the duty he has to perform. The food should be chiefly flesh of some kind, boiled and cold; if given raw, it has a tendency to foster ferocity of disposition, and will cause the animal to be offensive in smell. No pet-dog, especially, should ever be allowed to eat raw meat. Any common pieces of flesh or tripe will answer for dog's meat. Some persons give liver, which is decidedly bad; it relaxes the bowels, and is otherwise objectionable. Besides the piece of boiled meat considered necessary, give dogs a few bones from the dinner table; they are fond of these, and they are useful in cleaning and preserving their teeth, and keeping their bowels in order. If the dogs will take it, they should also be given a little farinaceous food, as morsels of bread or a little oatmeal porridge with milk.

The nature of the dog leads him to feed well when food is offered to his appetite, and to feed seldom. Once a day, therefore, is, in ordinary circumstances, sufficiently frequent for his meals. Present him with his allowance in the morning or forenoon, and give him no more till next day. He, however, requires to drink frequently; and it is a leading rule in keeping a dog, to have at all times a pan of clean cold water ready for his use. Change the water daily, or oftener.

For the feeding of hounds, Daniel recommends that flesh meat should be alternated with a diet of oatmeal porridge, made with broth in which meat has been boiled. Greens boiled in their meat is also proper. 'A horse killed and given to the hounds whilst warm, after a very hard day, is an excellent meal; but they should not hunt till the third day after it. The bones broken are good for poor hounds, as there is great proof in them. Sheep trotters are very sweet food; and bullock's paunches may also be of service in a scarcity of horse flesh. Hounds should be sharp-set before hunting; they run the better for it.' The same excellent authority continues to observe that hounds should be fed once when returned from the fatigues of the chase, and again some time afterwards. 'It is the best plan to feed twice the hounds that have been out. Some hounds will feed better the second time than the first; besides, turning them out from the lodging-house refreshes them; they stretch their limbs, and the litter being shaken up, and the kennel cleaned out, they settle themselves better on the benches afterwards. At all times, after being fed, the hounds should be turned into the grass court to empty themselves; it will not a little contribute to the cleanliness and health of the kennel.'

Lodging—Kennel Treatment.

Dogs require to be lodged in a dry situation, at a moderate temperature. The practice of keeping dogs out all night during frosty weather, or of putting them into cold coach-houses, is most inhumane and disgraceful. Those kept for watching the outside of premises should be provided with a comfortable house of wood, bedded with clean straw, and sheltered from cutting winds. A dog kept in a dwelling-house should have an appointed place, as in a lobby, for sleeping; its berth should consist of a basket, open box, or small house, according to the taste of the animal. A spaniel will not go into a dog-house; a terrier prefers it. In any case, the berth should be laid with a mat or carpet, which must be frequently washed.

Damp is seriously injurious to dogs. It produces rheumatisms, which show themselves by lameness in the shoulders, and other disorders detrimental to their usefulness. It is therefore of great importance to build kennels in airy situations, and to keep them dry and airy. The best kennels are paved with tiles or stone, but on the floors there are raised benches, littered with straw in winter, on which the dogs repose. The straw should be daily changed, nothing being of so much consequence as cleanliness, both for the sake of general health, and preserving the powers of scent of the animals. For this latter purpose some keepers of packs of hounds have a change of rooms, one being used while the others are becoming sweet after cleaning. On this subject Daniel observes—'The excellent sense of smelling, so peculiar to the hound, is what our sport entirely depends on; care therefore must be taken to preserve it, and the utmost cleanliness is the surest method: to keep the kennel sweet cannot be too much recommended, and is on no account to be neglected. The exactness of the master in this particular will insure that of the feeder.

Hounds that come home lame should not be taken out the next hunting day, since they may appear sound without being so. At the beginning of a season, the eyes of hounds are frequently injured; such hounds should not be hunted; and if their eyes continue weak, should lose a little blood. Such as have sore feet should have them well washed out with brine or pot-liquor. Hounds unable to work should be permitted to run about the house; it will be of great use to them; and such as are ill or lame ought to be turned into a kennel by themselves; there it will be more easy to give that attention both to their medicine and food which is requisite.'

Hounds which are properly disciplined are obedient in a very extraordinary degree to the orders of the huntsman. 'To see,' says the writer of the article *Hunting*, in the Encyclopedia Britannica, 'sixty couples of hounds, animals all hungry as tigers, standing aloof in their yard, and without even hearing, much less feeling, the whip, not daring to move until the order is given to them. And what is the order given? Why, at the words "Come over, bitches," or "Come over, dogs," every hound of each individual sex comes forward, as the sex it belongs to may be called for, leaving those of the other sex in their places. Then the act of drawing them to the feeding-troughs is an exceedingly interesting sight—often, with the door wide open, having nothing to do but to call each hound by his name, which of course he answers readily to. The expression of countenance, too, at this time is well worthy of notice; and that of earnest solicitation, of intreaty, we might almost say of importunity, cannot be more forcibly displayed than in the face of a hungry hound awaiting his turn to draw. He appears absolutely to watch the lips of the huntsman, anticipating his own name.'

Health—Disease.

All dogs whatsoever, but those designed for field-sports in particular, require to be kept in what is called 'condition;' that is, neither too fat nor too lean, but the body in that hardy and active state that will enable the animal to perform its duties. If loaded with flesh or fat, it will not possess wind, or a due power of quick breathing, for any length of time in the chase. Colonel Cook observes, on what constitutes a proper condition—'The ribs should be visible, and the flank moderately hollow, but the loins must be well filled up in a dog in perfect condition. When dogs exhibit general fulness and too much flesh, commence by physic and a regular course of exercise, which should be mild at first, but increased until it is severe. Avoid too great a privation of food, otherwise the conditioning process will be retarded.'

To keep a dog in a state of good health, he must not only be regularly fed and admitted freely to water, but be allowed plenty exercise daily in the open air, and kept in a cleanly condition. If his bowels appear relaxed, he is not in sound health; and as a preventive of this, let his food, as already said, be substantial, and consist partly of bones; let him also have access to grass; every proper kennel has a grass-yard to which the dogs can resort. In the pan of water used by house-dogs put a piece of brimstone; it slightly affects the water by lying in it, and helps to keep the animals cool.

All dogs are liable to be troubled with fleas, which they get from the ground; the skin also contracts dirt, and from that or other causes becomes offensive in smell. The remedy is cleanliness. Every lap or house-dog should be washed at least once a week with soap and water. Some dogs have a great dislike to washing, but it must nevertheless be performed. After washing thoroughly, rub the animal dry with a hard cloth, and comb and brush it. If there be fleas, a small-toothed comb will remove them, and they should be killed as they appear. Wash and dry delicate dogs before the fire.

On the subject of physicking as a preventive of disease, or when there are symptoms of diseased skin, a little sulphur and antimony is recommended, mixed with the meat, or done up as a bolus or pill, and in this latter form pushed over the throat. 'Once a week or fortnight,' says Daniel, 'during the hunting season, hounds should have one pound of sulphur given them in their meat; and when the season is over, half a pound of antimony should be added to the sulphur, and well mixed with the meat. This cools, and is doubtless of service to them.'

The *Mange* is a cutaneous disease in dogs, very closely resembling itch in the human species, but more inveterate, and is hereditary as well as contagious. Mr Blaine, in his 'Encyclopedia of Rural Sports,' thus speaks of this nauseous complaint:—'Of all the causes which beget mange, and they are not few, the acrid effluvium from their own secretions is the most common; when it is generated by numbers, particularly when it is confined within a limited space, it is sure to appear. Close confinement of any dog will commonly produce it, and most certainly so if it be at the same time fed on salt provisions; thus there are few dogs on shipboard that do not contract it, except such as are allowed full liberty of the deck. Food too nutritive in quality, and too considerable in quantity, is productive of mange; and, on the contrary, food in a great measure withheld, or being very poor in quality, is equally a parent of the disease.' The same authority gives several receipts of medicine to be employed; the leading are—powdered sulphur, four ounces; muriate of ammonia (sal-ammoniac) powdered, half an ounce: aloes powdered, one drachm; Venice turpentine, half an ounce; lard or other fatty matter, six ounces: the whole to be mixed and administered in boluses. In all bad cases, however, we should recommend no one to attempt doctoring his dog, but to apply to a regular practitioner.

Distemper.—This disease is most common among dogs which are much kept in the house and subjected to artificial treatment. The disorder is epidemical, affects the constitution, and is very difficult of removal. W. H. Scott, in his work on 'British Field-Sports,' thus describes the symptoms of distemper in a young dog:—'Sudden loss of usual spirit, activity, and appetite; drowsiness, dulness of the eyes, and lying at length with the nose to the ground; coldness of the extremities, ears, and legs, and heat of the head and body; sudden emaciation, and excessive weakness, particularly in the hinder quarters, which begin to sink and drag after the animal; an apparent tendency to evacuate from the bowels, a little at a time; sometimes vomiting; eyes and nose often, but not always, affected with a catarrhal discharge. In an advanced stage of the distemper, such symptoms will occur as spasmodic and convulsive twitchings, the nervous and muscular systems being materially affected; giddiness and turning round, foaming at the mouth, and fits. The disease is then often taken for incipient madness, into which it might not improbably degenerate.' The same authority adds—'I have found daily mild doses of from two to three grains of calomel alone, lapped by the animal in milk, continued for four or five days, with intermissions when necessary, fully sufficient to carry it safely through the disease, even when the fever has been very high. James's powder has, however, always proved the most certain remedy.' To aid recovery, nourishing diet should be given. In cases of severity consult the veterinary surgeon.

Canine madness, rabies, or hydrophobia, is the most fatal malady to which dogs are subject, and for which, as far as we have heard, there is no certain cure. Blaine considers that rabies is never produced spontaneously in dogs or any other animals, but is invariably the effect of inoculation by a bite from a dog already mad. But as the disease must have commenced spontaneously in some dog at first, we do not understand why it may not do so again; in short, the doctrine, in the exclusive form in which it is put, seems untenable. Rabies is little known in hot or cold countries; it is common chiefly in temperate regions, but shows itself principally in summer, when it may be supposed to be excited by a feverish condition of body.

The leading symptom of the rabid state is an apparent discomfort and unsettledness of purpose, with a desire to gnaw and eat anything within reach, as straw, wood, coal, or any other rubbish; as the disease advances, the animal snaps and bites at everybody, or any animal near it. This is, however, no effect of bad temper; the dog has no wish to go out of his way to bite; he is under the influence of a derangement which makes him catch only at what is near. Like the unnatural appetite he possesses, the snapping propensity may also partly arise from the irritated state of the stomach and intestines, both of which are greatly inflamed. The throat is likewise livid; and by a constriction of parts, soon prevents the animal from swallowing. That the rabid dog has a terror of water (hence the origin of the name *hydrophobia*) is now beginning to be doubted; and at all events it is not an invariable symptom, for mad dogs have been known to lap water the day before their death. In the later stages of the disease paralysis comes, and from the fourth to the seventh day the dog expires. It is humanity to shoot the animal before this final catastrophe.

With respect to the production of rabies in the human species, there have latterly been some very grave doubts. An idea has been started, and supported with considerable plausibility of argument by certain medical practitioners, that hydrophobia in the human being is merely a nervous affection, very much, if not almost altogether, arising from the influence of the imagination; the person bit fancies he is going mad, and mad he becomes. It is very desirable that the medical world should investigate and arrive at some determinate conclusion respecting this remarkable doctrine; meanwhile, till the matter is settled one way or other, we must speak of rabies in the human subject as a real disease, against which every reasonable precaution should be adopted. On being bit, it is always safe to wash the wound immediately, and have the parts burnt with a hot iron, or cut out. In every case let a skilled surgeon be immediately consulted—one who will not hesitate to act with promptitude and decision.

Many cures have been mentioned for the bite of a mad dog. We shall notice a few. The following, according to Blaine, is the famous Herefordshire cure, commonly called *Webb's drink*:—'Take the fresh leaves of the box-tree, two ounces; of the fresh leaves of rue, two ounces; of sage, half an ounce; chop these finely, and after boiling them in a pint of water to half a pint, strain and press out the liquor; beat them in a mortar, or otherwise bruise them thoroughly, and boil them again in a pint of new milk, until the quantity decreases to half a pint, which press out as before. After this mix both the boiled liquors, which will make three doses for a human subject. Double this quantity will form three doses for a horse or cow; two-thirds of it is sufficient for a large dog, calf, sheep, or hog; half the quantity is required for a middle-sized dog; and one-third for a smaller one. These three doses are said to be sufficient; and one of them is directed to be given every morning fasting.' Blaine has not much confidence in this remedy, but allows it is worth trying. Mr Murray, known as a lecturer on chemistry, mentions, in a letter to a newspaper, the following remedy:—'Let a mixture of two parts of nitric and one part of muriatic acid, both by measure (evolving chlorine in a concentrated form) be applied to the wound as soon as possible, and more than once.' He adds that he has found this a preventive. M. Buisson, a Parisian physician, declares that madness from the bite of a rabid dog may be thoroughly cured by fumigating the patient in a hot vapour bath, and afterwards keeping up the copious perspiration in bed; this he recommends to be done for several successive nights.*

FIELD-SPORTS.

Conducted on principles of moderation, humanity, and fair-play, the sports of the field may be said to be those exhilarating and healthful pursuits by which the tribes of wild animals are made subservient to man's use, or removed from a sphere in which they are inconvenient and unsuitable. In taking amusement from such sports, it is the glory of the true English gentleman to avoid every proceeding which can give unnecessary pain to the animals over which he claims dominion, and to discountenance by every means in his power such odious abuses of sport as baiting, worrying at the stake, or any other method of protracting the death of the creatures who have the misfortune to be objects of the chase. Our limited space will permit us to notice only the leading field-sports of Britain in past and present times.

FALCONRY.

Falconry was the favourite field-sport of the middle ages, as shooting with the gun is the predominant one of the present day. It appears, in this country, to have declined and gone out of use in the seventeenth century, in consequence of the gun having then become, by the addition of the lock and flint, a much more ready means of bringing down game than the use of hawks had ever been. Falconry, while it existed, was the peculiar sport of kings, and princes, and nobles, many of whom were painted in life with their hawks seated on their wrist, and were sculptured on their tombs after death with the same creature placed at their feet; thus marking the special regard in which they held the animal which was the means of giving them so much amusement.

The sport, we need scarcely remark, was founded on the natural instinct of the rapacious order of the feathered creation, as the chase may be said to be founded on the instinct of the dog to pursue the hare, fox, and other animals. The rapacious order of birds—of which the eagle, falcon, and owl are the three principal types—are formed in such a way as evidently fits them for pursuing, seizing, and destroying the smaller birds; a part in creation which at first sight appears to involve much cruelty, but which has been clearly shown to be intended to save rather than to produce pain, and to be indispensable to a system of things in which one leading feature is, that there shall always be as many living creatures as can possibly be supported. The falcon family were alone employed for purposes of sport, as alone possessing the required docility; and of this family two or three species were more frequently used than any other. Of those possessing long wings, the falcon proper and the ger-falcon; and of the short-winged, the goshawk and sparrow-hawk, seem to have been the favourite kinds. Species called the hobby, the kestral, the merlin, and buzzard, were the next in request. The female, which is in all the varieties of this tribe considerably larger than the male, was alone employed in sport, and the common names of all the species apply to that sex, the male having usually some distinctive appellation: thus the male of the ger-falcon was called the *jerkin*; of the falcon proper, the *tierce gentle*; of the goshawk, the *tiercel*; and of the sparrow-hawk, the *musket*.

These birds naturally choose retired habitations. The falcon, in particular, builds her nest amongst cliffs in wild and unpeopled regions. In order to fit birds

* See an account of Buisson's proceedings in 'Chambers's Edinburgh Journal,' No. 257, old series.

for the sport of *falconry*, it was necessary to take them from the nest at a very early stage of their existence (then technically called *eyasses*), or to ensnare them in their more mature age, and then train them for the purpose. A falcon in its natural state was said to be a *haggard*; hence, apparently, the term by which we still express a wild or agitated aspect. The first step in training the falcon was to *man* it, or accustom it to the presence of human beings. Feeding was the grand source of the power which its keeper acquired over it. When it did as required, it was fed, and thus taught to know that it had done right, and not otherwise. If extremely refractory, a stream of cold water was directed at its head, as an admonition that nothing was to be gained by such conduct. From the very first, the animal was accoutred with certain paraphernalia, the names of which at least must be familiar to most readers. First, its head was covered by a leathern *hood*, fitting close all round, so as to shut up its eyes, and calculated, by a slit behind, to be readily slipped on and off. On the top of the hood there was a tuft of feathers, which usually has a graceful effect in the old pictures representing ladies or gentlemen travelling with their hawks upon their wrist. Leathern straps, called *jesses*, a few inches in length, were fitted to the legs of the bird by a button slipping through a slit or loop. Close beside the end attached to each leg was a small spherical *bell*, like that of a child's rattle, and composed of silver, for clearness of sound, the one being in some nice instances made a semitone higher than the other. The other ends of the jesses were furnished each with a ring, which could be readily fitted upon the swivel designed to connect them both with the *leash*, a long slender strap, sometimes prolonged by a *creance*, or common cord, and designed as a tether by which to restrain the animal, at the same time that it should be allowed considerable room for free motion. Two great objects in training were to teach the bird to fly at its proper game, and to habituate it to come back to the hand of its master, after on any occasion having been let free in pursuit of its prey. For the first of these ends, in the case of long-winged birds, an implement termed the *lure* was used. It consisted either of a stick or of a cord, on the end of which were fixed pieces of flesh, with a bunch of the feathers of the prey which it was designed that the bird should fly at, or perhaps an actual resemblance of the prey in its entire form. The falcon being set loose by one man, another stood at a distance waving the lure around his head, thus tempting the animal to advance and strike at it. A whistle was the implement used to *reclaim* or bring back the hawk. When a hawk was to be kept on the hand, strong gloves were worn for protection from its talons. It may here be remarked that the training of falcons was altogether a most laborious business, and that trained birds were accordingly to be only purchased at a high price. At the beginning of the seventeenth century, a trained goshawk and tiercel brought one hundred marks, and it was considered a favour to part with them. The extreme labour attending the training of the animals must have been sufficient in early times to confine the sport to persons of birth and fortune, if there were no other cause; and it must also have conduced to the rapid decline and extinction of the sport, after a ready means of killing wild-fowl by the gun became attainable.

The sport, after being long given up, was revived in England some years ago by Colonel Thornton, the Duke of St Albans, and a few other gentlemen, chiefly through the influence of a taste for whatever is elegant and romantic in the usages of our forefathers. It is said to be a gallant and goodly sight, when a train of well-mounted English ladies and gentlemen rides forth on a clear sunshiny day to pursue this sport, attended by their falconers, each with his hawk on his wrist. In the present day, as of yore, various kinds of feathered game are flown at. Heron-hawking is, we believe, in greatest esteem. The heron, as must be generally known, is a large bird in appearance, with a long neck, long legs, and a long sharp bill, being designed to haunt marshes and pools, and feed upon whatever fish it can find therein. It is, however, a light unsubstantial bird, with nothing to protect it from enemies but its sharp bill. Herons are gregarious, and the lonely places where they live are called heronries. These explanations will introduce the following account of heron-hawking, from Blaine's 'Encyclopædia of Rural Sports:'—

'The daily visitations of the heron to its feeding-places are watched by the falconers, who station themselves to the leeward or down wind of the heronry, so that the heron, on its return, must fly against the breeze, which gives a great advantage to its enemy. As soon as one is discovered on the return, a cast of falcons is let loose, who, catching sight of the quarry, rise in pursuit. The heron, instinctively aware that its life is at stake, prepares for the fray by disgorging the contents of its stomach to lighten the weight of the body. The coursing falcons ascend the airy vault in spiral gyrations, by which the atmospheric resistance to their flight is lessened. These circlings, it has been observed, have frequently the curious effect of presenting the three birds as flying in different directions; whereas the real intentions of the two hawks are steadily directed to one point, which is that of contact with the heron, whose entire efforts are as steadily engaged in avoiding it. To effect this, the affrighted heron strenuously endeavours to rise above the hawks, who, however, by the superior power of wing, commonly succeed in getting the upper station, from which one presently makes its stoop; and happy it is for the poor heron if he can evade the blow, which he occasionally does, either by shifting his station, or by receiving the falcon on his sharp bill, which instantly transfixes it. This danger is, however, denied on authority, but we feel assured that it does occur. The second hawk, if the first fails, stoops in his turn; but the meditated blow of this also is frequently evaded like the former. The trio then still rising higher and higher, the sight becomes interesting in the extreme, and the spectators are scarcely less agitated than the feathered warriors above. At length another stoop takes place, and the fatal seizure is made by one hawk, while the other *binds* to his fellow, and all three quickly descend together, but not with a dangerous rapidity, as their powers of inflation and the action of their wings break the fall. It is now that the mounted horsemen make the best of their way to the assistance of their falcons, and their first efforts must be directed to secure the head of the heron, that the sharp beak may not take effect on one or both of them.'

Pheasants are objects of this sport, but not to a great extent, on account of the inconvenience presented by the sylvan ground in which the sport must be practised. Partridge-hawking is found to be a more convenient sport. To quote the same authority—'The scene of practice is commonly on large fields or open tracts of country, where the horsemen and company generally can beat in line, and the attendant falconer or master, being well-mounted, can ride forward, and be ready to receive the quarry. Either pointers or spaniels are necessary, or both. The partridge being flushed, the hawk will stoop with astonishing rapidity, and seize on it; at which time neither horses, dogs, nor company should press forward; on the contrary, they should permit the falconer only to advance, who, approaching the hawk with caution, must walk quietly round her, when, gently kneeling down with his arm extended, as though in the act of feeding the hawk, he should lay hold of the partridge, and at the same time place the hawk on his fist. This done, restore the hood, and reward the hawk with the head of the quarry; and if she be not intended to be flown again, let her be fed immediately.

A somewhat different method of partridge-hawking is practised in the latter part of the season, when the country is very bare, and when the partridges are often very wild, and lie indifferently even to the dog. In such cases it is recommended that the company "draw up in line at fifty or sixty yards' distance from each other, and gallop across the plain with a hawk upon wing," the falconer being in the centre of the line, that he may regulate the pace by the situation of the hawk. Sir John Sebright informs us that this method of partridge-hawking has afforded him more sport than any other, and that when the face of the country was so bare, and the birds so wild, as to make it impossible to approach them in the usual way.

Brook-hawking, as it is often termed, was much in vogue formerly. The practice was not, however, confined to brooks, but extended to rivers, sea-shores, moors, and ponds. It engaged, according to Blome, "the jer-falcon, the haggard-falcon, the jerkin, and the tassel gentle." Waterfowl of every description were made prey of; but some particular objects, according with the training of the falcons, were particularly sought for. Dogs were employed to rouse the fowl, being led on by men who traversed the water's edge; while horsemen, with the hawks on their fists, were at hand to *cast off* one or more, according to the nature of the game. A heron or mallard would require two, while a widgeon or a teal (being small) would probably engage only one.'

DEER-HUNTING.

Deer-hunting was another principal amusement of past times, but has now been abandoned in the form in which it used to be conducted. The species of animals chiefly hunted in England was the fallow-deer, a beautiful creature with stately horns and antlers, and of great speed in running. Fallow-deer are now closed up in parks, at least in Britain. The stag, red deer, or hart, whose female is called the hind, differs in size and in horns from the fallow-deer. He is much larger, and his horns are round, whereas in the fallow species they are broad and palmated. Red deer are now, we believe, the only objects of field-sport in this country, and principally in the Highlands of Scotland, where they still exist in considerable numbers. Hounds, however, as in the chase in former ages, are now seldom or never employed—the hunter depending on his gun and his skill in approaching the animal noiselessly. This, which is called *deer-stalking*, is a sport requiring a vast deal of tact, knowledge of the animal's habits, and patience, as whole days are occasionally taken up in stealthily watching an opportunity for a shot. Such is the power of sight, scent, and hearing, that to approach unperceived on a plain is impossible. They must be approached down the wind, and from behind thickets or hillocks. A telescope is required in these difficult manœuvres. When it is impracticable to reach them in this artful manner, attendants drive them into gorges among the mountains, and the sportsman singles out an object for his gun as it passes his concealed station. A lively work on deer-stalking has lately been written by Mr Scrope, to which we beg to refer those who are interested in the subject; and some very graphic pictures may also be found in Mr St John's attractive volume on 'The Wild Sports and Natural History of the Highlands.'

FOX-HUNTING.

The variety of fox most common in Britain is called the *cur fox*, which is of a brown colour, with generally some white on the breast and belly, and a light tip to the long bushy tail. Foxes go to *clicket* in winter, and cubs are produced in the latter end of March; they breed but once a year, and have from three to six young ones at a time. In his nature the fox is playful, but rapacious in his appetite, and his predominating characteristic is great craftiness. He usually fixes his abode on the border of a wood, at no great distance from a farmhouse or village; he listens to the crowing of the cocks and the cries of the poultry; he scents them, and chooses the time of his attack with judgment; he conceals his road as well as his design; he slips forward with caution, sometimes even trailing his body, and seldom makes a fruitless expedition. He plans similar encroachments on the nests of birds, rabbit warrens, &c.; and, in a word, is so destructive to poultry, game, and even young lambs, that it is absolutely necessary to take and kill him.

Fox-hunting on a proper scale requires to be conducted with the class of active horses termed hunters, a pack of foxhounds to scent and run down the prey, and terriers to turn the animal from his hole, should he take to earth. A pack of hounds varies from twenty to thirty couples; but besides these, some hounds are always left undrafted into the field. The cost of a well-bred pack is reckoned at from £1000 to £1200, and the annual expense of its keep and management about as much. The huntsman, as the grand leader of the chase, is a functionary of no small importance; he is assisted by two whippers-in, who bring up and take charge of the hounds.

The fox being an early riser, and his scent lying best on the damp grass, he is hunted in early morning; and the first business on taking the field is to ride to and draw cover—that is, bring out the fox from his retreat. At the first sight, the view halloo is given by the huntsman, and all follow the sweeping track of the hounds. It is a rule in hunting never to get before the dogs, or to throw them out any way by a false signal; on the contrary, the great art is to keep them to the scent, and to aid their search. The run is considered the exhilarating part of the sport, and consists of a rapid chase through a broken or rough country, with the hounds in full cry. Then is the ardour of the chase shown; and it continues till the fox, by some clever manœuvre—such as tracking up a brook—throws the hounds off the scent, and the party is brought to check. The scent and track of the animal being again found, off all go once more in pursuit, but with generally frequent doubts of the result. 'See,' says Beckford, in his enthusiastic style, 'where the hounds bend towards yonder furze brake! I wish he may have stopped there. Mind that old hound; how he dashes o'er the furze! I think he winds him! Hark! they halloo! Ay, there he goes! It is nearly over with him! Had the hounds caught view he must have died!' He will hardly reach the cover. See how they gain upon him at every stroke! It is an admirable race; yet the cover saves him. Now be quiet, and he cannot escape us; we have the wind of the hounds, and cannot be better placed. How short he runs! He is now in the strongest part of the cover! What a crash! Every hound is in, and every hound is running for him! That was a quick turn! Again, another! He's put to his last shifts! Now mischief is at his heels, and death is not far off! Ha! they stop all at once; all silent, and yet no earth is open! Listen! Now they are at him again! Did you hear that hound catch him!—they overran the scent, and the fox had lain down behind him. Now, Reynard, look to yourself! How quick they all give their tongues! The terriers, too, are now yelping at him. How close *Vengeance* pursues!—how terribly she presses!—it is just up with him! What a crash they make; the whole wood resounds! That turn was very short! There!—now!—ay, now they have him! Who-hoop!' The chase is over: Reynard is no more; and his *brush* or tail being cut off as a trophy by the huntsman, his unfortunate carcass is thrown to the hounds, and in a few moments destroyed, leaving scarcely a wreck behind.

HARE-HUNTING—COURSING.

Hares are hunted in much the same manner as foxes, the chief difference being, that harriers are employed instead of hounds: both hunt by the scent. Of this branch of field-sports, the writer of the excellent article on *Hunting*, in the 'Encyclopædia Britannica,' makes the following mention:—

'Hare-hunting claims precedence of fox-hunting in the sporting chronology of Great Britain, and we believe of all other countries, inasmuch as a hare has always been esteemed excellent eating, and a fox the rankest of carrion. We gather from Xenophon that it was practised before his day, and he wrote fully three centuries before the Christian era, both hounds and nets being then used in the pursuit. Neither can we marvel at hare-hunting being the favourite diversion in all nations given to sporting, where the use of the horse in the field had not become common. But we will go a point farther than this, and assert, that how inferior soever may be the estimation in which hunting the hare is held in comparison with hunting the fox, no animal of the chase affords so much true hunting as she does, which was the opinion of the renowned Mr Beckford.

The difficulty of finding a hare by the eye is well known. It is an art greatly facilitated by experience, although not one person in ten who attempts it succeeds. But here we recognise the hand that furnished her with such means for her security; as, from the delicacy of her flesh, she is the prey of every carnivorous animal, and her means of defence are confined only to flight. In going to her form she consults the weather, especially the wind, lying always, when she can, with her head to face it. After harvest, hares are found in all situations; in stubble fields, hedgerows, woods, and brakes: but when the leaves fall, they prefer lying upon open ground, and particularly on a stale fallow; that is, one which has been some time ploughed; as likewise after frost, and towards the spring of the year. In furze or gorse, they lie so close, as to allow themselves nearly to be trodden upon, rather than quit their form. The down or uplandbred hare shows best sport; that bred in a wet marshy district the worst, although the scent from the latter may be the strongest. If a hare, when not viewed away, runs slowly at first, it is generally a sign that she is an old one, and likely to afford sport; but hares never run so well as when they do not know where they are. Thus trapped hares, turned out before hounds, almost invariably run straight on end, and generally till they can run no longer; and they generally go straight in a fog. The chase of the hare has been altered, and rendered less difficult in some degree by the improvement of the hound used in it.

The difference in the terms used in hare-hunting and fox-hunting is comprised in a few words:—Harriers are cast off in the morning; foxhounds throw off: the hare is found by the quest or trail; the fox by the drag: the hare is on her form or seat; the fox in his kennel: the young hare is a leveret; a fox a year old is a cub: the view hollo of the hare is "Gone away;" of a fox "Tallyho:" the hare doubles in chase; the fox heads back, or is headed: the harrier is at fault; the foxhound at check: the hare is pricked by the foot; the fox is balled or padded: the hare squats; the fox lies down, stops, or hangs in cover: the "who-whoop" signifies the death of each.'

Hares are hunted with packs of generally twenty couples of harriers; but whatever number is employed, it is the established rule not to run in upon the hares as soon as discovered in their forms, but to allow them a little space before the dogs are set on. The hares also must not be pressed upon in the chase by the company; neither are the dogs, in losing scent, to be called on the right path; for this leads them to depend on the sight of the huntsman instead of their own nose. Leave the harriers pretty much to themselves.

Coursing is the chasing and taking of the hare by means of greyhounds, which hunt by the sight only. Among fox-hunters it is considered an inferior kind of sport, but many country gentlemen find in it an exhilarating recreation, and it is patronised by numerous coursing clubs. 'There is,' says Blaine, 'even a philanthropic character about coursing almost unknown to other huntings. It may be said to offer a kind of refuge for the sporting destitute, for it holds out innocent recreation to those whose means or whose prudence will not allow them to risk either their neck after a fox, or their wealth after a racer. Here the octogenarian, at once labouring under his increased years and his decreased energies, may solace himself with an epitome of former huntings; and farther, that the joys of this chase are within the reach of every state or stage of life.'

The greyhound, whose form so eminently adapts him for competing with the hare in a race, requires to be well trained in the art of turning suddenly, and determinedly pursuing his game on a new line of pursuit. His eye should be clear and quick, and his wind good, to enable him to hold out to the last. Greyhounds are delicate in their nature, and require very careful treatment; their lodging must be dry and comfortable; and when taken out in a cold morning, they must be held in leash, with jackets on, ready to let slip. In any case, they are not uncoupled or let go till the hare has been seen and started. A single pair of dogs is generally sufficient for the sport; and betting often ensues as to the *points* in the course. There are numerous rules of ancient and modern date on the subject of coursing. The following, established by the Duke of Norfolk in Queen Elizabeth's reign, are yet held applicable:—

'The feuterer, or person who lets loose the greyhounds, was to receive those that were matched to run together into his leash, as soon as he came into the field, and to follow next to the hare finder, or him that was to start the hare, until he came to the form, and no horse or footmen were to go before, or on either side, but directly behind, for the space of about forty yards.

A hare was not to be coursed with more than a brace of greyhounds.

The hare finder was to give the hare three "sohos" before he put her from her form, to give notice to the dogs that they may attend her starting.

The hare was to have twelve score yards law before the dogs were loosed, unless the small distance from the cover would not admit it without danger of immediately losing her.

The dog that gave the first turn, and during the course, if there was neither cote, slip, nor wrench, won.

A cote is when the greyhound goes endways by his fellow, and gives the hare a turn.

A cote served for two terms, and two trippings or jerkins for a cote; if the hare did not turn quite about, she only wrenched; and two wrenches stand for a turn.

If there were no cotes given between a brace of greyhounds, but that one of them served the other at turning, then he that gave the hare most turns won; and if one gave as many turns as the other, then he that bore the hare won. A "go-by," or bearing the hare, was equivalent to two turns.

If neither dog turns the hare, he that led last to the cover won. If one dog turned the hare, served himself, and turned her again, it was as much as a cote, for a cote was esteemed two turns.

If all the course were equal, the dog that bore the hare won; if the hare was not borne, the cause was adjudged dead. If a dog fell in a course, and yet performed his part, he might challenge the advantage of a turn more than he gave.

If a dog turned the hare, served himself, and gave divers cotes, and yet in the end stood still in the field, the other dog, if he ran home to the cover, although he gave no turn, was adjudged the winner.

If by accident a dog was run over in his course, the course was void, and he that did the mischief was to make reparation for the damage. If a dog gave the first and last turn, and there was no other advantage betwixt them, he that gave the odd turn won.

He that came in first at the death, took up the hare, saved her from being torn, cherished the dogs, and cleansed their mouths from the wool, was adjudged to have the hare for his trouble.

Those that were judges of the course were to give their decision before they departed out of the field.'

SHOOTING—GROUSE—PARTRIDGES, &c.

The leading sports with dog and gun are the shooting of grouse, partridges, and pheasants, which differ in some respects from each other. The first thing to be attended to in either case is having a good fowling-piece or gun; and the second is, to know how to use and clean it. Next, the sportsman must be provided with a dog trained to point the kind of game for which he is taken to the field: to take a dog accustomed to point partridges on a grouse-shooting excursion would be improper. The gunpowder employed should be kept very dry in a metal flask, and of proper strength and purity. Patent shot is now commonly used; it is of eight sorts, each numbered, and rises from 83 pellets to 620 pellets in the ounce. The more tender the birds, the smaller may be the pellets or drops. For grouse, shooters begin with No. 7, or 400 to the ounce; ducks require shot No. 4, or 105 to the ounce.

The following hints to a beginner in shooting are by Hawker and others:—'In raising the gun, let him remember that the moment it is brought up to the centre of the object the trigger should be pulled, as the first sight is always unquestionably the best. Then send him out to practise at a card with powder till he has got steady; and afterwards load his gun occasionally with shot, but never let the time of your making this addition be known to him; and the idea of it being perhaps impossible to strike his object will remove all anxiety, and he will soon become perfectly firm and collected.

The intermediate lesson of a few shots at small birds may be given; but this plan throughout must be adopted at game, and continued, in the first instance, till the pupil has quite divested himself of all tremor at the springing of a covey, and observed in the last, till most of his charges of shot have proved fatal to the birds. If he begins with both eyes open he will save himself the trouble of learning to shoot so afterwards. An aim thus, from the right shoulder, comes to the same point as one taken with the left eye shut, and it is the most ready method of shooting quick. Be careful to remind him (as a beginner) to keep his gun moving, as follows:—before an object, crossing; full high for a bird rising up or flying away very low; and between the ears of hares and rabbits running straight away. All this of course in proportion to the distance; and if we consider the velocity with which a bird flies, we shall rarely err by firing, when at forty yards, at least five or six inches before it. Till the pupil is *au fait* in all this he will find great assistance from the sight, which he should have precisely on the intended point when he fires. He will thus, by degrees, attain the art of killing his game in good style, which is to fix his eyes on the object, and fire the moment he has brought up the gun. He may then ultimately acquire the knack of killing snap shots, and bring down a November bird the moment it tops the stubble, or a rabbit popping into a furze-brake, with more certainty than he once used to shoot a young grouse in August or a partridge in September.

Many begin with very quick shooting, and kill admirably well, but are often apt not to let their birds fly before they put up their gun, and therefore dreadfully mangle them; and, I have already observed, are not such every-day shots as those who attain their rapid execution on a slow and good principle.

If a rival shooter (some stranger) races to get before you, push him hard for a long time, always letting him have rather the advantage, and then give him the double without his seeing you. Having done this, go quietly round (supposing you have been beating up wind); and on reaching the place where you began, work closely and steadily the whole of the ground or covert that you have both been racing over, and you will be sure to kill more game than he will, who is beating and shooting in haste, through fear of your getting up to him, and (if the wind should rise) driving the dispersed, and consequently closest-lying birds, to your beat as fast as he finds them.

Beware of the muzzle of the gun being kept hanging downwards; when so carried, the shot is apt to force its way from the powder, especially in clean barrels. If it happens that a space of sixteen or eighteen inches is thus obtained, and the gun fired with its point below the horizon, it is ten to one but the barrel bursts. There are other perilous consequences besides those that generally accompany the disruption of a barrel; for the men, horses, and dogs, are in perpetual danger of being shot when a gun is carried in the before-mentioned pendent manner.

When a gun begins to exhibit symptoms of having done its work, the sooner a man discards it the better. An injured barrel or enfeebled lock may prove fatal to the owner or his associates. Accidents occur every day, and very lamentable consequences proceed, from a culpable neglect in retaining arms which should be declared unserviceable and disused.'

Grouse Shooting.—This favourite field-sport, as is well known, commences annually on the 12th of August, when thousands of persons adjourn to remote parts of the country to follow it, with all its toils and privations. Among the varieties of this game are numbered the cock of the wood or capercailzie; the black cock, heath-cock, black game, or black grouse; the red grouse, moor-fowl, or gorcock; and the white grouse or ptarmigan. Moor-fowl are the most common, and seem to be peculiar to Britain. They are very plentiful in the Highlands of Scotland, and by no means scarce in any of the wild, heathy, and mountainous tracts in the northern counties of England and Wales. Red grouse pair early in spring, and lay from six to ten eggs; the young brood follow the hen during the whole summer; and in winter they unite in flocks of forty or fifty. They are never seen in the valleys, but always keep on the summits of the hills, where they feed on mountain berries and the like; and are exceedingly shy and wild. Being generally hatched in April, if the summer has been dry, the young birds will be pretty strong on the wing and ready for the sportsman on the legal 12th of August.

The best weather for shooting is that which is dry, clear, and warm; wet makes them lie still on the ground. No one must attempt grouse shooting who is of delicate health, or not well trained by previous feeding and exercise. The labour of walking over heather is most toilsome, and the danger of colds from rain or wet feet considerable. The dress ought to be very strong, without any regard to fineness; stout shoes or quarter-boots are indispensable.

The times of day best suited for grouse shooting are the morning and evening, when the birds are in quest of food; but few are able to reach their haunts till eight o'clock, when the sport commences. 'To find the birds,' says the author of Wild Sports of the West, 'when, satisfied with food, they leave the moor to bask in some favourite haunt, requires both patience and experience; and here the mountain-bred sportsman proves his superiority over the less practised shooter. The packs then lie closely, and occupy a small surface on some sunny brow or sheltered hollow. The best nosed dogs will pass within a few yards and not acknowledge them; and patient hunting, with every advantage of the wind, must be employed to enable the sportsman to find grouse at this dull hour. But if close and judicious hunting be necessary, the places to be beaten are comparatively few, and the sportsman's eye readily detects the spot where the pack is sure to be discovered. He leaves the open feeding-grounds for heathery knowes and sheltered valleys; and while the uninitiated wearies his dogs in vain over the hill-side, where the birds, hours before, might have been expected, the older sportsman profits by his experience, and seldom fails in discovering the dell or hillock where, in fancied security, the indolent pack is reposing.'

Our most practical authority on this exciting topic is the Oakleigh Shooting Guide:—'Grouse shooters should separate and range singly; they should have no noisy attendants. In wet weather one dog is sufficient; we advise rest from eleven till two. The flight of grouse is generally about half a mile. Their favourite haunts, when undisturbed, are those patches of ground where the young heather is most luxuriant. They avoid rocks and bare places where the heather has been recently burnt; at anyrate they are not to be approached in such localities. It is in young heather that grouse most frequently feed. They are seldom found in the very long thick heather that clothes some part of the hills, until driven there for shelter by shooters or others. It is early in the morning and towards evening that grouse are to be found in young heather. During the middle of the day the shooter should range the sunny side of the hill, and avoid plains.

No species of shooting requires the aid of good dogs more than grouse shooting, and in no sport does so much annoyance result from the use of bad ones. The best dog perhaps for the moors is a well-bred pointer, not more than five years old, which has been well tutored—young in years, but a veteran in experience. The setter is occasionally used with success, but we prefer the pointer. The latter has unquestionably the advantage when the moors are dry, as it not unfrequently happens that they are in August. If a setter cannot find water wherein to wet his feet every half-hour, he will not be able to undergo much fatigue. Some sportsmen will hunt a couple of mute spaniels for grouse shooting in preference to any other team of dogs. Of course when this method is pursued the birds are never pointed, and the shooter must ever be on the look-out, for the game is generally sprung very near to the gun.' Grouse shooting, we may add, legally terminates on the 9th of December.

Partridge Shooting.—Of partridges there are two kinds, the red and gray, the latter being that which is common in this country; the plumage is of a brown and ash colour, elegantly mixed with black; the tail is short, and the figure more plump than handsome. Partridges pair about the third week of February, and sometimes, after being paired, if the weather be severe, they all gather together and form a covey, and are then said to pack. They begin to lay in six weeks after pairing. The female lays her eggs (from twelve to twenty) on the ground, scraping together a few bents and decayed leaves into any small hollow. The young birds begin to appear about the first ten days in June, and the earliest will take the wing towards the latter end of that month. In dry seasons they are most numerous. So many are the enemies of the partridge, that it is believed never more than a half of those produced come to perfection; and yet there is in general abundance for the sportsman during the shooting season. The affection of both parents for their young is very remarkable; they lead them out in quest of food, shelter them with their wings, and resort to many tricks to lead supposed enemies away from their broods. Corn-fields are the places which partridges most delight in, especially while the corn is growing; for that is a safe retreat where they remain undisturbed. They frequent the same fields after the corn is cut down, and there feed on the dropped grains, finding a sufficient shelter under cover of the stubble. When the winter comes on, and the stubble-fields are either trodden down or ploughed up, they then retire to the upland meadows, where they lodge in the high grass; they also sometimes resort to the low coppice-woods, especially if they are contiguous to corn-fields.

Partridge shooting commences, by law, on the 1st of September, when the birds are strong, and terminates on the 1st of February. In the course of September, the short flights of the coveys, in tolerably well-preserved grounds, afford abundance of sport. In more open districts of country, where there is a wider range, partridge shooting requires more skill, and the aid of a steady pointer or setter. In shooting either at a flight of grouse or covey of partridges, select a bird on the outside, and fire at it alone; it is only over-hasty or ill-taught sportsmen who let fly indiscriminately at the centre of a group of birds.

Pheasant Shooting.—Pheasants are a species of birds allied to domestic fowls, and partake of some of their habits; no birds of the game kind possess such elegant plumage, and few are so large. They breed on the ground, and, like partridges, are fond of nestling in clover; but their chief resort is shrubberies or secluded spots in plantations. The pheasant and its brood, if undisturbed, remain in the stubbles and hedgerows some time after corn harvest; if molested, they seek the woods, and only issue thence to feed in the stubbles at morning and evening. Besides corn, the birds will live on wild berries, or any seeds they can pick up. As the cold weather comes on they begin to fly up at sunset into trees, where they roost during the night.

'For shooting pheasants it often becomes necessary to start very early in the morning, as they are apt to lie during the day in high covert, where it is almost impossible to shoot them till the leaf has fallen from the trees. We can never be at a loss in knowing where to go for pheasants, as we have only to send some one the previous evening, for the last hour before sunset, to watch the different barley or oat stubbles of a woodland country, and on these will be regularly displayed the whole contents of the neighbouring coverts. It then remains to be chosen which woods are the best calculated to shoot in; and when we begin beating them, it must be remembered to draw the springs, so as to intercept the birds from the old wood. If the coverts are wet, the hedgerows will be an excellent beginning, provided we here also attend well to getting between the birds and their places of security. If pheasants, when feeding, are approached by a man, they generally run into covert; but if they see a dog, they are apt to fly up.

There are very few old sportsmen but are aware that this is by far the most sure method of killing pheasants, or any other game, where they are tolerably plentiful in covert; and although, to explore and beat several hundred acres of coppice, it becomes necessary to have a party with spaniels, yet on such expeditions we rarely hear of any one getting much game to his own share, except some sly old fellow, who has shirked from his companions to the end of the wood, where the pheasants, and particularly the cock birds, on hearing the approach of a rabble, are all running like a retreating army, and perhaps flying in his face faster than he can load and fire.'

It is necessary in pheasant shooting to use a short double-barrelled gun of wide bore, and large shot. Fire at not a greater distance than thirty yards, and only when the bird has risen clear of the bushes; aim is to be taken at the head; but if the pheasant is crossing your path, fire a little before the head, the rapid flight of the animal bringing it in contact with the shot. Towards November, this field-sport—which commences on the 2d of October, and terminates on the 1st of February—may be united with woodcock shooting.

GAME.

Though, according to law, wild animals are no one's property, yet only certain kinds may be killed without a license. Those protected from indiscriminate slaughter are called *game*, and are deer of every species, hares, partridges, grouse, pheasants, woodcocks, snipes, &c. The wild animals not reckoned game are rabbits, rats, mice, crows, rooks, pigeons, sparrows, all kinds of sea-birds, &c.; any one may kill and appropriate these, provided it be in a highway, the sea-shore, or any other public ground. Game cannot be legally taken or killed in any form without a license procured from the competent officer of the crown, and a permission from the proprietor of the ground on which the game happens to be. To shoot or hunt without a license is called *poaching*; to shoot or hunt with a license, but without a permission, renders the person liable to an action for *trespass*. These game-laws are relics of ancient laws instituted by the Anglo-Saxon and Norman sovereigns for protection of the royal forests; and though some of these provisions are useful, they are, generally speaking, a disgrace to the statute book, and ought to be simplified and amended. Of late, some slight modifications have been sanctioned by the legislature, but these are not of a kind to affect in any sensible degree either the spirit or bearing of the general question.

ANGLING.

ANGLING is the art of alluring and capturing fish by means of a rod, line, and baited hook—the bait being made to resemble some object on which the animals naturally prey. The art is so termed, according to some, because an angle, as it were, is formed by the apparatus when held over the surface of the water; while others trace it to the angular shape of the hook, as originally fashioned of wood or bone, such being still the form and materials employed by savage nations. Whatever the origin of the term, the practice of taking fish in this excusably crafty manner, either for profit or for amusement, is of great antiquity, as we may learn from the mention made of it by the prophet Isaiah: 'The fishers also shall mourn, and all they that cast angle in the brooks' (chap. xix. verse 8). As well as fishing with nets, the practice has continued through all ages to the present time, and in almost all countries. In the British islands, it has long formed a favourite pastime among every class of society, lay and clerical, and to all presents many features of attraction. 'It is,' to use the words of Mr Blaine, 'far from dangerous or expensive, but on the contrary is productive of interest and amusement without an extraordinary sacrifice. Its *apparent* simplicity lures many into the practice; and as a trifling success elates the tyro, and leads him on by its fascinations, so he pursues it, although he soon discovers that extreme nicety and precision, great patience, caution, and perseverance, are essential requisites to the attainment of proficiency in the art. Nevertheless, he still continues the pursuit; difficulty after difficulty is overcome; each succeeding year adds interest to the practice, which he continues with undiminished ardour to the latest period of his life. It is asserted, and we believe with truth, that there is not one among the field-sports that takes so permanent a hold on the passions as this. It is no less remarkable for the variety it offers, for it presents itself under many forms, some of which are suited to the taste of every age, of every rank, and every variety of character and habit. The sedentary, the thoughtful, and the advanced in life, may watch the float as it slowly moves with the stream, without disturbance to the train of thought, or without any fatiguing exercise to their person. The active and volatile may throw afar the leaded bait for the pike, or may engage in the graceful evolutions of the fly-rod. Its seductions, therefore, prove universal, and it owns votaries of every age and station.' As the sport is pursued on the banks of rivers or lakes, in the midst of purely natural scenery, and in weather which invites to out-of-door recreation, everything conspires to render it in a peculiar manner exhilarating and healthful, when indulged in with judicious moderation.

No kind of amusement has been the object of such frequent description as angling. Hundreds of treatises have been written descriptive of the sport in all its departments, and with reference to all varieties of fish and the waters to which they resort. Indeed several of our rivers are the subjects of illustrated monographs, detailing not only what is peculiar to the angling of their waters, but whatever in the way of anecdote, tradition, or history, seems likely to render the practice of the 'gentle craft' inviting and agreeable. The first writer of note on the subject, and who has been acknowledged the great father of the angle, was Isaac Walton (born at Stafford 1593, died 1683), who in the year 1653 gave to the world his 'Complete Angler,' a work afterwards enriched with additions by his friend Charles Cotton, and which till this day is esteemed not more for the correctness of its details than the singularly happy humour of its apologues, poetical pieces, and disquisitions. According to old Isaac, all recreations sink into insignificance in comparison with angling, which in almost every page he lauds for its moral qualities, and the health and happiness it is calculated to yield. 'Will you hear,' says he, on one occasion, 'the wish of an angler, and the commendation of his happy life, which he sings in verse:—

"Let me live harmlessly, and near the brink
Of Trent or Avon have a dwelling-place,
Where I may see my quill or cork down sink
With eager bite of perch, or bleak, or dace;
And on the world and my Creator think,
Whilst some men strive ill-gotten goods to 'mbrace,
And others spend their time in base excess
Of wine—or worse, in war and wantonness.

Let them that list these pastimes still pursue,
And on such pleasing fancies feed their fill,
So I the fields and meadows green may view,
And daily by fresh rivers walk at will,
Among the daisies and the violets blue,
Red hyacinth and yellow daffodil,
Purple narcissus, like the morning rays,
Pale gander-grass, and azure culver-keys.

I count it higher pleasure to behold
The stately compass of the lofty sky,
And in the midst thereof, like burning gold,
The flaming chariot of the world's great eye;
The watery clouds that in the air up-rolled,
With sundry kinds of painted colours fly;
And fair Aurora, lifting up her head,
Still blushing, rise from old Tithonus' bed.

The hills and mountains raised from the plains,
The plains extended level with the ground;
The grounds divided into sundry veins,
The veins enclosed with rivers running round;
Those rivers, making way through nature's chains,
With headlong course into the sea profound;
The raging sea, beneath the valleys low,
Where lakes, and rills, and rivulets do flow.

The lofty woods, the forests wide and long,
Adorned with leaves and branches fresh and green,
In whose cool bowers the birds, with many a song,
Do welcome with their choir the summer's queen;
The meadows fair, where Flora's gifts among
Are intermixed with verdant grass between;
The silver-scaled fish, that softly swim
Within the sweet brook's crystal watery stream:

All these, and many more of His creation
That made the heavens, the angler oft doth see;
Taking therein no little delectation,
To think how strange, how wonderful they be,
Framing thereof an inward contemplation
To set his heart from other fancies free;
And whilst he looks on these with joyful eye,
His mind is rapt above the starry sky."'

So much for the *poetry* of the art; we shall now speak of its practice, beginning with a few remarks on the

GENERAL CHARACTERISTICS OF FISH.

The fish which are the object of attention to the angler are all confined to fresh water, and are chiefly found in rivers or small brooks; some are found in lakes and ponds. All, except eels, have a pretty uniform character (more fully detailed under the head ZOOLOGY), though differing in appearance and size. Their form is suitable in a remarkable way to give celerity and ease of motion—a small head swelling into a thick body, and tapering off towards the tail. Those designed for slower motion are more thick and lumpy in figure. The power of moving quickly, and of buoying themselves in the water, is very nicely provided for by their specific gravity, which is nearly the same as the water in which they move; in other words, they are about the same heaviness as the water which they displace, and consequently they are almost destitute of any feeling of weight. On this account they are not in the slightest degree encumbered in their movements, and are difficult to tire in their exertions.

The tail is the grand instrument of motion; it is a thin delicate membrane, whose smallest bending to and fro impels the body forward in any required course. The fins are principally required for balancing and regulating the movements of the fish; if any be cut off, the animal loses the power of keeping itself with the back fairly upwards; should it be deprived of the tail, the ability of moving forward is gone, and it lies a hulk at the mercy of its enemies. Not the least remarkable peculiarity in the economy of the fish is the existence of an air-bladder, by the dilatation or contraction of which it possesses the power of rising or sinking in the water, according as it feels inclined. It may be observed that fish, while in water, are constantly moving the gills, which is analogous to the art of breathing. The water sucked in by the mouth, and vented by the gills, contributes a minute portion of air, but enough to keep up the circulation of the blood and sustain life; if we were to tie up the gills, the fish would be immediately suffocated. The blood of fish is cold, being only about two degrees warmer than the water in which they live.

The senses of fish have engaged much attention from naturalists. Their quickest sense is that of sight; but they are destitute of the power of contracting the iris of the eye, so as to accommodate themselves to different degrees of light. In ordinary circumstances this is of no consequence, as the water diminishes the intensity of light, and the animal has the means of retiring to the bottom, or into holes, to escape the glare of the mid-day sun. It has been doubted if fish have any organs of hearing; but it is certain they do possess them, and hear to a limited extent. They are affected by any loud noise, though this may be partly ascribable to feeling the vibrations of the water. The taste of fish is allowed to be very blunt, if it exist at all; and so likewise is their smell. Whatever may be their deficiencies in these respects, they are provided with an appetite of boundless voracity.

'Every aquatic animal that has life,' observes Daniel, 'falls a victim to the indiscriminate voracity of one or other of the fishes. Insects, worms, or the spawn of other tenants of the waters, sustain the smaller tribes; which in their turn are pursued by millions larger and more rapacious. A few feed upon mud, aquatic plants, or grains of corn; but the far greater numbers subsist upon animal food alone; and of this they are so ravenous as not to spare those of their own kind. That there are vegetables in both fresh and salt waters admits no doubt, and these may furnish food to particular fishes; but these sorts are few, perhaps no one kind can be pointed out that subsists entirely upon them; and although most fishes eat flies and terrestrial worms when they come in their way, yet in the immeasurable waste of waters surrounding this globe, the swarms of fishes are so immense, that the subsistence to be derived from the above sources appears to be altogether disproportioned to their wants, and those of a smaller size seem to constitute the principal food of nearly all the fishes known to us. Charr kept in a pond, if scantily supplied, frequently devour their own young; other fish, that are larger, go in quest of more bulky prey—it matters not of what sort, whether of their own or of another species. If we turn our attention, in this argument, to sea-fish, those with the most capacious mouths pursue almost everything that exists, and often meet each other in fierce opposition, when the fish which has the widest throat comes off with victory, and devours his antagonist.

The voracious fishes differ widely from the predatory kinds of terrestrial animals; they are neither limited in their number nor solitary in their habits. Their rapacity is not confined to a few species, one region of the sea, or individual efforts. Almost the whole order is continually irritated by the cravings of an appetite which excites them to encounter every danger, and which, by its excess, often destroys that existence which it was intended to prolong. Innumerable shoals of one species pursue those of another through vast tracts of the ocean, from the vicinity of the pole to the equator. The cod pursues the whiting, which flies before it from the bank of Newfoundland to the southern coasts of Spain. The cachalot drives whole armies of herrings from the regions of the north, devouring at every instant thousands in the rear. Hence the life of every fish, from the smallest to the greatest, is but a continued scene of rapine; and every quarter of the immense deep presents one uniform picture of hostility, violence, and invasion.

In these conflicts, occasioned by the voracity of the different kinds of fishes, the smaller classes must have long since fallen victims to the avidity of the larger, had not nature skilfully proportioned the means of their escape, their numbers, and their productive powers, to the extent and variety of the dangers to which they are unceasingly exposed. To supply the constant waste occasioned by their destruction in the unequal combat, they are not only more numerous and prolific than the larger species, but, by a happy instinct, are directed to seek for food and protection near the shore, where, from the shallowness of the water, their foes are unable to pursue them. These, however, yielding to the irresistible impulse of hunger, become plunderers in their turn, and revenge the injuries committed on their kind by destroying the spawn of the greater fishes, which they find floating upon the surface of the water.

In what manner digestion, to such an amazing extent and rapidity, is carried on in the stomach of fishes, the inquiries of naturalists have at present been unable to ascertain. It so far exceeds everything that can be effected either by trituration, the operation of heat, or of a dissolving fluid, that a celebrated physiologist (Dr Hunter), after various experiments, was of opinion that none of these causes were equal to the effect, and that the digestive force in the cold maw of fishes is so great as to overturn the systems that have attempted to account for it on those principles; that by some power in the stomach yet unknown, which from all kinds of artificial maceration acts differently, the meat taken into the maw is often seen, although nearly digested, still to retain its original form; and whilst ready for a total dissolution, appears to the eye as yet untouched by the force of the stomach.' It may be added, however, that although generally voracious, fish have a remarkably accommodating appetite, and will endure hunger without injury a much longer period than most terrestrial animals.

Fishes are for the greater part oviparous—that is, produced by eggs or spawn, in the deposition of which a male and female fish are concerned. It is usual to call the male a *milt* or *milter*, and the female a *roe* or *roeman*. The process of spawning, which takes place in secluded parts in the beds of rivers, is involved in considerable obscurity. The salmon, of which most is known, seeks the higher parts of rivers for spawning, and there the deposit is made. Mr Halliday, in his communications to the House of Commons on this subject, describes the process as follows:—'When they proceed to the shallow waters, which is generally in the morning, or at twilight in the evening, they play round the ground, two of them together. When they begin to make the furrow, they work up the gravel rather against the stream, as a salmon cannot work with his head down the stream, for the water entering his gills in this manner would drown him. When they have made a furrow, they go to a little distance, the one to one side, and the other to the other side of the furrow, and throw themselves on their sides when they come together, and, rubbing against each other, they shed their spawn both into the furrow at once. They do not lay it all at once; on the contrary, it requires from about eight to twelve days for them to emit their stock of spawn, which being deposited, the bed is made and covered as they go along, both male and female assisting in the operation.'

Immediately after spawning, all fish are thin and poor, and not worth the trouble of catching. In about twenty days, if the circumstances be favourable, the eggs are hatched, and emit the young fry of fish. The number of young is in some cases enormous. Carp, perch, or roach, produce from 30,000 to 200,000 young; a herring from 20,000 to 36,000; a mackerel from 400,000 to 500,000; and a cod between three and four millions. Of the young of any fish, however, comparatively few reach maturity, the greater proportion being devoured by enemies shortly after hatching. As if for the sake of mutual protection, most fish of a kind, as may be observed in the case of minnows and parr, associate together and swim in flocks or shoals.

That fishes are liable to diseases, arising from variations of temperature and other causes, there is no reason to doubt; but few are ever seen dead in the water, there being too many scavengers of the deep to allow of this waste of food. In general, the weak fall a prey to the strong before the period of natural death. It is understood that fishes possess a blunted nervous energy, which renders them almost insensible to any ordinary infliction; and so mean are their reflective faculties, that after escaping from a hook which has lacerated their palate, they will in the next minute catch at a similar bait, and be hooked a second time and drawn from the water. A number of years ago, two young gentlemen, while fishing in a lake in Dumfriesshire, having expended their stock of worms, had recourse to the expedient of picking out the eyes of the dead perch they had taken, and attaching them to their hooks—a bait which this fish is known to take as readily as any other; one of the perch caught in this manner struggled so much when taken out of the water, that the hook had no sooner been loosened from its mouth than it came in contact with one of its eyes, and actually tore it out. In the struggle, the fish slipped through the holder's fingers, and again escaped to its native element. The disappointed fisher still retaining the eye of the aquatic fugitive, adjusted it on the hook, and again committed his line to the waters. After a short interval, on pulling up the line, he was astonished to find the identical perch that eluded his grasp a few minutes before, and which literally perished in swallowing its own eye.

Fishes are exposed not only to external foes, which it requires all their dexterity to elude, but to the torment of parasitical marauders in their own person. Besides creatures which make a lodgment in the intestines, various parasites fix themselves beneath the scales, in the mouth, and upon the gills. Salmon, perch, trout, and other fresh-water fish, are preyed upon in this manner by different species of lice; and as some of these parasites cannot live in salt water, it has been supposed that one of the reasons for the salmon migrating to the sea is to relieve itself from the lice (*Lernæa salmonia*) which have adhered to its gills. The trout louse, or *L. truttæ*, is not unknown to fishers.

FISHING-TACKLE.

The equipment of the angler consists mainly of his rods, lines, hooks, and baits, with the means of keeping them in order, or supplying their place in the event of an accident. To these dealers have added numerous accessories, more cumbrous than useful, and always more sought after by the holiday angler than the genuine disciple of Walton. As one-half the art depends on proper equipment, we shall describe the leading implements in detail.

The Rod.

This is the chief implement of the angler. It ought to be strong, but perfectly elastic, and bend, on being waved, through its upper half, but particularly at the small tapering point. The wood most suitable is hickory or ash, with yew for the upper part, to which a point of whalebone is attached. The size and strength must depend on the nature of the duty to which the rod is put. One for trout, perch, &c. ought to be from twelve to fifteen feet in length, and a salmon one from sixteen to twenty feet, besides being considerably stronger. Whatever be the length, it must be quite straight, and on all occasions bend back to its original straightness. If there be a single knot in the timber, reject it, for it will certainly snap at the first severe pull or jerk. It should be varnished, to protect it from the action of the water. The rod is not all of one piece. For the sake of convenience, it is divided into four, or perhaps six pieces in the length. These pieces are usually joined by means of screws and ferules; but if this be the plan of the rod offered to your choice, take care to see that these metal junctions do not impair the bending properties of the instrument, or render it too heavy. Rods of a plain kind made in the country are spliced with wax threads, and these are generally more serviceable than the fine-looking rods manufactured in cities. Listen to what John Younger of St Boswell's (a village on the Tweed) says on this subject:—'To those who reside near the water, I would recommend a rod all of glued and tied joints as best in point of real use, and not so liable to break in the moment of action. Or, indeed, even for travelling, I would prefer tied joints, as wherever a person has time to stop to fish, though only for a day or two, he has at least five minutes to spare for tying his rod in a sufficient manner. Rods are often breaking at brass joints; and those who use them, instead of bringing in a back-load of fish, are constantly arriving home from the water, telling you, "I've broke my rod!" Such sickening news may generally be prevented by tied joints.'

At the bottom of the rod, where it is grasped by the hand, a brass reel or *pirn* is attached, and on this the line is wound. It should be simple in its mechanism, so as to allow of expeditious winding or unwinding. The line is conducted from the reel to the upper termination through small wire-loops, in Scotland called *mylics*, which are fixed to the rod; these must be in an even line when the pieces of the rod are joined together, and be about a foot asunder. In *fashionable* rods, the mylics are small rings held by wires to the rod, and they conveniently fall flat when the rod is not in use. Good serviceable rods require no such elegance of design. The angler who is skilled in his art cares nothing for finery of apparatus, and will pull out dozens of fish in a day with an instrument which many would think not worth the carrying. Indeed, one of the best day's sport ever we enjoyed was with a sapling ash, lithe and green, from the banks of the river over which it was plied with such memorable success.

Lines.

These should be long, smooth, light, and flexible, and of a material which will not be easily injured by wet. These qualities are found in lines made of horse hair and gut, which we recommend in preference to any other. The part of the line which is wound on the reel, and goes along the rod, is called the *reel-line*; and being designed to be let out only on occasions when a fish darts off with a hook in its mouth, it need not be so thin and light as the bulk of the portion termed the *casting-line*. The reel-line, which may be about thirty yards in length for ordinary trout-fishing, is formed by spinning together horse hairs, so as to make a fine even cord. As it is troublesome to make, it should be purchased from a respectable dealer in fishing-tackle. It should be from twelve to fifteen hairs in thickness, the hairs being white, fresh, and well cleaned. The line for salmon should contain from eighteen to twenty-four hairs, and extend to at least sixty yards in length.

The casting-line, which is united by a loop to the reel-line, may be also of horse hair, but of a smaller texture and lighter in weight. It should be five lengths of hairs in extent, the uppermost length being eight hairs in thickness, and gradually diminishing the number to three or four in the lowest length. To the lower end of this casting-line is added the *gut-line*, which is the part that actually falls upon the water, and therefore requires to be very fine. It consists of a series of strong gut, and to it is attached the short lengths or casts of gut on which are the hooks. In some instances, the casting-line is altogether made of gut, on which more dependence can be placed than on hair; if of gut, three threads are sufficient for the thickness.

On the article gut, Mr Stoddart, in his 'Art of Angling,' has the following observations:—'This article, originally imported from the East, and now brought in considerable quantities from Spain and Italy, is, as far as we have been able to learn, fabricated from the male silk-worm in a state of decomposition. The operation is principally conducted by children, and consists in removing the external slough of the worm with the fingers, elongating at the same time the gluey substance which composes its entrails. To do this properly requires some care and attention. Should the worm be kept too long, a hard crust forms itself over it, in destroying which the application of the nail is necessary; hence the gut becomes flattened, and loses much of its value. The sinews of herons and other birds are also manufactured in Spain into a sort of gut, and are much used, although unwittingly, by our salmon fishers. Worm-gut varies in length from nearly two feet and downwards. We have seen, however, an article very closely resembling it from the Archipelago, which measures at least a yard and a-half. This is not to be confounded with sea-weed, although a vegetable fibre, and drawn out of a plant. It is much stronger and better suited for angling. The inhabitants of the Greek islands use it for catching mullet, and will often toss a fish some pounds weight over their heads by a thread or two. We ourselves have found it excellent for the larger sorts of tackle. Animal gut is, however, more generally used, and better adapted for trouting. It ought to be small, round, and transparent, without any flaw or roughness. When worn or disordered, the application of a piece of India-rubber will at once renovate it. In joining threads together for the purpose of making casts, the single knot properly drawn is quite sufficient. One should avoid clipping the useless extremities too closely in this operation, as in that case the knot is somewhat liable to give way. Gut, to keep well, should be moistened with fine oil (almond or olive), and stored in oiled paper.'

To these recommendations we may add, that lines of all kinds should be kept dry. On returning from a fishing excursion, draw out the line, and let it be thoroughly dried by waving in the air before being wound up or laid aside. When to be again used, look it over, giving it a gentle tug here and there to try its strength, and repair damaged parts. On coming to the water-side, and just before throwing, allow the casting line to be wetted in the water, and this will at once give it smoothness and elasticity.

Hooks.

These are small instruments made of tempered steel, and of whatever size, they require to possess the qualities of lightness and great strength. They have been always principally manufactured at two places—Kendal in Westmoreland, and Limerick in Ireland. The Kendal circular bends, as they are called, are reckoned the best hooks of a small size, while the Limerick hook is preferable for salmon. Many of the fish-hooks of ordinary English makers are worthless. Hooks range in size from about an inch and a-half in length down to a quarter of an inch, with a proportional diminution of thickness. Some makers number them from No. 10, the smallest, to No. 20, the largest, while others number from 1, the largest, to 14, the smallest. The Limerick hooks are denoted by letters, commencing with A, and so on. In purchasing hooks, see that the body is of equal thickness throughout, and that the barb is boldly yet firmly set. Try their power of resistance by forcing the bend with the fingers, and urging the point against the thumb-nail. Hooks for fly-fishing should be thinner in the shank than those designed for bait. An angler should keep a small stock of hooks of various sorts, to be ready on all emergencies; with the tackle to which they are attached, they require to be kept very dry.

Landing Net—Gaff—Drag-Hook.

The *landing net* is considered in England a necessary implement for an angler, but in our opinion they must be poor hands at fishing who cannot drag a trout or any similar small fish from the water after hooking it without resorting to such a cumbrous apparatus. Perhaps it is found to be essential, in consequence of the feebleness of the rods and tackle usually employed. It consists of a small bag net stretched on a hoop at the extremity of a pole four or five feet in length. Mr Blaine, in his 'Encyclopædia of Rural Sports,' seems to think a landing net of first importance; and for the use of tyros in the art, he gives the following directions:—'In fly-fishing, when the line is long, and there is not much space to step backward, or the reel clogged, it is necessary sometimes to lay hold of the line with one hand; but this should be done with great caution, and then only after the fish is well-nigh spent, or one struggle may carry away line, hook, and fish. In all other cases avoid touching the line if possible; but having sufficiently played the fish, whether taken by bottom or by fly-fishing, bring him within reach of the landing net, and then carefully conduct or slide the net obliquely under the foreparts of his body, which, if the fish be completely exhausted, will fall into it; but if he has still sufficient vigour, it will be prudent rather to slide him over the net than the net under him. It must have occurred to every angler to have supposed a trout or salmon to be completely spent, who, the moment he has been touched by the net, or has even caught sight of the fisher, has sprung off with most annoying violence. Against such an accident it is prudent to be ever prepared by keeping the rod in an upright position, acting on a tightened line, but yet so disposed that it can run at liberty if required. When the head and shoulders of the fish are once fairly within the net, a slight turn of it will take in the whole body, and the net being then kept horizontally, will insure his safety; for with the head downwards, he cannot disengage himself from the net: but if he be received tail foremost, as is sometimes done in deep waters, from overhanging banks, &c. beware of his plunges.'

The *gaff* is another aid to landing fish, and is employed in cases in which the landing net would be too small. It is used chiefly for landing salmon, and consists of a peculiarly-shaped hook at the end of a staff. When the salmon flounders about and incommodes the fisher, he is expected to secure the animal, and prevent it from breaking his line and rod by hooking it with the gaff at the gills, the tail, or any part he can conveniently lay hold of.

The *drag-hook* is an implement with three bent prongs or hooks, with a long cord line attached. It is used for casting into rivers to clear away any object at the bottom upon which the hook is caught. We pity the angler who attempts fishing in weedy puddles requiring such a clearer of hindrances.

Angler's Pocket-Book, &c.

The angler's equipment is completed by the addition of a basket for holding his fish, which is slung on the back by a shoulder-belt; also a pocket-book for holding hooks and other trifles; and a round flat tin box for his fly-casts. Many carry their supply of fly-casts wound round their hat, and some keep them within the leaves of their pocket-book. This pocket-book, which is the storehouse of all kinds of odds and ends—we have seen a good one made out of an old pocket almanac—should have two or three pockets for holding an assortment of hooks, silk thread, stuff for making flies, gut, wax, small cord, fly-nippers, scissors, &c.—all to be used in case of breakage of tackle or rod, or any other accident. In fishing for perch, gudgeons, bream, &c. a small float is often used. Floats are made of cork, quill, reed, and other materials; and a choice, according to circumstances, can be added to the contents of the pocket-book.

For an angling dress all finery is worse than useless. Fish are easily scared with the appearance of any light or showy object on the banks. Let the angler, therefore, dress himself in a plain dull-coloured suit, with a hat equally sober in its aspect; and let him use only strong shoes on boots, which will not be injured by water. A suit of gray-coloured Tweed, with a felt or flap hat, is at present reckoned orthodox; and to these we may safely suggest the addition of a pocket-flask, to be filled at the outset of the day's excursion according to the taste of the bearer.

Baits.

A bait is any substance put upon a hook to act as a lure to the fish; and when used, the baited hook is dropped into, and allowed to sink in, the water, instead of being kept near or upon the surface, as in the case of fishing with fly. The materials, living and dead, used for bait are very numerous; but the leading kinds are worms, maggots, minnows, insects, and salmon roe. The hook employed in either case is tied by the shank to the gut with waxed silk, and the preparation is therefore not at all difficult. When dressed to the gut, it is called bait or worm-tackle.

Worms used for bait are of various sorts; but that which is most commonly employed is the lob or garden-worm, a long reddish-coloured reptile found in abundance in many gardens, grass-plots, under old cow-droppings in fields, and in any rich old soil. They may be dug up with a spade, or caught while crawling from their holes at twilight, and particularly after heavy showers. 'He who seeks them,' says Daniel, 'must move cautiously without noise, or they will quickly retreat into the earth; draw them gently out of their holes without nipping; those that sever in taking must be thrown away, as they will soon become putrid, and infect the others; when as many are collected as are wanted, having plenty of good moss freed from dirt, dip it into clean water, and wring it nearly dry; put it into an earthen pot proportioned to the quantity of worms, laying it regular, and forcing it down with the hands; strew the worms on the surface, after dipping them in clear cold water to rid them of the soil that may adhere to them; such as are not injured will soon bury themselves in the moss, and those that do not must the next morning be picked off as useless; they must be inspected every three or four days, the dead ones removed, and have fresh moss, or that wherein they have been kept well washed and picked, and the water squeezed out at least once a week; they must be so placed summer and winter as to be safe from the extremity of the weather at both seasons. In a week's time they will be fit for use; and upon the angler coming home from fishing, he will return from his worm-bag into the pot those which he has not used. By observing the above carefully, they may be kept a month in summer, particularly by now and then giving them, drop by drop upon the moss, a small quantity of new milk and the yolk of an egg well beaten together, and warmed so as to thicken it; but when a stock of lob-worms is meant to be retained for a considerable length of time, a large vessel must be filled half or three-quarters full of good mould, in the middle of which is to be placed some moss or old coarse linen cloths, hopsack, or rags wetted; in hot dry weather, clean water must be sprinkled upon the earth with a watering-pot, so as to keep them moist, but not wet; they may thus be preserved as long as is requisite; and a week before angling, what are wanted may be drawn from the store, and put into moss to scour themselves.' Another worm, which is found in dunghills, called the *brandling*, from its striped appearance, forms a good bait, but it is seldom used.

Maggots, or the larvæ of insects, as is well known, are found on fly-blown meat or any putrid animal substances; very fine ones are procured from game in a *high* condition. Daniel calls these creatures *gentles*, and describes them as of great virtue in certain kinds of fishing:—'Gentles,' he observes, 'may be procured almost at any time at the tallow-chandlers, and should be kept in oatmeal and bran, as bran by itself is too dry. Those who live in or near London may buy them in proper condition for the day on which they wish to use them; but for the accommodation of those who reside in the country, remote from such convenience, the best modes of breeding them will be here mentioned, in order to prevent disappointments. Coarse fish, such as *chub* and *roach*, may be laid in an earthen pot, in the shade, and will soon be fly-blown; when the gentles are of the proper size (but not before), put some oatmeal and bran to them, and in two days they will be well scoured, and fit to fish with; in about four more they become hard, assume a pale red colour, and soon after change to flies: the red ones should not be thrown away, as frequently roach and dace take these with a white one, in preference to all other baits. Some have recommended a piece of liver suspended by a stick over a barrel of clay, into which the gentles fall and cleanse themselves; but clay will not scour them, and, besides, they fall from the liver before they have attained their full size. The before-mentioned is a less disgusting plan; for a short time after oatmeal and bran are put to the gentles, the fish in which they are bred will be found perfect skeletons, and may be thrown away; however, if they are to be bred from liver, it should be scarified deeply in many parts, and then hung up, and nearly covered over, as in that way the flies will blow it better than when wholly exposed. In two or three days the gentles will be seen alive; the liver is then to be put into an earthen pan, and there remain until the first brood are of full growth; a sufficient quantity of fine sand and bran (letting the liver remain) is then to be put into the pan, and in a few days they will come from the flesh, and scour themselves in it. The liver should then be hung across the pan, and the latter brood will soon drop out, and be fit for use; and by thus breeding them in October, and keeping them a little warmer than those bred in the summer, until they arrive at their full growth, and afterwards putting them in the same pan into a dampish vault, they may be preserved for winter fishing. Those bred in summer, but for the bran and sand, would soon sink into a dormant state. The skins take on a blackish-red, full of white matter, and shortly after become flies: those produced in autumn, from whatever substance, will continue in this state all the winter, provided they can shelter themselves under the surface of the earth in fields, gardens, &c.; and in the warm weather of the ensuing spring they change into flies, thus preserving their kind from year to year. Gentles are so universal and so alluring a bait, that the angler should never be unprovided with them. Trouts have been taken with them in clear water, when they have refused all kinds of worms and artificial flies.'

Caddis, or *cad-bait*, is another kind of larva, inhabiting pieces of straw, or little cylinders formed of bits of stick or sand at the sides of rivers. Daniel has some interesting observations on this species of bait:—'The several kinds of cadews in their nympha or maggot state thus house themselves: one sort in straw, thence called straw-worms; others in two or more parallel sticks, creeping at the bottom of brooks; a third in a small bundle of pieces of rushes, duck-weed, &c. glued together, therewith they float on the surface, and can row themselves about the water with the help of their feet: both these are called cad-bait. It is a curious faculty that these creatures possess of gathering such bodies as are fittest for their purpose, and then so glueing them together, some to be heavier than water, that the animal may remain at bottom where its food is, and others to be so buoyant as to float, and there collect its sustenance. These houses are coarse, and show no outward art, but are within well tunnelled, and have a tough hard paste, into which the hinder part of the maggot is so fixed, that its cell can be drawn after it without danger of leaving it behind; and it can also thrust out its body to reach the needful supplies, or withdraw into its covering for protection and safety. These insects inhabit pits, ponds, low running rivers, or ditches, in cases of different forms, and composed of various materials: some of them enclosed in a very rough shell, found among weeds in standing waters, are generally tinged green; others are bigger than a gentle, and of a yellowish hue, with a black head: they form an excellent bait, and are found most plentifully in gravelly and stony rivulets, and by the sides of streams, in large rivers among stones.

To collect them, turn up the stones, and the best will adhere to them; when the quantity wanted is obtained, put them into a linen bag for five or six days, dip them, together with the bag, into water once a day, and hang them up; they will then turn yellow, become tough, and fitter for angling than when first got from the brook. If meant to be kept long, they must be put into a thick woollen bag, with some of the moist gravel or sand from the same rivulet whence they are taken; they must be wetted twice a day, but oftener in very hot weather: when you carry them abroad, fill the bag with water, and holding the mouth of it close, let the water run from them; in this way they may be kept three weeks. Another way of preserving them is by placing them in an earthen pot full of river water, with some of the gravel they were bred in at the bottom; but the preceding method is preferable. Some use bait pans of different sizes for insects, the tops punched full of holes, not so large as to admit of their escaping when placed in the river, which not only keeps them cool, but supplies them with aliment in the fresh water; some keep them in moss in a woollen bag on a damp floor, taking care that the bag retains a proper moisture. A third mode of preserving caddis, and also grasshoppers, caterpillars, oak-worms, or natural flies, is to take the green withy bark from a bough six or seven inches round, and about a foot in length: turn both ends into the form of a hoop, and fasten them with a large needle and thread; stop up the bottom with cork, and bore the back full of holes with a red-hot wire; tie over it a colewort leaf, and lay it in the grass every night. In this manner caddis may be preserved until they turn to flies. When grasshoppers are to be preserved in the case, some grass must be put into it.

In angling with caddis, the line, when all out, should be as long as the rod, for three lengths next the hook, of single hairs, with the smallest float, and the least weight of lead that the swiftness of the stream will allow to sink; and that may be aided by avoiding the violence of the current, and angling in the returns of a stream, or in the eddies betwixt two; which are also the most likely places wherein to kill fish, either at the top or bottom. The caddis may be at times, with very good effect, joined to a worm, and sometimes to an artificial fly, to cover the point of a hook; and also two or three together may be put in upon the hook. It is always, however, to be angled with at the bottom, especially when by itself, with the finest tackle, and at all seasons forms a most holding bait for trout and grayling.'

Minnow bait.—Minnows are a small fish, from an inch to two inches in length. They swim in flocks, and may be captured by a hoop-net on the end of a staff, or more simply by a crooked pin baited with a small worm. Anglers generally hire a boy to catch a quantity of them. The tackles used for minnow bait are various in their formation; some are single hooks; others a pair of hooks dressed back to back; and a third kind are a series of pairs, one above another. We cannot do better than give Mr Stoddart's description of these deadly instruments, and the mode of baiting them. He alludes to Kendal hooks:—

'The most simple, and in some places the most deadly, is a common single bait-hook. This we insert through the back of the minnow, and drawing it out, run below the gill, allowing the barb to protrude from the mouth; we then tie up the tail along the gut, either with a piece of silk thread, or more expeditiously with the gut itself, hitched over the part. This is angled with in the same manner as the worm, allowing plenty of time for the fish to gorge. A tackle similar to it may be used in standing-pools or lochs. Here, however, the shank of the hook (a long one) is loaded, and the bait allowed to descend rapidly towards the bottom. Large cautious fish are sometimes taken by this method of angling. Of all minnow tackles, that with swivels is the commonest and most agreeable to employ. There are many ways of constructing it. Two of these we shall mention as preferable to all others. One is simply a large hook, No. 11, fastened to good round gut with two smaller ones, No. 7, tied back to back above, and looped in the dressing, so as to slide along, and shorten or lengthen the tackle to the dimensions of the bait. In using it, enter the lowermost hook through the mouth, and bring it out near the tail of the minnow; insert one of the hooks on the slider through its lips, noticing that the fish be slightly curved so as to spin properly. The other tackle is composed of six hooks, No. 7, dressed in pairs, and is angled with only when the trout are in a taking mood. Two or more swivels are required for both of these contrivances—the lowermost fastened about two feet or so above the bait. Leaden pellets may also be used, but many think them unnecessary. Some anglers attach behind the whole apparatus an extra hook, No. 12 or 13, dressed upon a hog's bristle, which, should the trout miss the minnow, is apt to catch him, when retiring, by the middle or other part of the body. This is a superfluity, and, like many superfluities, does more harm than good, alarming the fish without securing them. Tackle for trolling with par or small trout ought to be constructed on the same principles as the minnow-tackle; only the hooks should be larger and dressed upon gimp instead of gut. Snap-hooks, also, are in use for this kind of angling. Small silk cord oiled will be found the best trolling-line.'

The perfect insects used for baits are grasshoppers, crickets, day-flies, spring-flies, May-flies, humble bees, and various others. The ephemeræ, or those fragile creatures that live but for a day or even a few hours, and therefore called day-flies, are found sporting by the low banks of rivers in warm weather, and form a taking bait for trout and some other fish.

Salmon Roe.—The efficient use of this as a bait is a modern discovery, and has added largely to the angler's means of capturing the finny tribes. The roe is taken from a salmon a fortnight before spawning, at which time it is best for the purpose. Some prepare it for use by salting it a little, and drying it to a state in which it will keep; others cure it with sugar instead of salt. Blaine recommends the following as a method by which it may be kept good for two years in a cool situation:—'A pound of spawn is immersed in water as hot as the hands can bear it, and is then picked from membraneous films, &c. It is now to be rinsed with cold water, and hung up to drain for twenty-four hours, after which put to it two ounces of rock or bay-salt, and a quarter of an ounce of saltpetre, and again hang it up for twenty-four hours more. Now spread it on a dish, and gently dry it before the fire or in the sun, and when it becomes stiff pot it down. We should, however, recommend that the potting be not in one mass, but, like the shrimp-paste sold at the fish-sauce shops, that it be divided into small pots, pouring over each some melted suet, by which method a pot can be opened when wanted, instead of disturbing the general store. It forms an additional security to cover each over with a moistened skin or bladder. Trout roe is also said to make a good bait, but we have no personal experience of its efficacy—in fact, we never tried it; but it has been so strongly recommended, that it would be but fair to give credence to its value until numerous trials have proclaimed it as totally inert.

To bait with salmon roe, first put on the hook (which should be sized according to the fish intended to be tried for) a mass which shall fill up the hollow of the bend and hide the steel. On the point put two or more firm large grains of it, both to conceal the snare and tempt the fish. In this way it is said to be principally a winter and a spring bait, but we know no reason why it may not be advantageously used at other times, for spawn of some kind is almost always to be found.'

Pastes made of shrimps, of cheese, of bread crumbs mixed with honey, and of other materials, are also employed, according to the fancy of the angler, and the nature of waters and sport he intends to pursue; our limited space, however, obliges us to refer those who are curious in the subject of baits to the Encyclopædia of Blaine, where there is a vast body of highly interesting matter on angling. Those who are disinclined to prepare roe and pastes, or have not the means of doing so, may be supplied by the dealers in fishing-tackle.

Artificial Flies.

Hooks dressed up so as to bear something like a resemblance to actual live flies, are by far the most important lures employed by the angler. The principal materials employed in dressing are light portions of cock's hackle or other feathers, to form wings, the fur of a hare's ear or some other substance to make the body, and waxed silk thread, by which the whole is tied in an artful manner on the shank of the hook. A whole sheet might easily be filled with descriptions of artificial flies suitable to different fish, waters, and seasons; but the bulk of what has been written by Walton, Daniel, and many others, is now considered superfluous, experienced fishers having arrived at the conclusion that fishes in general are such eager and heedless fools as to be satisfied with a very limited choice of deceptions. The author of the article *Angling*, in the 'Encyclopædia Britannica,' has some clever remarks on this branch of the art:—

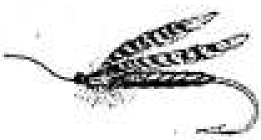
'As simulation,' says he, 'consists in the adoption or affectation of what is not, while dissimulation consists in the careful concealment of what really is—the one being a positive, the other a negative act—so the great object of the fly-fisher is to dissimulate in such a manner as to prevent his expected prey from detecting the artificial nature of his lure, without troubling himself by a vain effort to simulate or assume with his fly the appearance of any individual or specific form of insect life. There is, in truth, little or no connection between the art of angling and the science of entomology; and therefore the success of the angler, in by far the greater proportion of cases, does not depend on the resemblance which subsists between his artificial fly and the natural insect. This statement is no doubt greatly at variance with the expressed principles of all who have deemed fishing worthy of consideration, from the days of Isaiah and Theocritus, to those of Carrol and Bainbridge. But we are not the less decidedly of opinion, that in nine instances out of ten a fish seizes upon an artificial fly as upon an insect or moving creature *sui generis*, and not on account of its exact and successful resemblance to any accustomed and familiar object.

If it is not so, let us request to be informed upon what principle of imitative art the different varieties of salmon-fly can be supposed to bear the most distant resemblance to any species of dragon-fly, to imitate which we are frequently told they are intended? Certainly no perceptible similarity in form or aspect exists between them, all the species of dragon-fly, with the exception of one or two of the sub-genus Calepterix, being characterised by clear lace-like pellucid wings, entirely unadorned by those fantastic gaudy colours, borrowed from the peacock and other "birds of gayest plume," which are made to distinguish the supposed resemblance. Besides, the finest salmon-fishing is frequently in mild weather during the cooler seasons of the year, in autumn and early spring, several months either before or after any dragon-fly has become visible on the face of the waters, as it is a summer insect, and rarely makes its appearance in the perfect state until the month of June. If they bear no resemblance to each other in form or colour, how much more unlike must they seem when, instead of being swept like lightning down the current as a real one would be, the artificial fly is seen crossing and recrossing every stream and torrent with the agility of an otter and the strength of an alligator! Or darting with regular jerks, and often many inches under water, up smooth continuous flows, where all the dragon-flies on earth, with St George to boot, could not maintain their place a single second! Now, as it is demonstrable that the artificial fly generally used for salmon bears no resemblance except in size to any living one—that the only tribe which from their respective dimensions, it may be supposed to represent does not exist in the winged state during the period when the imitation is most generally and most successfully practised—and if they did, that their habits and natural powers totally disenable them from being at any time seen under such circumstances as would give a colour to the supposition of the one being ever mistaken for the other—may we not fairly conclude that, in this instance at least, the fish proceed upon other grounds, and are deceived by an appearance of life and motion, rather than by a specific resemblance to anything which they had previously been in the habit of capturing? What natural insect do the large flies, at which sea-trout rise so readily, resemble? These, as well as grilse and salmon, frequently take the lure far within the bounds of the salt-water mark; and yet naturalists know that no such thing as a salt-water fly exists, or at least has ever been discovered by their researches. Indeed, no true winged insect inhabits the sea. What species are imitated by the palmer, or by three-fourths of the dressed flies in common use? An artificial fly can, at the best, be considered only as the representative of a natural one which has been drowned, as it is impossible to imitate the dancing or hovering flight of the real insect over the surface of the stream; and even with that restricted idea of its resemblance to nature, the likeness must be scarcely perceptible, owing to the difference of motion and the great variety of directions in which the angler is obliged to drag his flies, according to the nature and special localities of the current, and the prevailing direction of the wind.

We are therefore of opinion that all or a great proportion of what has been so often and sometimes so well said about the great variety of flies necessary to an angler—about the necessity of changing his tackle according to each particular month throughout the season—about one fly being adapted solely to the morning, another to noonday, and a third to the evening—and about every river having its own particular flies, &c. is, if not altogether erroneous, at least greatly exaggerated and misconceived. That determinate relations exist between flies of a certain colour and particular conditions of a river, is, we doubt not, true; but these are rather connected with angling as an artificial science, and have but little to do with any analogous relations in nature. The great object, by whatever means to be accomplished, is to render the fly deceptive; and this, from the very nature of things, is continually effected by fishing with flies which differ in colour and appearance from those which prevail upon the water; because, in truth, as we shall afterwards have occasion to show, none else can be purchased or procured. Even admitting for a moment the theory of representation, when a particular fly prevails upon a river, an artificial one in imitation of it will never resemble it so closely as to appear the same to those below (that is, the fish); on the contrary, a certain degree of resemblance, without anything like an exact similitude, will only render the finny tribe the more cautious through suspicion, while a different shape and colour, by exciting no minute or invidious comparisons, might probably be swallowed without examination. Indeed it seems sufficiently plain that where means of comparison are allowed, and where exact imitation is at the same time impossible, it is much better to have recourse to a general idea, than to an awkward individual representation.'

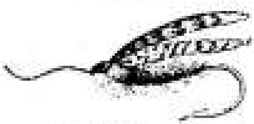
Mr Stoddart, one of our most experienced anglers, entertains a similar opinion:—'The colours of water and sky,' he observes, 'are the only indicators which can lead us to select the most killing hook, and even these are often deceptive. We have fished in one stream where dark, and, in the next, red flies took the lead. There is no trusting to the fancy in certain places. On Tweed, we have seen it veer about, like the wind, in one moment, without a note of preparation. Most rivers, however, are more steady; and when the water is of a moderate size, may be relied on with at most two sorts of flies all the year round. For ourselves, our maximum in every Scottish stream is reduced to only four descriptions of artificial flies, with one or other of which we engage to catch trout over all the kingdom. Knowledge and practice have convinced us of the needlessness of storing up endless and perplexing varieties, which some do, in order to appear knowing and scientific.'

The following, according to these and other trustworthy authorities, form a very serviceable set of lures for fly-fishing:—*First*, there is a fly which has been called *the professor*, after Professor Wilson of Edinburgh. The wings are formed of a mottled brown feather, taken from the mallard or wild-drake, the body being composed of yellow floss silk, rather long, and wound about close to the bend with a fine red or black hackle. This simulated fly has a tight clever aspect, and is reckoned a powerful killer.



The Professor.

Second, a fly which differs from the above only by being a little shorter, more thick, and with a body made of pale-green instead of yellow silk. Green worsted may be used.



Fly with Green body.

Third, a rough powerful hackle, with wings of white and black marked feather, a bristling body of dark-green wound about with gray or mottled hackle, to which is given a pointed tail.

Rough Hackle.

Fourth, a fly of a sombre cast, the wings formed of woodcock, snipe, or lark feather, and the body of hare's ear, darker or lighter, according to individual fancy.

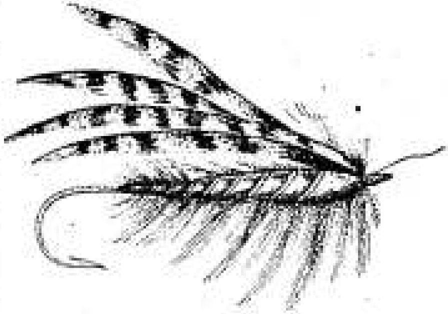
Fifth, a fly with wings of the starling or fieldfare, and having a body made of mouse or water-rat fur.

Sixth, a plain hackle, black or red, without wings, and commonly called *palmer*.

Seventh, a red hackle with wings of the starling, and a body formed of light-red mohair and a red cock's hackle.

To these may be added any other variety of fly that the fancy suggests as being suitable to the time or place of fishing. Flies for salmon-fishing must be of a much more large and powerful kind, as representing insects of larger proportions. In the adjoining figure, a specimen is given of a powerful spring lure, with wings of variegated turkey feather, a body of orange camlet, mixed with mohair, and a brown cock's hackle. A thread of gold may be wound round the body for summer fishing. We refer to the work the 'Rod and the Gun' for further information on salmon-flies, which in all cases require to be dressed on double gut.

From dealers in fishing-tackle all sorts of artificial flies may be obtained at a reasonable advance upon the raw material; persons, however, who intend to make themselves masters of the art of angling, should not be dependent on tradesmen for their supplies, but learn to dress hooks for themselves. Mr Stoddart offers the following explicit directions on fly-dressing:—



Salmon-Fly.

'Our materials for the making up of flies are as follow:—Hooks, and small round gut; a pair of brass nippers for twisting hackles; a point for dividing the wings; a pair of fine scissors; orange, yellow, and green silk thread of all sizes; good cobblers' wax enclosed in a piece of soft leather; a hare's ear; some brown wild-rake, teal, and pheasant feathers; the fur of a mouse, squirrel, and water-rat; a few wings of lark, snipe, landrail, and starling; and lastly, red and black hackles, taken from the neck and head of an old cock at Christmas; these should be fully formed, and free from softness. Plovers' herls, and those of the peacock, are used by some, yet we deem them superfluous, as also tinsel, except for large flies.

Commencing your operations, the first step is to lay out the intended wings and body before you; wax your silk, and applying one end of it to the gut and hook together, wrap them both round four or five times, commencing a little below the end of the shank, and proceeding downwards; you then fasten, by drawing the disengaged end of the thread through under the last turn of the wrapping. Work the silk upwards to where you commenced, then take your wings, which are still unseparated, and lay them along your hook, so that their extremity or tips shall reach its curve; twirl the thread twice round the upper part, which lies along the shank top; then taking it under, press firm, and clip off the unnecessary portion of the feather; divide with your point or penknife, so as to form the two wings; take up the silk betwixt them, and wrapping again round at the head, bring it back crosswise; then lift your hackle, and lay the root of it down along your hook; whip the thread over, as far as your first fastening; seize the top of the hackle with your nippers, and whirl it round in the same manner; fasten and lengthen the body to your liking with fresh floss silk; fasten once more, and your fly is made. This last fastening ought, in our opinion, to be the same as that used in arming bait-hooks, for which we quote Hawkins's directions:—"When you are in about four turns of the bend of the hook, take the shank between the fore-finger and thumb of the left hand, and place the silk close by it, holding them both tight, and leaving the end to hang down; then draw the other part of the silk into a large loop, and with your right hand turning backwards, continue the whipping for four turns, and draw the end of the silk (which has all this while hung down under the root of your left thumb) close, and twitch it off." When the body of your fly is required to be of hare's ear or mouse skin, pull out a small quantity of the fur, and lay it along the silk, after the wings are formed; twist together, and then wrap as if the thread were bare, and fasten as above. In making flies, keep all tight, guard against heavy wings and much dubbing; the fibres of your hackle ought to be short and lie near the head of the fly; they are intended to resemble legs, which in the real insect are always so placed. Such is our method of fly-dressing, commendable both for its simplicity and expedition. It differs, we find, somewhat from that generally practised, being in a manner self-taught, and not encumbered with any unnecessary display.'

Having now described the various parts of the angler's apparatus, and the lures which he generally employs, we proceed to show how he is to practise his craft when fully equipped for the purpose.

PRACTICE OF ANGLING.

There are two distinct kinds of angling—bait-fishing and fly-fishing, and these are variously practised according to the depth, current, and state of the water, or the nature of the fish sought to be caught.

Bait-Fishing.

This kind of angling is practised to a great extent in the Thames, the Lea, and other deep and somewhat dull rivers of England. The fish usually sought for in these waters are gudgeon, dace, roach, bream, chub, barbel, tench, carp, perch, and pike; all are sometimes taken by fly, but a bait of worms, gentles, roe, or some other material, is commonly employed. The angler in these rivers usually stands on the shore while fishing, but in some instances he fishes from a punt, or small flat-bottomed boat, in which his chief occupation is to sit watching his float, and pulling in his line when a fish appears to be hooked. Among the apparatus of this order of deep-water fishers, a plummet and line is carried, in order to sound the depth of the river, which having ascertained, the angler puts his float upon the line, at that point which will allow the bait to trail slightly on, or just free of the bottom, while the float swims on the surface.

The first thing the bait-fisher has to learn is the art of baiting his hooks. Taking the hook in his right hand and the bait between his fingers in the left, let him enter the hook at the head of the worm, and carry it through the animal to near the tail, covering the entire hook and its tying. The worm should be broken or mangled as little as possible; and the more life-like it appears, the greater the probability of its proving an effectual lure. There must not, however, be too much spare worm left dangling from the hook, otherwise the fish will keep nibbling it away without biting at the bait bodily, and taking it into its mouth, the thing which the angler desires.

In throwing the line with bait, take care not to splash the water, but throw somewhat horizontally forward, so as to let the bait fall gently on the surface, and sink slowly in the water to the required depth. After sinking, the rod and line should be very slowly moved in a direction against the stream, or in some other way to give motion to the bait, which the fish perceiving to glide through the water, will hasten to seize upon. As fishes, however, are always on the outlook for floating garbage, one-half the dragging and twittering which bait-fishers generally employ is altogether useless, often positively hurtful, as scaring rather than alluring the objects of their capture.

Occasionally the angler will *feel* a nibble, but he must not be in a hurry to *strike*—that is, to draw the fish from the water. Perhaps it is no more than a nibble, and it is well to allow the fish time to get the hook in his mouth. If drawn too quickly, you may actually pull away the hook after it is half gulped. Experience and dexterity are required in this ticklish part of the craft. As a general rule, do not strike till the line has been distinctly tugged; then strike by a slow side motion at first, then a more quick jerk, so as to cause the hook to catch in the jaws of the animal. Supposing the fish to be hooked, do not draw it violently out of the water, as if in a transport of delight, but wind up part of your loose line if necessary, and holding up your rod, retire gradually backward, by which the fish may be landed on the shore. A good angler does not lay aside his rod to take a fish from the hook, unless it be of great size, requiring two hands; if small, hold the rod in the right hand while you catch the fish with the left; unhook it without mangling, place it in the basket, put on a new bait, and once more proceed to your sport.

The *gudgeon*, a fine large fish of the trout shape, affords a favourite amusement to anglers in the Lea, a river near London, and also in the Thames. Blaine thus speaks of this branch of angling:—'Fishing for gudgeons in the Thames is usually practised by means of a punt, which is fixed across the stream part of the river just above a tolerably sharp scower, running over a fine gravelly bottom, free from weeds, at depths varying from five to eight or ten feet. As the eddy is greater generally, and the water deeper in these scowers than in those of the Lea, so the tackle used is commonly somewhat stronger, and a fine gut-line is more frequently met with there than one of single hair. Fine tackle, however, in a good hand, is to be always preferred; and we have seen many hundred dozens of gudgeons taken in the sharpest currents of this river also with a single hair only for the two bottom links. Punt-fishing for gudgeon in the Thames is a delightful amusement, particularly to the luxurious angler who is not inclined to take much trouble. The scenery, the quietude, and safety from interruption, the cleanliness of the practice, where the bait is put on the hook by the attendant fisherman, and where even the prize it gains is removed by the same hand, all tend to make it epicurean in the extreme. But the thorough-bred fisher is soon tired with it after this method, for the very reason that there is actually too much luxury in it to constitute true sporting, which must of necessity present some labour to keep up the attention, and some difficulty to enhance the value of the prey. In the Thames, so many as fifty dozen of gudgeons have been taken in a day; but in the Lea seldom half that number are caught. Yet the Lea angler has the best scope for his sport, for he can commence it in March, whereas in all that part of the Thames within the liberties of the city of London, it must not be attempted until the beginning of June, at which time the gudgeons have spawned, and continue for some time afterwards inferior in point of their gastronomic worth. Gudgeon-fishing seems to have varied little from the ancient practice, and the angler who has aught of the antiquarian about him, will be amused probably at the close parallel between the present method and the gudgeon-fishing of early times, as it is described by John Davers or John Dennys, Esq., for it is a disputed point to which of these worthies the "Secrets of Angling," in which it is contained, owes its birth. Walton ascribes it to Davers, and gives the name at full length in the fifth edition of "The Complete Angler:"—

"Loe, in a little boat where one doth stand,
That to a willow bough the while is tied,
And with a pole doth stir and raise the sand,
Whereat the gentle streame doth softly slide;
And then with slender line and rod in hand,
The eager bite not long he doth abide.
Well leaded is his line, his hooke but small,
A good big cork to bear the stream with all.

His bait the least red worme that may be found,
And at the bottome it doth alwayes lie;
Whereat the greedy gudgion bites so sound,
That hooke and all he swalloweth by and by.
See how he strikes, and pulls them up as round
As if new store the place did still supply:
And when the bit doth die, or bad doth prove,
Then to another place he doth remove."'

The roach is a thick fish, deep from the back to the belly; it inhabits the bottom of deep rivers or lakes, and is usually reckoned so incautious and silly as to be called the water sheep; nevertheless, it is not taken without some degree of skill. It is angled for by means of bait sunk to within a few inches of the bottom. The fish may be attracted by throwing in some crumbs of bread. It is caught in the Thames some time after the end of August. The baits used are gentles, red paste, and boiled malt or wheat; one grain of the latter is sufficient. Great attention is required to strike quick when the bait is taken. Dace and tench are angled for much in the same manner. Carp is angled for in stagnant waters from February to September, and the baits are worms, larvæ, grain, and pastes. The perch also inhabits dull waters, and is a short unshapely fish, soft in the flesh, and seldom worth cooking. It is so eager to bite that little skill is required in pulling out a whole fry; the baits employed for it are worms, insects, and minnows.

Pike-Fishing.

The pike is a voracious fish, and may very appropriately be termed the fresh-water shark; it does not confine itself to feed on worms, insects, fish, and frogs, but will devour water-rats and young ducks, and attack much larger animals. All small fish are terrified at the approach of this marauder, which, if permitted, would soon clear a pond of all its finny tribes. 'Pike,' says Daniel, 'love a still, shady, and unfrequented water, with a sandy, clayey, or chalky bottom (arriving at a larger size in pools than rivers); and from May to the beginning of October they usually place themselves amongst or near flags, bulrushes, and water-docks, and particularly under the *Ranunculus aquaticus* when in flower, and which floats on the surface; they will sometimes be found in the termination of sharp currents; from March to the end of May they resort to back waters that have direct communication with the main stream; as winter approaches they retire into the deeps, under clay-banks, bushes impending over the water, stumps and roots of trees, piles of bridges, and flood-gates. They spawn in March or April, according to the coldness or warmth of the weather, quitting the rivers for the creeks and ditches communicating with them, and there dropping their ova in the grass and reeds; in ponds they choose the weeds upon the shallows for depositing it; ducks and other wild-fowl eagerly devour the spawn, and by them it is transported to other waters. The appearance of the pike in ponds where none were ever put, has been deemed as extraordinary as its asserted longevity; it is, however, easily accounted for upon the well-known principles of the generation of fishes. If a heron has devoured their ova, and afterwards ejected them while feeding in one of these ponds, it is highly probable that they may be produced from this original, in the same way as the seeds of plants are known to be disseminated.

Pike are in season from May to February (the female fish are to be preferred), are bold biters, afford the angler good sport, and may be fished for all the year; but the best months (especially for trolling) are February, before the weeds shoot, and October, when they have rotted down; the latter is to be preferred, as the pike are fattened by their feed during the summer; and from the lowness of the waters, their harbours are easily discovered.'

The same author thus describes the method of trolling for pike:—'For trolling, the rod should be twelve or fourteen feet long; but a strong top for this fishing, with a ring at the end for the line to run through, may be fitted to a fly or general rod; there should be one ring upon each joint to conduct the line, which is better than a greater number (and these rings must be set on straight, that it may run freely, so that no sudden check after the bait is taken prevent the pike from gorging it): the line should be of silk, with a swivel at the end to receive the armed wire or gimp, and at least thirty yards long, wound upon a winch or reel fixed to the butt end of the rod. Hooks for trolling, called dead gorges, and other sorts for trolling, snap, and trimmer, and fishing-needles, are to be bought at every shop where fishing-tackle is sold. In the choice of the first, let them not be too large, nor their temper injured by the lead on the shanks, nor the points stand too proud; and although usually sold on wire, it is recommended to cut off the wire about an inch from the lead, and with double silk well waxed, fasten about a foot of good gimp to the wire, with a noose at the other end of the gimp large enough to admit the bait to pass through, to hang it upon the line. The best baits are gudgeons or dace of a middling size; put the baiting-needle in at the mouth, and out at the middle of the tail, drawing the gimp and hook after it, fixing the point of the hook near the eye of the fish; tie the tail to the gimp, which will not only keep it in a proper position, but prevent the tail from catching against weeds and roots in the water; thus baited, the hook is to be fastened to the line, and dropped gently in the water near the sides of the river, across the water, or where it is likely pike resort; keep the bait in constant motion, sometimes letting it sink near the bottom, and gradually raising it. The angler need not make more than two or three trials in a place, for if a pike be there, he will within that time bite if he means to do so. When the bait is taken, if at a depth too great to see, it will easily be ascertained by the line being drawn tight, and by some resistance; let the pike have what line he chooses, it will be soon known when he has reached his harbour by his not drawing more; allow from five to ten minutes for his gorging the bait; wind up the line gently until the pike is seen (which he will permit though he has not gorged); should the bait be across his mouth, give more time; but if he has swallowed, manage him with a gentle hand, keeping him, however, from roots and stumps, which he will try to fasten the line upon; in clear water veer out line until he is sufficiently tired, and a landing-net can be used; but by no means, however apparently exhausted, attempt to lift him out with the rod and line only; for the moment he quits the water he will open his mouth, and from his own weight, tear the hook from his stomach; and the fish will be lost to the angler, although it must inevitably perish. In trolling, the bait should never be thrown too far; in small rivers, the opposite bank may be fished with ease; and the violence of its fall upon the water, in extensive throws, soon spoils the bait by rubbing off its scales, and alarms the pike instead of enticing him. Pike are to be allured by a large bait, but a small one is more certain to take them; never suffer weeds to hang upon the hook or bait when recast into the water, and which cannot touch the surface too softly. Always prefer a rough wind, and when the stream is clear, for trolling; pike never bite in white water after rain or freshets. If a pike goes slowly up the stream after taking the bait, it is said to be a signal of a good fish.'

Mr Stoddart's methods of angling for pike here deserve notice:—'In rod angling for pike, we adopt three methods, employing the gorge tackle, the swivel tackle, and the fly. Our gorge-hook is double brazed, and armed upon brass wire. A par or small trout inverted is the usual bait. We insert the wire of our tackle through the fish, bringing the upper end of it out at the tail, and allowing the two barbs of the hook to protrude from its mouth. In angling, we both throw and drop the bait, as the nature of the water demands, moving it slowly towards the surface. When a pike seizes it, there is at first no perceptible tug; one feels as if he heard the shutting of a pair of jaws on the bait; and if you can manage to see your fish, you will observe him holding your trout by the middle, as if crushing the life out of it. Keep a tight line, but do not pull or strike. Too much resistance places your intended victim on his guard; a little, however, sharpens his appetite. After a few seconds, the pike will begin to move towards his den, still grasping your bait betwixt his teeth, and intending to bolt it immediately. Let out line with your hand from the reel; and now he is fixed, and darts off like a tiger, shaking his chain, and with open mouth tossing himself out of the water at thirty yards' distance—the worst is over, and he turns revengefully towards the shore; wind up—ha! he is out again, and again he makes for the shallows; but the monster is exhausted and moves heavily; lead him with caution to the edge, lay down your rod, and lift him upon the bank. In order to disengage your hook from the entrails of this formidable fish, the gills should be forced open, and a knife introduced for the purpose, taking care previously to thrust it through the spine-bone of your victim, and so prevent the possibility of your catching a Tartar. Unfasten your hook from the wire before drawing the latter through the mouth of the pike, as otherwise it is again apt to catch among the teeth, from which it may be somewhat difficult to extricate it, without incurring a few scratches.

Should a fish, after having bitten, abandon your gorge-hook, try him with a running bait upon swivels, and let this be a fresh trout of a smaller size than your other, and fixed upon a gimp tackle with the tail downwards, as in minnow-fishing. See that it spins judiciously; and when the pike rises, let him turn with the bait before you strike. River pike, it may be remarked, seldom play so well as those in lochs. They push generally below the banks instead of striking across, and look out for old stumps upon which to entangle and break your line. One ought, therefore, to make quick sport with such rascals—running them down upon level banks in a twinkling, and before they are able to get under weigh.

The third method of angling for pike is with the fly—a kind of fishing not much in use, but still on some waters very deadly. The pike-fly should be large and gaudy, fabricated of divers feathers and tinsels, to resemble the king-fisher, or a huge dragon-fly. Use it in a strong warm wind, upon water from six to two feet deep, and near weeds. You will kill with it fish of various sizes, from ten inches in length and upwards: very heavy ones, however, refuse to take it, on account, probably, of the exertion necessary in order to come to the surface. We have always noticed that the biggest pike are caught during close sultry weather with a ground bait, and at those times when trout refuse food altogether; also at night, with set lines, in the summer months, when they leave the weeds and bulrushes in quest of food.

Although the pike is often nice and suspicious in places where trout abound, still, when provoked, he becomes bold and unwary, treating your presence as no constraint upon his temper and appetites. He will follow the bait to your very feet, and should it escape him, will retire a yard or two, waiting eagerly for its reappearance. When angry, he erects his fins in a remarkable manner, as the lion doth his mane, or the porcupine his quills; moreover, the pike appears careless of pain, if indeed fishes in general feel it to any great degree. We have actually landed one of these fish, couped him alive in our creel, and when by some negligence of ours he made his escape into the water, have succeeded a second time in securing him. On another occasion, we remember having a part of our tackle, consisting of a large double gorge-hook dressed upon brass wire, carried off by a pike; and yet, upon renewing it, the aggressor returned to the charge, and was taken. The former hook we discovered gorged by him in such a manner as must, we thought, not only have suffocated any other animal, but done so by the medium of the most exquisite internal agony.

Great injury has of late years been done by the transference of the pike to many of our best trouting lochs, where a single individual has been known to consume nearly its own weight of fish daily. This was the case on Loch Turit, near Crieff, where the trout, formerly abundant, are now greatly reduced by the hostile and merciless depredations of their natural enemy. The pike at table is reckoned by some a coarse dry fish, and so in general they are; yet to our knowledge, in certain lochs, for instance that of the Lowes in Selkirkshire, they almost rival the turbot, and should be cooked somewhat in a similar manner. They are none the worse for being kept a few days, especially if of any size. A good eating pike ought to weigh at least from five to twelve pounds—the smaller ones being without exception bad.'

Trout-Fishing.

The trout is of different species and varieties, as the common trout, the gillaroo or gizzard trout of Ireland, the bull trout, and the salmon trout. The shape is handsome; the flesh firm and sweet, and coloured pink or white, according to species and feeding-ground; and the weight varies from half a pound to four or five pounds. In one or other of its varieties, the trout is a universally-known fish in temperate climates; its favourite haunts are clear running rivers; and there, both in England and Scotland, it affords a favourite object of sport to the skilful angler. Sometimes bait is employed, but the fly is more common. In some cases the bait and fly must be tried alternately in one day, as the fish is capricious, and requires to be tempted in all kinds of ways. The season most favourable for trout-fishing is spring and early summer.

Fishing with bait.—'Trout,' says Blaine, 'begin to take a bait on or near the ground early in the year, and before March, will readily take most bottom baits all day long in favourable weather; but as the summer advances, it is only very early or very late in the day that they will take a bait near the ground, they being at the intermediate hours more disposed to rise to the surface for winged insects. In March and April, use the worm in the forenoon, and a fly or minnow, according to the state of the water, the rest of the day, in the swiftest and sharpest currents, provided the day be warm and bright, and in the deeps early and late; but if the water be discoloured, or very thick, try the gravelly shallows near the sides and tails of streams with a worm only, to run on the bottom with one large shot a foot at least from it. When there is a small *fresh*, or the water is clearing off, and is of a dark-brownish colour, first use the worm, which should be a well-scoured brandling, cast in as a fly at the head of the stream, and move it gently towards you, still letting it go down with the current, so as to keep it a little under water: the line should be rather short, with no lead upon it, and the hook fine; then try the minnow, and as the water clears, the artificial flies should be tried. In fishing for trout with the worm, use running-tackle, and employ a strong line, but let its strength consist in the excellence of its material rather than its bulk, to which end the hook should be small, the gut fine, the shotting fine also, and let the whippings be well concealed, for in bright water trout are singularly wary and suspicious. In some instances a float is indispensable; and when such is the case, let that likewise be as light and fine as the water will allow.'

A short line and quick striking are recommended by Mr Stoddart, who says the line 'ought always to be kept at its full stretch, and moved in a half circle with the angler. It requires some degree of perception to know the exact instant when the fish first seizes your bait; it does so with such softness, and with no likeness of a tug, as one is apt to imagine; nay, it merely closes its jaws upon the hook, as a gaping oyster would do upon one's finger. Then is your opportunity for striking; if you neglect it, you allow the trout its more leisurely process of nibbling, and its chances of escape. In striking with the short line, do it sharply, and never against the current, but rather with it, in a diagonal direction, and not too high. The reason of this advice is obvious, for all fish feed with their heads pointing up the stream—kindly giving you the choice of pulling the hook into or out of their mouths; the latter of which purposes you accomplish, to a dead certainty, by striking against the current. This whip-jack manner of bait-fishing is very deadly with an experienced hand. The long-line anglers make nothing of their method comparatively; and yet, among clear waters, and where fish are few, or bite shyly, patience and a long line will carry the day. Remarkably fine gut ought to be used by all ground anglers, whatever be the practice. Trout are a suspicious, distrustful set, and three in general slink off for one that nibbles, terrified no doubt by those singular accompaniments of your worm, a line and hook.

To all bait-fishers Scotland affords excellent sport; her rivers run so strongly, and are maintained by so many sources in the shape of mountain burns. These romantic streamlets abound in trout; every stone shelters its inhabitant, and the meanest pool is peopled with numbers. Burn fish, however, are generally of a small size; they seldom exceed a pound in weight, except in the spawning season, when larger ones ascend from broader streams, or lochs at a distance. Still, the taking of them is a pleasant pastime, especially when they bite eagerly at your worm, as they do during rain and in discoloured water. At such times, you have only to drop your bait without art, and the fish will manage its own ruin. Worms are taken greedily towards night and early in the morning; also when the sun is very powerful at mid-day. Akin to this sort of angling is fishing with salmon roe, concerning which we remark, that in autumn it is the most fatal method of capturing trout, and is coming much into practice in the south of Scotland.'

The same enthusiastic brother of the rod next proceeds to treat of minnow-fishing, which he says is by far the pleasantest mode of capturing trout, next to angling with the fly:—' If you wish to engage in this pleasant sport, provide your minnows by means of a small drag-net or hook. Select those of a moderate size, and which shine whitest. They may be salted, but are best perfectly fresh. The tail of a small trout or par is no bad substitute, if minnows cannot be had. Our only reason for preferring the fresh to the salted minnow is, that by its silvery appearance, and more rational form, it better attracts the fish; at the same time it is well known that a trout loves a salt bait, and will repeat its attack upon a minnow of that description, while it refuses to do so upon one newly taken. Fish in rapid streams, also in deep discoloured pools, and during a smart curl. Manage the minnow as you would your fly, throwing it down and across as far as you are able; bring it towards you about six inches or more below the surface, spinning rapidly by the aid of several swivels. When a fish rises, give him time before you strike; let him turn and gorge the bait, then strike sharply, and he is yours: all fly-fishers are apt to strike too soon, and miss the fish.

Trout seize a minnow by the middle or near the head, and you generally hook them on the upper hooks. In rivers where numbers of minnows are found, you must angle with the very smallest, not above an inch in length, and use a proportionate tackle. The trout in such waters love delicate tid-bits, and are absurdly nice in their feeding. Artificial minnows are sometimes employed by anglers, but generally fail, except in muddy waters and lochs. Mother-of-pearl makes one of the best imitation—there is a virtue in it which few fish can resist.'

'Trolling with par for large trout,' he continues, 'is a glorious pastime, especially on a Highland loch circled with mountain scenery—the craft of nature by incantation wrought, when the morning stars sang together. It needs intellect to enjoy it well, and a poet's heart to know its luxury. Take with you some choice and idle spirit, a rower he must be, that can manage your airy shallop as the winds do a weathercock—can chant a ballad of yore, of ladye and chieftain, and pranksome elf and kelpie wild—can speak to the echoes and to yourself, cheering you with wit and wisdom, and admiring your science and skill, and the gorgeous fish you are playing, twenty fathom off, with a strong and steady hand, your heart "high fluttering the while, like woman's when she loves."

Tackle for trolling should be dressed upon tried gimp. Bait as you do with a minnow; use a strong rod, heavy lead, and a long line of oiled cord wound upon an easy reel. Choose a sunny day, with a stiffish breeze, and troll near, but not amongst the weediest parts of the loch. Plant yourself at the boat stern, and get rowed gently at the rate of three miles an hour, letting out from twenty to thirty yards of line betwixt you and your bait. Trout from six to nine pounds' weight cause the best sport when hooked; a larger one seldom leaps or makes any violent exertion to escape; he swims sullenly, and at ease, regarding the angler with a sort of sovereign contempt. You must row after him, and turn him if you can before he gets among weeds; never slack your line for an instant, and look well about you. Land as soon as you are able, and play him from the shore. Your companion will assist you at the death.

So much for the different kinds of bait-fishing practised in Scotland. We esteem it folly to talk of the less popular baits used by the *virtuosi*—of frogs, grubs, and leeches, water-rats, and mice—all of which animals trout will devour. It might be asked, may fish not be taken with anything? They have been known to swallow money, rings, and many other glittering marvels; nevertheless they seem to have no pleasure in snapping at the bait of the unskilful angler, and refuse to die under his hands.'

Fishing with Fly.—This, after all, is the true angling, all other efforts at taking fish being either somewhat childish or murderous. A long flexible rod, fine lines, and appropriate flies, are the necessary equipment; and the best time for making the attempt is on a dark lowering day, at anyrate not in bright sunshine. If the moon has shone brightly the previous night, it will have prevented the trouts from feeding freely, and they will accordingly bite more readily when tempted with the artificial fly. Great skill and nicety are required in throwing the fly-line. Mr Stoddart gives the following directions how to proceed:—

'Your rod and tackle being ready, the wind in your favour down the river, draw out with your left hand a few yards of line from your reel, dip the top of your rod in the water, and with a rapid jerk you will lengthen as you wish that part you intend for throwing. A thirteen-foot wand will cast from six to seven fathoms of line. With a large double-handed rod you may manage a much greater length. Always, if you can, angle from a distance. Trout see you when you least imagine, and skulk off without your notice. Noise they care little about; you may talk and stamp like a madman without frightening them, but give them a glimpse of your person, and they wont stay to take another. Some ichthyologists attribute to them an acute sense of hearing: this we are disposed to question; for how happens it that the most obstreperous rattling of stones, when wading, causes no alarm, although conveyed to them through the medium of water, a good conductor of sounds? We remember angling one still night by St Mary's Loch, when our movements were heard distinctly by some shepherds at the distance of a mile, and yet the fish rose eagerly at our very feet, following our fly to the shallowest parts of the margin—a fact which, if it does not prove obtusity of hearing on the part of the fish, at anyrate renders it a matter of little consequence to the angler.

It requires some art to throw a long line. The beginner should commence with a short one, and without flies, lengthening it gradually as he improves. The best method of casting is to bring the rod slowly over the right or left shoulder, and with a turn of the wrist, make the line circle behind you, then, after a pause, fetch it forward again in the same manner, and your flies will descend softly upon the water. All jerks are apt to whip off your hooks or crack your gut. A fly-fisher may use two, three, or four flies on his casts, according to pleasure. When angling with small hooks, we adopt the medium number. Large ones ought to be fished with in pairs, and well separated. In throwing the cast, the lowermost or trail-fly should be made to alight foremost; its fall ought to be almost imperceptible; it should come down on the water like a gossamer, followed by the droppers. The moment a fly touches the surface, it is ten times more apt to raise a fish than during the act of drawing it along. At no time are we stanch advocates for the system of leading our hooks either against or across a stream; our method is rather to shake them over it for a moment, and then repeat the throw. A trout will discover your fly at the distance of several yards, if feeding, and will dart at it like lightning. Always, if you can, fish with the wind, and do not concern yourself, as some do, from what quarter it comes. In spring, no doubt, a south-west breeze is preferable to all others; yet we have seen even easterly winds not the worst on many waters, especially during summer months, when the natural fly is apt to become over-plenty.

Trout will sometimes take in the most unlikely weathers, so that the angler should not despair at any time. Hunger causes them to feed at least once in the twenty-four hours, and generally much oftener. If the wind blows down the river, commence at the pool head, and fish every inch of good water; you may pass over the very rough and very shallow parts, also those which are absolutely dead calm, and clear, unless you see fish rising in them, when, should your tackle be light, there is no harm in taking a throw or two. Dead water, however, when rippled or discoloured, may be angled in with great success. When you raise a good trout, strike slowly, or hardly at all; only continue the motion of your hand without slacking it; the fish, if large, will hook itself. Small trout and par may be whipped in with rapidity: it is folly to play or use ceremony with such trifles. Should the fish miss your fly altogether, give him another chance, and a third, if that will not do; a touch of your barb, however, will sharpen his wits, so as to prevent him from again rising. He prefers flies without stings. When you hook a trout, if you can, turn his head with the stream, and take him rapidly down. Thus you will exhaust him in the shortest time; whereas by hauling against the current, you allow him to swim freely in his natural direction, and also exert three times more strength upon your tackle than is really needful. A good-sized fish, handled in this foolish manner, can never be taken; it is impossible to tire him out, and the strongest line will give way to his resistance. When your victim is exhausted, draw him gently ashore upon the nearest channel or most level part of the margin. He will come in sideways, and generally lie motionless for a few seconds, during which time you will be able to run forward and seize him. Beware of catching hold of your line until he is properly banked. Many a famous trout have we seen lost by this inadvertence on the part of anglers, who think so to save time and labour. One should remember how the spring of the rod is thus removed, and how there remains no proper curb to the strength of the fish, which easily breaks a single gut, or tears itself from a sharp hook, and wishes the astonished angler better sport further on.'

The practice of double-rod fly-fishing for trout or for salmon is a murderous kind of sport, and should be prohibited by law. A line stretched between two rods, and hung with flies, is taken down the stream by two individuals on its opposite sides, so that every part of the water is gone over, and every feeding trout raised. By this plan large numbers are caught, but many also are wounded, and escape, to pine away for months at the bottom, unable either to feed or spawn.

Salmon-Fishing.

This may be described as a gigantic trout-fishing, the principle of alluring and capturing being the same, but all the tackle requiring to be stronger, and a greater degree of physical power being necessarily called into operation. The salmon has a peculiar habit very likely to upset the calculations of beginners: it consists of the ugly practice of running off at a violent speed as soon as he feels himself hooked, darting up the stream, throwing himself several times out of the water, and generally in the end hastening into some sheltered haunt under the banks where he expects to be safe. Great tact is necessary on these occasions, first to give line, and then to keep him from burying himself in these unapproachable nooks.

With respect to the minutiæ of the art, both in throwing and striking, the recommendations of Mr Younger of St Boswell's are well worthy of attention:—'I recommend a beginner,' says he, 'to practise throwing the line on a broad smooth pool, where he can see that it is delivered out properly, and falls lightly, without splashing. In such a case the practitioner will perceive something which he cannot easily account for: and that is, that after he has even attained a great degree of perfection in the art, he will not be able to distinguish how it happens that in one throw his long line will proceed direct out, his fly alighting first on the water; in another throw the middle of his line will fall first, while the further part, still obedient to the general impulse, will proceed out the full length, the fly falling the last on the surface. This last throw is not so good as the former; for this reason, that the main current having caught the middle of his line first, carries it too quickly down, leaving the fly lagging, to form an awkward curve, as, before it comes over above the fish, the fly should lie on the water, so as to have the appearance of plying at an angle against the current. And the angler should so manage his rod, that while he lets his line float round at its full length, yet to cause his fly to come as slowly as possible over the main spot. In this case the salmon will sometimes rise at once, rather before you expect him, but more generally will follow the fly to the eddy, or edge of the deep, where, if on examination he feel disposed to seize the hook, he has it before you perceive a head, fin, or tail above the surface. Indeed, before you perceive the web of his tail, he generally has the hook in his jaw a foot below water, as in descending he goes, like other divers, head foremost.'

Having managed to place the fly over the desired spot, our authority continues—'He will make no perceptible motion to keep his fly on the surface (except on a sluggish pool), but let it sink a little, depending on feeling rather than on sight; and though apparently keeping no pull on his line, yet all the while able to detect the touch of a minnow. On a *boil*, or other appearance of a fish, he pulls up his line, not twitchingly but actively, steps a yard or two back, rests a minute to let the fish resume his lair and attention, and perhaps feels inclined to alter his fly, before he annoy and disgust or alarm his fish, to a shade darker or a size smaller, when he will most probably come up and seize it in earnest. Should he not rise again, or rise and pass it thrice, leave him quietly alone for the present, and return to try him some time afterwards. On taking the fly, the fish means to return with it to his precise select *spot* of lair, on rock, stone, or gravel, at the bottom; and the fine angler, holding him gently, often in the first instance allows him to do so, but soon, too surely feeling his awkward predicament, he bolts off "indignant of the guile." Then is the time when the fisher is attentive; with the butt end of his rod resting on his thigh or groin, he keeps the top nearly erect, never allowing it to fall below the proper angle of forty-five degrees, as relative to the situation of the fish, as in this position the elasticity of the rod never allows the line to slacken in the least degree for a single instant, however the fish may shake, flounce, jerk, or plunge. With two or three fingers and the thumb of his left hand the angler holds his rod while the wheel-line runs out, regulated by the first or first and second fingers, relieved or assisted as occasion may suggest by the right hand, when it can be spared from its necessary occupation of rolling up the wheel line, as the fish settles a little or returns inwards. In this manner the fish is allowed to run right out, up, down, or across, as he may choose. But if in an outright dash of thirty or fifty yards salmon, ending in an outward-bound fling above water, the inexperienced angler should feel flustered, which he is very likely to do, and by some involuntary twitch of the running line let the top of his rod be pulled down to a level with his own head, then the tug of the last plunge will assuredly break his hook or line, or tear the hook from the mouth of the fish. Or, what is as bad, a sudden jerk or turn of the fish will give the line a momentary slackening, when the hook's hold, already so strained as to have widened its incision, will fall out, and your fish is gone for ever.'

Now is the critical moment for the salmon-fisher, who must keep up his rod and give line. 'The fish will then,' continues John, 'allow himself to be led at ease to the angler's side of the river, like a bridegroom to the altar, when, on finding the water shallowing, he will again make another desperate effort, probably a new dash into the middle current; but too much exhausted to resist the still continued pull upon him, he will soon again fall into the shallow, where, on a sight of his enemy, he is again alarmed into a new effort, and again exhausted by turning his outward-bound head down with the water, again and again, and again, as if the parties were in the amusement of forming circles, until his own last efforts to keep swimming are made subservient to the cautious angler in moving him by degrees into the shallow, where, half dry, he must, like all the strong, at last yield to his fate, and fall panting on his side, while the line rolled up to within rod length, which is to be held with its top landwards, without slackening, and the fisher seizing him with the fore finger and thumb of his right hand across by the root of the tail (which is by far the surest method of seizure), lifts or rather slides him out head foremost over gravel and grass, and in mercy fells him with a blow on the back of the neck.

After going through this process with a twenty-two pounder (and the process would be the same with a forty-four), the writer can aver, that he does not conceive that from the moment he has hooked such until he was laid on the grass he ever for an instant had three ounces of more or less pull on the fish; for in all circumstances of run, regularity of pull is the sure test of true skill and final success. Indeed I have seen many a fine fish laid on the dry gravel when the hold of the hook in the lip of his mouth was so slight as to be smaller than the steel of the hook—so much for equal pull and cautious management in the run. And, in short, a man is never a master angler so long as a desire to have his hooked fish to land excites in his feelings the least agitation, as the matter should be managed with that cool philosophical ease of mind which is alike above the paltry calculations of loss and gain and the common ridicule, which often tends to stir up a degree of childish fretfulness. This perfect nonchalance is absolutely necessary to first-rate excellence and ultimate success.'

Leistering is the name usually given to a murderous kind of sport pursued by salmon fishers in Scotland. Armed with *leisters*, or spears with three-barbed prongs, a set of fishers proceed to the river's bank, and there attract the fish by the glare of torches held over the water by members of the party. When a salmon is discovered, one selects it as his prey, and by a cool but rapid blow transfixes it with his spear. In many cases the fish cannot be secured or landed without plunging into the water; but this usually forms no obstacle, and several men may be seen floundering in the depths of the stream while shouts and confusion prevail among the spectators on the banks. Sir Walter Scott in his novel of 'Guy Mannering,' has presented a vivid picture of this species of sport, which is still pursued on the Tweed and its tributaries, but mostly by parties of rude marauders who are regardless of law, and kill vast numbers of fish during 'close time,' or when the rivers are legally shut. As the law at present stands, all salmon-fisheries north of the Tweed close on the 14th September; Tweed net-fishing on the 15th October; and Tweed rod-fishing on the 7th November. The fisheries north of the Tweed open on the 1st of February; and those of the Tweed, both for rod and net, on the 15th of the same month.

The Par.

The par is a small fish, which is found in great abundance in almost all rivers which are clear, and have a free communication with the sea. It varies in size of course according to its age, but seldom reaches a greater length than six inches, and is usually found below that magnitude. It is silvery in appearance, and marked by peculiar bluish bars or marks along the body; while a more nicely-forked tail, and one regular row of scarlet spots along the sides in place of two or three, aid further in distinguishing the par from the trout, the fish which it most resembles.

Of the actual character of the par, whether it is an independent species or the fry of salmon, there has been a long-continued controversy. Many naturalists were inclined to hold it as a kind of mule—a creature betwixt the trout and salmon breeds. The dispute, however, may be said to have been terminated recently by Mr Shaw of Drumlanrig, whose lengthened and ably-conducted experiments establish the par to be the natural produce or fry of the salmon. In a memoir communicated to the Royal Society of Edinburgh, Mr Shaw mentions that his first experiment on the subject consisted in the removal of a number of pars from their native stream to a pond, when he found that all of them assumed the perfect appearance of *salmon fry* or *smolts*, at the end of periods of time proportioned to their bulk when placed in the pond. He also satisfied himself that the change from the state of par to that of smolt, which is marked by the appearance of a covering of silvery scales over the blue bars, always takes place at the age of *two years*; and that then, for the first time, the metamorphosed fry take their downward departure for the sea.

But it was objected to these experiments, that Mr Shaw might have mistaken young salmon for pars in the first instance, so rendering his conclusions of no weight. To settle all disputes, he began his experiments with the *ova* or *eggs* of the salmon, first constructing ponds for their reception. These ponds, three in number, he protected by falls, pipes, and gratings, in such a way as to seclude them in a perfect manner from all interference on the part of any other fishes whatsoever. Having provided a proper net, Mr Shaw was successful in capturing a pair of adult salmon, male and female, while engaged in depositing their spawn. By expressing a portion of the ova from the female, and of the milt from her companion, he had it in his power to transfer fertilised ova to his ponds on the 27th of January 1837. 'On the 21st of March, fifty-four days afterwards, the embryo fish were visible to the naked eye. On the 7th of May, they had burst the envelop, and were to be found among the shingle of the stream. It is this brood which I have now had an opportunity of watching continuously for a length of time.'

Mr Shaw's descriptions of the brood, read to the Royal Society, and accompanied with specimens, will best show the general scope of the results. At the age of forty days after the exclusion from the egg, the symmetry of the young fish's form was but imperfectly developed. 'After the lapse of two months (7th July) the shape was found to be materially improved, and to exhibit in miniature much of the form and proportions of a mature fish. At the age of four months (7th September), the characteristic marks of the par were clearly developed. Two months later (six months old, 7th November), an accession both of size and strength was apparent; and on comparing the pond specimens with those of the river, no marked difference was perceptible. The average length at this time was 3 inches.

During the winter months, the general temperature of the rivers is so low, and the consequent deficiency of insect food so great, that the whole of the Scottish salmonidæ which inhabit the fresh waters during that season are well known to lose rather than gain in point of condition. The same rule holds in regard to the young salmon in the experimental ponds, although not to the same degree, they having maintained comparatively a superior condition throughout the winter to those found in the river of a corresponding age and size. The temperature of the ponds, averaging about 40 degrees during the winter, not only keeps the young fishes which occupy them in a more active condition, but the insects themselves are also more abroad, and thus afford a convenient supply of food not to be obtained by those at that time in the river, the average temperature of which, in ordinary winters, barely exceeds 34 degrees. I shall now refer more specially to the specimens before the Society.

Number six is a specimen from pond number one, of the age of nine months, taken in the middle of February 1838. It exhibits little or no particular accession of size or condition to that of number five, but may serve to show the general appearance of the several broods of the young salmon in my possession at the age of nine months.

Number seven is a specimen twelve months old, taken from pond number one, on the 10th May 1838. It is much improved in condition, as well as in external appearance, in comparison to that taken in February, and has exchanged its dusky autumnal and winter coating for that which may be called its summer dress. It measures about three and three-quarter inches in length, and is denominated, along with those of a corresponding age and size in the river, the *May Par*. Immediately after the migration of the two-year-old par (which the latter always effect about the beginning of May, under the name of salmon-fry), there is no other par, besides such as have been recently hatched, to be found in the river, save those which correspond with this specimen, which is the *Pink* of the river Hoddor, alluded to by Mr Yarrell. As the summer advances they increase in size, and are actually the little fish which afford the angler in salmon rivers so much light amusement with the rod during the months of August, September, and October. They remain over the second winter in the river, during which period the males shed their milt, and are found continuing their kind along with the female adult salmon, although still bearing all the external markings of the par, as I shall afterwards more particularly mention.

Number eight is a specimen eighteen months old, taken from pond number one, on the 14th November 1838. It measures six inches in length, and has now attained that stage when all the external characteristic markings of the par are strikingly developed, and, in point of health and condition, cannot be exceeded by any taken from the river. All the males, at the age of eighteen months, of the several broods in my possession, last autumn (1838) attained a most important corroborative stage—namely, that of showing a breeding state, by having matured the milt, which could be made to flow freely from their bodies by the slightest pressure of the hand. The females of the same broods, however, although in equal health and condition, did not exhibit a corresponding appearance in regard to the maturing of roe. The male and female pars in the river, of a similar age, are found respectively in precisely a corresponding state, which may surely be admitted as important evidence in support of the fact, that all these individuals are, in truth, specifically the same.

Number nine is a specimen two years old, taken from pond number one on the 20th May 1839, *after having assumed the migratory dress.* The commencement of the change, which was perfected by the whole of the broods about the same time, was first observable about the middle of the previous April, by the caudal, pectoral, and dorsal fins assuming a dusky margin, while at the same time the whole of the fish exhibited symptoms of a silvery exterior, as well as an increased elegance of form. The specimen in question, so recently a par, exhibits a very perfect example of the salmon fry or smolt.'*

These experiments, conducted in an unexceptionable way, were confirmed by other observations. Being satisfied that the par never migrated to the sea until the age of two years had been attained, and the change from par to smolt had taken place, Mr Shaw watched to discover the descending shoals. He was successful on three occasions. 'The first of these was in the first week of May 1831. I was able deliberately to inspect them as the several shoals arrived behind the sluices of a salmon cruive; and while they yet remained in the water, and were swimming in a particular direction, indistinct transverse lateral bars might still be seen; but as they changed their position, these became as it were lost in the silvery lustre. I also examined many of them in the hand, and could there also, by holding them at a certain angle in relation to the eye, produce the barred appearance; but when the fish were held with their broad side directly opposed to view, the character alluded to could not be seen. Its actual existence, however, could be easily proved by removing the deciduous silvery scales, when the barred markings became apparent, and of course continued so to whatever light exposed. The third opportunity to which I shall here refer occurred in May 1836, at which time, as I have stated, I compared a few of the descending smolts with those which (having been two years in my possession as par) had, in the confinement of the pond, assumed the corresponding silvery aspect of the salmon fry. The river during this month being remarkably low, I was thus enabled to ascertain more accurately the time during which they continued to migrate, which I found to be nearly throughout the whole of the month, but more especially in the course of the second week, in which the shoals were both larger and more frequent in their successive arrivals. Their external aspect was the same as that of the former shoals, and the average length, as usual, from six to seven inches.'

To conclude this subject, it may be added that pars are never found where salmon do not exist; and that large pars are always observed to disappear when smolts disappear; being, indeed, as Mr Shaw shows, the same animals slightly changed. Other points in the history of the par are fully elucidated by Mr Shaw, whose memoir the disciple of Walton would do well to consult. The same subject has more recently engaged the attention of several experimentalists who have arrived at similar results.

Pars are caught by the rod and fly, or with worm-bait, in the same manner as trouts; and fishing for them forms a common and amusing sport to the juvenile anglers in our Scottish rivers. At two years old—that is, after passing from the par state—the salmon weighs six or eight pounds, and generally requires five or six years to attain the weight of ten or twelve pounds. A young fish under two pounds weight is called a *salmon-peel*, and a larger one a *grilse*. The adult fish having spawned, being out of condition, and unfit for food, are considered as unclean. They are then termed *kelts*; the male fish is sometimes also called a *kipper*, and the female a *shedder* or *baggit*.

FISH PONDS.

Artificial ponds for the rearing of fish and supplying them when wanted for the table, were common in ancient times. The luxurious Romans possessed such preserves, and we learn that one belonging to Lucullus sold after his decease for upwards of £24,000. Comparatively little has been done in modern times in the way of establishing artificial ponds, and those which exist are chiefly to be found in noblemen's preserves. Yet artificial fish ponds may, with little or no trouble, be made to yield a large and regular supply of fish, and may be constructed at a most insignificant expense in any piece of low-lying waste ground intersected by a rivulet of pure water.

The fish most suitable for ponds are trout, carp, dace, roach, bream, tench, perch, and minnows. Eels also thrive in ponds; and what has frequently been a matter of surprise, these animals sometimes find their way to ponds of their own accord, without actual transfer. It is extremely probable that the spawn or young of eels and other fish is gobbled up and voided by birds in appropriate localities; there is at least no

* One or two of each of the three broods assumed the migratory or smolt dress at the age of twelve months.

other rational means of accounting for the spontaneous stocking of remote fish ponds and lakes.

The size of a pond may be from one to twenty acres; but a piece of water of from two to three acres is considered the most convenient dimensions. Of whatever size, the pond must not be overstocked, and it must not be left too long unfished. Fish ponds, to be on the most effective scale, should be in a series of two or three, the water running from the one to the other. This will allow means for periodical changing, if required, and for having a choice of fish. Some remarks of Daniel may here be introduced:—'In ponds so situated as to have communication with each other, never put into the upper of them either a pike, a bream, or a roach; the spawn will get through the gratings, and by that means all the lower ponds will unexpectedly swarm with them. The pike will destroy the fry of the carp and tench, and the two latter will consume all the food which should be the subsistence of both parents and progeny. Pike, bream, and roach should therefore on no account be ever put into the first or highest of a succession of ponds.' He continues—'Some have recommended, in raising carp, to have three ponds: one wherein the fish are to spawn (which is mostly from May to July), and in which they should continue during the summer and ensuing winter. A second for the convenience of nursing up the young fry, into which they should be put at the end of March, or early in April following, choosing a calm but not sunny day for their removal, and being careful to prevent their being destroyed when coming to the sides of their new habitation. In this pond they may remain two years, and become four, five, or six inches long. The third or main pond is for the reception of those that are so grown as to measure a foot or more in length, including their heads and tails.'

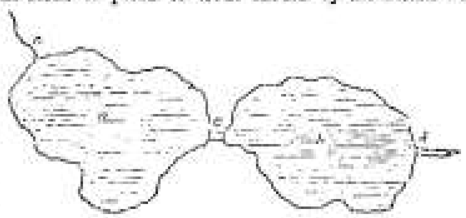
The proportions advised for the stocking these different ponds are—for the first sort, per acre, 'three or four male, and six or eight female carps, those of five, six, or seven years old, in good health, with full scale, and fine full eyes and a long body, without any blemish or wound,' are to be preferred. The pond must be previously cleaned of all sorts of voracious fishes and other animals, as 'perch, pike, eels, and trout; the water beetle, and also the frogs; the newts or lizards;' have a warm and open exposure with soft water, and all kinds of water-fowl kept from it. For the nursing pond, a thousand or twelve hundred carp may be not more than sufficient for an acre; and for the main pond, one to every square of fifteen feet is the allowed space, as their growth depends greatly on the room they enjoy and the quantity of food.' As to tench, which are not generally held in the estimation they deserve, Mr Yarrell recommends that large and fine fish be chosen as breeders, as being the most certain mode of obtaining sizeable fish for table in the shortest space of time. Two males to one female, or not less than three to two, should be the proportion of the sexes; and from the pond, which is found by experiment favourable for breeding, the small fish should be in part withdrawn from time to time, and deposited elsewhere, to afford more accommodation for all.

Our friend Mr Stoddart likewise treats of fish ponds, but mainly in reference to Scotland, where the fish must be of the hardier kinds—perch, pike, and trout. In either case the transfer of the fish to the ponds may be made with little difficulty. On being caught with a hoop-net, place them in large jars of water, and cart them to their new habitation; if this be inconvenient, they may be carried in wet moss or straw. All fish bear carriage best in winter, and better during the night than during the day.

'Ponds intended solely for perch do not require to be made large; they should slope gradually down towards the middle, from a depth of six inches to one of five or six feet. Water weeds ought not to be greatly encouraged. A series or chain of small basins, at different elevations, is preferable to a single large reservoir for this fish. These basins should be connected by a sluice and flood-gate, so that one may be readily emptied into another for the mutual convenience of cleaning and repairing. Also the uppermost ought to be shallower than those below, and more exposed to the sun, so as to serve for a nursery and breeding-pond. Bream live well with perch in a warm situation; they are not, however, obtained readily in Scotland. Perch ponds should be let off and paved with channel stones every four or five years; many allow them to remain fallow for some months, and others sow them with grass and oats—a conceit laboriously encouraged by theoretical writers of bygone days.'

The following engraving represents a pair of perch ponds: *a* is the upper or breeding-pond; *b*, the lower pond; *c*, a covered sluice with movable gratings; *d*, the sluice with outlet; and *e*, the small feeder.

'The pike-pond,' proceeds our authority, 'if for breeding and fattening to some extent, ought to be large, covering from eight to twenty acres; its mean depth six or seven feet. One end, however, should be much shallower, and sown with bulrushes or other water-plants. Previous to stocking it with this fish, a sub-stock of perch or trout should by all means be



introduced; otherwise, without a great supply of such sustenance, pike will not only become thin and ill-tasted, but quarrel and devour each other. To facilitate a steady supply of perch, small tanks should be constructed alongside of the leading preserve, with connecting sluices and flood-gates, so as to expel, when necessary, a shoal of live food.'

Our author next treats of trout ponds:—'Choose from six to twenty acres, less or more of an oval shape, but indented with small bays. Cast a long trench through the middle, from head to foot noticing that you can readily divert along it the stream just mentioned, which stream is intended as a spawning place, seeing that trout never shed their roe in dead water. Let this trench deepen gradually as the ground descends; so that at the intended foot of the pond it should sink nearly three yards, while the upper part thereof is kept shallow. Dig from either side of your trench, keeping its slope and level until within four fathoms of the intended margin of the fish pond. When this is done, turn your attention to what is called the dam-head, at the outlet or lowest part of the pond. From it continue your trench for a short distance in the form of a paved sluice. Build stones, grass-sods, and clay, along the bank on each side, if needful, and drive in a few piles to strengthen it. Then set a flood-gate at the outlet, and another to serve as a check in case of accident, three yards further down, where your paved sluice terminates. A few cart-loads of coarse channel, not from the sea, ought to be emptied over the earthy parts of your pond, which otherwise are apt to get covered with weeds, or else to encourage eels, the marked enemies of trout in all stages. After this is done, let loose your stream and form your preserve, introducing trout of about six inches in length, eight or ten to every acre. Raise also at the head a small nursery of minnows, connecting it by distinct sluices both with the pond and its feeder. These are favourite food of trout, and fatten them at a quick rate.'

To these remarks it may be added that little care need be taken to bring apparently fine breeds of any species of fish from a great distance, as what may seem poor fish at the period of transfer will greatly improve by good pond-feeding, and the easy unharassed life which they there enjoy.

SEA-FISHERIES.

Whether considered in reference to the natural history, the manual operations, or the economical advantages they involve, the marine fisheries of Britain form a subject of no inconsiderable interest. To the naturalist, the specific characters of the fish, their food, their migrations, and the seasons at which they become proper objects of capture, are points of attractive inquiry; while to the economist the various modes of capture and curing, the whole art, in fact, by which an unlimited natural production may be converted into a cheap and available source of human comfort, are matters of high importance. In the present sheet we mean to direct attention to this branch of our national industry—to its leading features in reference to the whale, seal, cod, ling, haddock, herring, pilchard, and the like—remarking at the outset, that in no department are our fisheries one-half developed, partly from imperfect modes of curing and preparing, but chiefly from the paltry and unskilful manner of capture. To this point we shall hereafter advert, urging not only the adoption of more skilful modes on the part of the fisherman, but the introduction of vessels constructed and equipped in a more systematic manner.

WHALE-FISHING.

The cetaceous order of animals, of which the whale is the most remarkable and important member, is distinguished by various peculiarities, which render it a link, as it were, between the creatures of the land and the sea. While living in part or wholly in the ocean, and so formed as to make their way through its waters with ease and velocity, the cetacea differ from the true fish-tribes in being *mammalian*, or suck-giving animals, in being warm-blooded, and in having organs for respiring the atmospheric air, like the ordinary inhabitants of the land. These striking distinctive features would be sufficient in themselves to render this order of animals an object of interesting study (see Zoology, p. 136); but the cetacea have also strong claims upon attention, as being of very great consequence to the wants and comforts of man. This is especially the case as regards the members of the whale family—*Balænidæ*—which form the subject of notice in the present section. With the exception of a few points, which will be noticed afterwards, the characters of the Greenland whale—*B. mysticetus*—are identical with those of the whole tribe, and by calling attention to the peculiarities of structure in this species, in the first instance, much repetition may be avoided.

Greenland Whale.

The size of the common whale was the subject of very exaggerated notions until within a very recent period. About fifty years ago, a standard writer in natural history asserted that whales were frequently 'to be seen above a hundred and sixty feet long;' and that even at this standard, the animal was much smaller than it had been before man began to disturb and destroy the race. Mr Scoresby, however, a very high authority on the subject, declares that the common whale seldom or never exceeds seventy feet in length, and is much more frequently under sixty. Out of three hundred and twenty-two whales which he had personally aided in capturing, *not one* exceeded fifty-eight feet; and the largest ever taken, of which he knew the reported measurement to be authentic, came up only to sixty-seven feet. The body of a large individual of this family measures from thirty to forty feet round the body at the thickest point, or a short way behind the head, which is of great proportionate size, and occupies about one-third of the whole extent from snout to tail. The bulk of the head, which is somewhat conical in form, and has a sort of round eminence above and posteriorly, renders the aspect of the mysticetus clumsy and unshapely. (See No. 9.) A very slight diminution of the circumference indicates the position of the neck, and behind this the body swells to its greatest calibre, whence it tapers sharply away again towards the tail. The animal has no back or dorsal fin. The two side or pectoral fins are placed about two feet behind the angles of the mouth, and are nearly five feet broad by nine feet in length. The tail is something in the shape of a crescent, with an indentation in the middle of the concavity, the convex side being united to the body. This appendage is placed horizontally, and is about twenty-four feet broad. It is an instrument of immense power, and the whale has sometimes given a stroke with it which has sent large boats high into the air in a thousand splinters. The colour of the body is mainly a velvety black; the under part of the head and abdomen, and the junction of the tail, being partly white, and partly of a freckled gray. In old whales, much more of the body assumes the latter tint, and the streaks sometimes resemble a beautiful landscape of trees. The eyes of the whale are about a foot behind the angle of the mouth, and are not much larger than those of the ox. The iris is of a white colour, and the organs are guarded by lids and lashes, as in quadrupeds. The two blow-holes of the whale, situated on the summit of the head, and descending perpendicularly through it for a length of twelve inches or so into the top of the windpipe, are the only other external features worthy of notice.

The mouth of the common whale is an organ of very wonderful construction. In a large specimen of the race, it may measure, when fully opened, about sixteen feet long, twelve feet high, and ten feet wide—an apartment, in truth, of very goodly dimensions. It contains no teeth; and enormous as the bulk of the creature is, its throat is so narrow that it would choke upon a morsel fitted for the deglutition of an ox. An inch and a-half is stated to be the diameter of the gullet in the very largest whales. From this peculiarity of formation, it may be anticipated that the food of the animal is of a very minute nature, notwithstanding the vastness of the cavity which is prepared for its primary reception. The animal is indeed supported upon a multitude of smaller inhabitants of the deep; and to permit this, its mouth is provided with a remarkable apparatus, composed of what is called the *baleen*, or the well-known *whalebone* of commerce. The baleen is arranged in two rows of laminæ or thin plates, projecting laterally from a line in the centre of the arch of the palate, somewhat like the laminæ of a feather. Towards the point of origin they are comparatively few in number, and strong, while towards the lips they divide and taper away into mere bristles, forming a loose hanging fringe or border. There are about three hundred of these plates on each side; and when dried, they weigh usually above a ton. The longest plate, which is always placed about the centre of the series on each side, measures about two feet in length by fifteen inches in breadth. The use of these elastic plates, with their pendulous fringes, is to retain, as in a net, the multitude of small animals which are floated into the mouth of the whale whenever it is opened. Were it not for such a drainer, formed by these fringes with the aid of the tongue, which is merely a great mass of fat tied down to the lower jaw, the emission of the water would be attended by the escape of all the objects which entered with it. As it is, the most minute matters are retained; and shrimps, sea snails, small crabs, medusæ, beroë, &c. are thus entrapped to support the great monster of the deep.

The remaining features in the structure of the whale need not be individually described at the same length. The skin consists, first of the scarf-skin, or epidermis, which is moistened by an oily fluid, enabling it to resist the action of water; secondly, of the *rete mucosum*, a layer usually held to contain the colouring matter of all animal surfaces; and thirdly, of the true skin, which, for particular purposes, is open in texture, so as to contain oil, or blubber as it is called, in great quantities. This mass of oil, surrounding the whole animal to a thickness of from one to two feet, and sometimes weighing more than thirty tons in all, serves the important end of keeping the animal warm by its weak conducting powers, amid the coldest recesses of the polar ocean, and is also calculated to resist the enormous pressure to which the body of the creature must be subjected at the depths to which it often descends. Moreover, being inferior in specific gravity to the water, it is obvious that all this body of oil must be of incalculable use in augmenting the buoyancy of the animal's frame. Below the skin are situated the muscles or flesh, and the character of this structure is much the same in the whale as in the ox or horse. With the exception of the tail, the arrangement of the various muscles of the whale does not differ very much from that of quadrupeds, and the same remark applies to the osseous structure. The fins are merely rudimental arms, containing nearly the same bones as in man, and the chest strongly resembles that of ordinary quadrupeds. The vertebral column of the rorqual whale contains sixty-three bones, those of the Greenland whale are not quite so numerous. The skull consists of the crown-bone, from which the facial bones and upper jaw project forward, while the lower jaw is composed of two long curved bones, that meet at the point or fore-part of the mouth. These are often put up over gates, and make a handsome archway. The whole of these bones are hard and porous, and some of them, as the lower jaw-bones, contain oil, but they have no proper medulla or marrow.

The organs of respiration in the whale are formed upon the same principle as those of land animals, but with modifications to suit the peculiar element in which the creature lives. It is plain that some provision was required to permit the whale to breathe, without the risk of having the lungs filled with water. This is accomplished by the extension of the top of the windpipe into the nostrils or blow-holes, or rather into the passage which terminates in these in the common whale. By this contrivance the creature can inhale air while it is feeding or has its mouth full of water. As with terrestrial animals, the air gives a red colour to the blood, or, in other words, oxygenates it, and sustains the animal heat. The whale has frequently to come to the surface, accordingly, to get its air, but this operation is rendered less frequently necessary by the provision of a reservoir of oxygenated blood, which can be drawn upon when required. This is the cause why the animal has such a vast proportionate quantity of blood in its frame. The brain of the whale is held by Cuvier to be large in relation to the animal, but no determinate conclusions have been reached on the subject. The arrangements of the whole nervous system are equally little understood. It is known that whales possess pretty acute vision, but there is a doubt whether or not they have any external ear. Their sense of smell seems to lie in the blow-holes; yet the strongest reason for ascribing such a faculty to them at all is founded upon the half-traditionary notion of sailors, that if certain strong-smelling substances are thrown overboard, whales will fly from the spot at once. The mammæ or dugs of the common whale are two in number, and attached to the abdomen; in the case of some other varieties they are placed on the breast. The milk of the animal is said to be rich and creamy.

Such are the general characters of structure in the whale tribe, and on regarding them attentively, one cannot but feel amazed at the seeming simplicity of the whole supplementary contrivances by which a mammalian animal, so thoroughly terrestrial, one would say, in its general formation, is fitted to live in the deep. The Greenland whale, or mysticetus, to which, more particularly, the preceding description applies, is said by Scoresby never to be found beyond the limits of the arctic seas. There is an excellent reason for this localisation. Within the polar latitudes, vast pasture-fields are spread out for the animal, which warmer climes have never been known to provide. These feeding-grounds, if they may be called so, consist of large tracts of *green water*, covering in all not less than twenty thousand square miles of the Greenland seas. This *green water* is of a deep olive hue, and remarkably opaque. Mr Scoresby discovered its peculiar appearance to arise from the presence of innumerable animalcules of the medusa family, one common species of which is known by the name of 'sea-blubber.' These creatures, many of which are visible only through the microscope, do not all directly serve as aliment to the whale, but they feed myriads of the smaller fishes upon which the whale does live. When feeding, it swims with open mouth under the water, and all the objects that lie in the way of that vast moving cavern are caught by the baleen, and make their egress no more. It is gregarious in its habits, being found in shoals, and migrating in this manner (according to most writers) from one ocean to another. When a herd of large ones is seen gambolling together, the sight is as magnificent as the range of nature presents. Let the reader imagine what an effect on the eye must be produced by the sight of one of these enormous living masses leaping right into the air, clear altogether out of the water. This is a feat which they frequently perform, to the high admiration of all who are at a safe distance. They effect it by means of their tail, which is the great instrument of motion, and which derives its prodigious power from the termination and concentration in it of all the muscles and tendons of the spinal column. With the aid of this same instrument they can travel through the water horizontally or downwards, at the rate of eight or ten miles an hour; but their usual undisturbed rate of travelling does not exceed four miles in that time.

When the Greenland whale ascends to the surface, which it does usually once in ten minutes, or at the most in twenty, it breathes nine or ten times, and a loud noise accompanies the act, along with an emission of light vapour in a straight column. This is called the *blowing* or *spouting* of the whale. When alarmed, it snorts much more loudly than usual. It is believed that some whales have other vocal organs, but the mysticetus seems to have no power of making noise but by the blow-holes. The spoutings of the whale consist of the ejection of jets of water to the height of twenty or thirty feet through the same apertures, in such a manner that the act is both seen and heard at the distance of several miles. There is a doubt among naturalists whether this be an ejection of mucus secreted in the blow-holes, or of water merely from the mouth. The quantity emitted would lead one at once to say that it must be water, were there not a doubt as to the possibility of water entering the blow-holes in this way. The most probable explanation is, that the animal, acting beneath the water, forces up the fluid by means of the air from the lungs.

No point relative to the habits of the Greenland whale affects one so much as the creature's love and care for its offspring. The period of gestation is supposed to be about ten months, and scarcely any dam has ever been observed to have more than one young one in attendance. In suckling, the mother throws herself on her side, for the convenience of her offspring, and this usually takes place on the surface of the water, to permit, no doubt, of free breathing. At birth, the young whale measures from ten to fifteen feet, and continues a nursling for about a year. It attains to its full growth very slowly; not sooner, according to most naturalists, than in twenty years. The whale-fishers turn the strong affection of the whale for its offspring to most fatal account. They try to strike the young one with the harpoon, and if they effect this, are sure of the old one, for she will not leave it. Mr Scoresby mentions a case where a young whale was struck beside its dam. She seized it and darted off, but the fatal line was fixed in its body. Regardless of all that could be done to her, she remained beside her dying offspring, without moving, until she was struck again and again, and finally perished. Sometimes, however, she becomes furious on these occasions, wheeling in rapid circles round the object of her affection, lashing the water with her tail, and anon dashing at the approaching boats with irresistible force.

The Greenland whale is captured, it is scarcely necessary to say, chiefly for its oil, about thirty tons of which are procured from the body of a large individual, being nearly the half of its whole weight. It is for this that mariners from all quarters of the civilised world expose themselves to the dangers and privations attending the pursuit of the animal in the polar seas. If recent statements be correct, however, these sufferings and risks may be greatly diminished by the adoption of new fishing routes. Scoresby, as has been mentioned, says that the Greenland whale is to be found only within the arctic circle; but other observers aver that the mysticetus, as well as other varieties, migrate southwards every year, and in reality make an annual tour round Cape Horn, beginning their travel about March or April. The main objection to this statement is, that the *green water* exists only near the poles, and that at the very time when these journeyings are said to be in progress, our fishers are finding and killing whales by hundreds in the north. At the same time it is undeniable that the whale is migratory in its habits, and the matter is worthy of a thorough investigation, as the establishment of fishing-stations in warm latitudes would prevent much of the suffering at present endured in the North-Sea fishing.

The Rorqual.

Being by far the most valuable and frequent object of the fisheries, the Greenland whale has received much more attention here than it is necessary to bestow on the great rorqual—*B. physalis*—though that variety exceeds all others in magnitude, and is indeed the largest of living creatures. Two specimens have been observed which measured the enormous length of one hundred and five feet. One of these, it is stated by Scoresby, was found floating lifeless in Davis' Straits, and the skeleton of the other was observed by Captain Clarke on Columbia River. This last individual, when alive, must have measured nearly one hundred and twelve feet, allowing six or seven for the tail, and it may therefore be regarded as the largest creature of which we have authentic measurement. Other specimens have measured a hundred, and others from ninety to eighty feet. That cast a-shore at North Berwick, and preserved by Dr Knox of Edinburgh, was eighty-three feet in length. The colour of the rorqual is a pale bluish-black, with the abdominal regions of a grayish tint. In shape, the body is not nearly so cylindrical as that of the mysticetus, but is compressed on the sides, and angular on the back. Hence the common name of 'razor-back;' and from the dorsal fin, which is low down, and of small size, springs the equally familiar name of 'finner.' The blubber of the rorqual is less abundant than that of the Greenland whale, and is seldom more than half a foot in depth, and eight or ten tons in weight; while its baleen also is much shorter, coarser, and everyway less valuable. This latter circumstance arises partly from the upper jaw being less arched than in the common whale. There is another cause for the inferior fineness of the baleen in the rorqual, which is the greater size of the objects which it employs as food. In the stomach of one individual, six hundred great cod, and immense quantities of other large fish, were found. The gullet, accordingly, is much wider than in the mysticetus. Another striking feature in the rorqual, and the one from which the name is derived, is an immense sort of fold or pouch along the under jaw. This was thought to be an air-bag or swimming bladder, till the observations of Dr Knox satisfied every one that it was merely a great water reservoir for augmenting the capacity of the mouth, otherwise so much diminished in this creature by the want of curve in the upper jaw.

The great rorqual has two blow-holes, through which it blows violently, and very loudly; and it swims with much speed, its rate of motion varying from five to twelve miles an hour. The species is very numerous in the arctic seas, and particularly about Spitzbergen and Nova Zembla. It is a much bolder animal than the mysticetus, and having so little oil in its frame, fishers seldom meddle with it, and dislike indeed to see it, as it is supposed to be avoided by the more valuable varieties of its race. If struck by the harpoon, it is excited to most dangerous energy; and on one occasion an individual drew a whole whaling-vessel, with its crew, with such violence on a bank of ice, that every man on board perished.

Spermaceti Whale.

The cachalot—*Physeter macrocephalus*—or spermaceti whale, of which there are several varieties, is distinguished by teeth in the lower jaw, by one blow-hole, and by the want of baleen. The leading distinctions between the various kinds of the sperm whale lie in the possession of two fins or three fins; of a spout in the neck or in the snout; of flat teeth or sharp teeth; and finally of a black, a blue, or a whitish back. But generally speaking, the characters now to be noticed are proper to all. The sperm whale attains to a great size, varying between sixty and eighty feet. The head is enormous in bulk, being fully more than a third of the whole body, and it ends like an abrupt and steep promontory in front. On the upper part of the snout is placed the blow-hole, often verging a little to one side; and it is a remarkable fact, that this is but one of the various deformities, whether congenital or acquired in the terrible battles waged by the creatures with one another, which are commonly found on the body of this whale. Its eyes are unequal, and the left frequently useless. The back has a greenish-gray tint, and below, much of the creature is white. On the back there are in most of the species one or two small fins, with large protuberances; the side fins are also of small size; but the tail is an instrument of amazing power. The teeth are usually about forty-two in number, and fit into depressions in the upper jaw. In this whale the gullet is wide enough to admit a man, and the animal feeds on large fish. A cephalopod mollusc (*Sepia octopus*), called *squid* by the sailors, is its chief food in deep seas. (See ZOOLOGY, pp. 177, 178.)

The size of head in the sperm whale has a very extraordinary purpose to serve. To assist in floating the animal, a great cavity in the interior of the skull is filled with a fine oil, which becomes concrete on cooling, and forms the spermaceti of commerce. Some of this oil is also found along the vertebral column; and in a bag in the intestines another valuable substance lies, the ambergris of traders. Some authors, it is proper to state, assert that the ambergris is merely the animal's fæces. These are the principal objects of the sperm whale-fishery, the blubber procured from this variety of the cetacea not being nearly so abundant as in the case of the mysticetus. At the same time, the blubber of the sperm whale is valuable, and is usually called sperm oil. The sailors know this whale at a great distance by the act of blowing, which it performs with great regularity, at intervals of ten minutes or so. The spout sent up is visible at a distance of two or three miles, and has the appearance of a misty cloud or bush. Having thus blown, or expired, sixty or seventy times, and made inspirations as often, the animal descends, and can remain under water more than an hour, subsisting on the store of blood which it has oxygenated, and keeps in the reservoirs already described. This alternation of appearances and disappearances is gone through by the animal with undevisiting regularity, unless it be disturbed. The sperm whale is timid before man, yet it fights fiercely with those of its own race. Fights usually take place when male whales, or 'bulls,' as they are called, and one or two of which always attend a particular herd of females, meet with rivals desirous of entering their company. They lock jaws with one another, and exert a dreadful degree of power at one another's cost. When alarmed, or harpooned, they sometimes roll over and over on the surface of the water in an amazing manner. Still they are not furious or dangerous towards the mariner, but are commonly killed with ease. The sailors call a herd a 'school,' and the old bulls the 'schoolmasters.' The females are said to be smaller than the males by a fourth. They are, like the Greenland whale, very fond of their young, and also of one another; so much so, that by cautious management, a whole herd may be destroyed, as they will scarcely quit a wounded companion.

Though exposing themselves on these occasions with so much simplicity, the sperm whales are nevertheless very careful to avoid peril in the first instance. They have the power of raising their heads perpendicularly out of the water to a very considerable height, and when in this attitude, which seems to be assumed for the purpose of viewing the surrounding expanse, they present the appearance of huge black rocks. They are said to have the ability also, on noticing any object, to communicate the intelligence to their companions, though the manner in which this is done remains a secret. Mr Beale gives it as his opinion that the sperm whale can communicate signals to a distance of four, five, and even seven miles. This cannot be effected by sounds, for, above water at least, the animal utters no noise whatever, if we except the hissing sound accompanying the act of respiration. With regard to its other habits, the sperm whale much resembles the Greenland whale. It is often seen, like its northern congener, to leap directly out of the water, or to *breach*, as the sailors call the action. Its purpose is to get rid of various sucking fish and crabs, which are fond of effecting a lodgment upon its mountainous body, and which often remain there till plucked from off the captured animal by the whalers.

The cachalot is seldom or never seen in the Greenland seas, at least by modern navigators. It is spread, however, over an immense expanse of the ocean, having been captured, at some time or other, almost everywhere between the latitude of 60° south and 60° north. The coasts of New Guinea and the adjacent archipelagoes, the shores of New Holland, Mitchell's Group, New Zealand, Navigator Isles, Ellis's Group, the shores of Peru, Chili, California, Japan, the Persian Gulf, the Chinese seas, the Moluccas, and many other regions of the ocean, abound more or less with this valuable cetaceous species.

Modes of Pursuit and Capture.

Whale-fishing is a practice of long standing in the world. It is natural to suppose that those nations dwelling on the shores of the arctic seas would be the parties earliest engaged in such pursuits; and accordingly we find that not only did the Norwegians and other Northmen precede all the other nations of Europe in this perilous but profitable line of enterprise, but they also were the first introducers of it among the southern nations. The shores of the Bay of Biscay, where the Normans formed early settlements, became famous, through them, for the whale-fishing there carried on. In the same region was it first made a regular commercial pursuit, and as whales then visited the Bay in great quantities, the traffic was convenient and easy. The Biscayans maintained it with great vigour and success in the twelfth, thirteenth, and fourteenth centuries. We find from the work of Noel, 'Upon the Antiquity of Whale-Fishing,' that in 1261 a tithe was laid upon the tongues of whales imported into Bayonne, they being then a highly-esteemed species of food. In 1338, Edward III. relinquished to Peter de Puyanne a duty of £6 sterling each whale, laid on those brought into the port of Biarritz, to indemnify him for the extraordinary expenses he had incurred in fitting out a fleet for the service of his majesty. The Biscayans, however, soon gave up the whale-fishing, from the want of fish, which ceased to come southward, no longer leaving the icy seas. The voyages of the Dutch and English to the Northern Ocean, in order to discover a passage through it to India, though they failed in their primary object, laid open the remote haunts of the whale. The British Muscovy Company obtained a royal charter, prohibiting all vessels but theirs from fishing in the seas round Spitzbergen, under pretence that it was discovered by Sir Hugh Willoughby. The fact, however, was, that Barentz, a merchant-seaman of Amsterdam, had discovered it in 1596; and neither Dutch, Spaniards, nor Frenchmen, were at all disposed to admit the justice or propriety of the claim made by the English. An extraordinary scene succeeded in the northern seas. The Muscovy Company sent out six or seven strongly-armed vessels, which took up a position near Spitzbergen, and commenced an attack on all foreign ships that refused either to quit the region at once, or pay the very moderate toll of one-half the proceeds of their fishing. The English succeeded so far as to annoy everybody else, and to prevent themselves from taking almost a single fish, so busy were they in looking after others. All the nations of Europe remonstrated loudly through their envoys against these proceedings; but the Dutch, ever fearless at sea, sent out a strong fleet, which effectually guarded their own fishing. At length, in 1618, a general engagement took place, in which the English were worsted. Hitherto the two governments had allowed the fishing adventurers to fight out their own battles; but in consequence of the event mentioned, it was considered prudent to divide the Spitzbergen bays and seas into fishing stations, where the companies might not trouble each other. After this period, the Dutch quickly gained a superiority over their rivals. While the English prosecuted the trade sluggishly, and with incompetent means, the Dutch turned their fisheries to great account, and in 1680 had about 260 ships and 14,000 sailors employed in them.

After the cessation of the Muscovy Company, a Greenland Company, with an actual capital of £45,000, entered on the trade, and in nine years came to a ruinous close. In 1725, the South Sea Company took up the adventure, and in eight years, after the outlay of a vast amount of money, they also were compelled to submit to a dead loss of their capital, and threw up the attempt. The legislature now tried a new scheme, being sincerely desirous to encourage and establish the trade, as well as to make it a nursery for seamen. In 1732, a bounty of 20s. a ton was granted to every ship of 200 tons burden that engaged in the fishing. In 1749, it was thought necessary to raise the bounty to 40s., when, as Mr M'Culloch observes, as many ships seem to have been fitted out for catching the bounty as for catching fish. But a trade supported on any other principle than that of direct benefit received from it by the parties engaged therein can never be of an enduring nature, and this truth soon appeared in the present case. In 1777, the bounty was reduced to 30s., the consequence of which was, that during the next five years the number of ships employed in the trade was reduced from 105 to 39! In 1781, the bounty was raised again to its old level, and an inducement was thus held out for the revival of the spirit of trade. But after all, what a million and a-half of money, expended in successive donations under the name of bounty, was totally inefficient to do, the spirit of private enterprise, once fairly awakened, speedily accomplished. The British whale-fisheries throve rapidly between 1781 and 1795; and the legislature found themselves justified in reducing the bounty, at intervals, from 40s. to 20s. The long continental troubles consequent on the French Revolution put a complete period almost to the Dutch fishing, while in the same space of time the British fisheries were continually improving, the conduct of them being left entirely to the private spirit of the nation. A small bounty, indeed, was given even down till 1824; but it was uninfluential, and was then withdrawn altogether. Of the change which has of late years come over the whaling traffic of Britain, a few words will be said before bringing the general subject to a close.

No species of fishery, prosecuted anywhere on the face of the ocean, can compare in intensity of interest with the whale-fishery. The magnitude of the object of the chase, and the perilous character of the seas which it peculiarly frequents, are features which prominently distinguish the profession of the whale-fisher from all similar pursuits, and which invest the details of its history with the strong charm inseparable from pictures of stirring exertion, privation, and danger. Such being the case, we shall present, chiefly from the writings of Captain Scoresby, the highest authority on the subject, a full description of the proceedings connected with the British whale-fishery.

The ships designed for the whale-fishery are usually from 300 to 400 tons in burden, and require to be very substantially built, in order to resist the pressure of the ice. With the view of increasing their strength, most of them have additional planks and timbers, and often also iron plates and stanchions, introduced into their structure, both internally and externally. Such appurtenances and provisions are technically known by the names of *doublings, treblings, fortifyings, pointers, carlings, &c.* Of course the whale-ship is also furnished with an ample stock of the apparatus and instruments used in the fishing, as well as with the peculiar boats which are employed in the capture.

The whale-boat is from twenty to twenty-eight feet in length, and provided with from four to six pair of oars. It should float lightly on the water, and be so formed as to move with speed, and to turn easily round. They are 'carver-built,' as it is called, and the best-made ones are composed of straight oak planks, suppled and bent to the required shape, by which means their elasticity is greatly increased. The rapid and dangerous movements of the whale render these various qualities indispensable. The principal weapons with which whale-fishers are supplied are the *harpoon* and the *lance*. The harpoon is an iron instrument about three feet long, and consists of three conjoined parts—the 'socket,' 'shank,' and 'withers,' or barbs. The socket is about six inches in length; the shank, which is between the withers and socket, is nearly eighteen inches long; and the withers are eight inches long by six in breadth. The united withers are triangular in shape, and the shank is fixed between them. The shank of the harpoon is the most important part of the weapon. It is formed of the most pliable iron, old horse-shoe nails being usually preferred for the purpose; and it is not more than four-sixteenths of an inch in diameter. Much attention is paid to the manufacture of the shank, because on its flexibility the retention of a harpooned whale depends. If the shank should break during the plunges of the whale, the animal is lost to the fishers. Unless the shank will bear to be wound round an inch bar of iron, in the form of a close spiral, and to be again unwound, it is held to be of imperfect materials. The socket is hollow, and strong, and swells, from the point of its junction with the shank, to a diameter of two inches. It is only necessary to add to this description of the harpoon, that each of the withers has at its point a smaller and reversed barb, like the beard of a fish-hook. The use of this provision is obvious.

The lance is a more simple instrument. It is nearly ten feet long, and consists of a hollow socket into which a fir stock is inserted, of a shank of iron about half an inch in diameter, and of a sharp flat point or tongue of steel, seven inches long by two in breadth. This instrument and the harpoon, together with lines and boats, are all the apparatus absolutely necessary for capturing the whale. Some ships have a harpoon gun, or a gun which projects the harpoon; but this weapon has been found extremely uncertain when put to use.

The ships destined for the Greenland fishery put to sea in March, or during the first days of April. The crew of one of these vessels usually consists of from forty to fifty men, comprising various classes of inferior officers, such as harpooners, boat-steerers, line-managers, carpenters, landsmen, and others. Steering from the direction of Shetland, on a course to the east of north, the whalers commonly reach and pass the west side of Spitzbergen in the end of the month of May. From this point they continue their course till they arrive at the latitude of 78° or 78½° (the best parallel for fish), or till they meet with whales. There is a remarkable indentation in the ice lying between longitude 5° and 10°, which the whalers for the most part strive to enter; but their course must be regulated greatly by the state of the ice. On reaching a fishing station where whales are seen, preparations are immediately made for commencing the business of capture. Two or three boats at the least are always kept suspended from cranes by the side of the ship, in such a position that they can be lowered into the water, with their complements of men, and the whole necessary apparatus, in the space of one minute. Previously to this time, the harpoons and lines have been got in order. The socket of the harpoon has been furnished with a stock or handle, six or seven feet long, and fastened in its place by means of a splice of strong rope, called a *foreganger*, the eye of which is kept firmly fixed to the iron of the harpoon by the *swelling* of the socket. To the loose end of the foreganger are attached five or six fathoms of line, called the 'stray line,' and this again is connected with the other lines of the boat. In each boat there are about 4320 feet of rope, neatly though loosely coiled up in six separate portions, and laid down in places appointed for the purpose. The line or rope is made of the best hemp, and is about 2½ inches in circumference. An axe, to cut the lines if necessary, a bucket to lave them, and keep them from being overheated by friction, and a few other articles, are also laid down in the boats.

Whenever there is a probability of seeing whales, the master, or some experienced officer, keeps a close look-out from the *crow's nest*, a station at the mast-head so called. With the assistance of a telescope he scans the surface of the waters around, ready, at the first glimpse of a fish, to give notice to the watch on deck. In fine weather a boat is kept afloat, manned, and engaged also in the look-out. The short time during which whales usually remain above water to breathe (being only two minutes), renders the discovery of them less easy than might be anticipated from their great bulk. Besides, while below water, the animal frequently traverses a space of half a mile in the ten or fifteen minutes intervening between the respirations; and hence the spot at which it may again rise, after being once seen and again disappearing, is left in a great measure a subject of conjecture. The previous direction of the whale's movements, and occasionally a sort of eddy on the surface, are the only guides to the boatmen in this particular. When the whale does come up within reach of a harpoon-cast, and lies unconscious of the approach of its enemies, 'then,' says Captain Scoresby, 'the hardy fisher rows directly upon it, and an instant before the boat touches it, buries his harpoon in its back. But if, while the boat is yet at a little distance, the whale should indicate his intention of diving, by lifting his head above the common level, and then plunging it under water, and raising its body until it appear like the large segment of a sphere, the harpoon is thrown from the hand, or fired from a gun, the former of which, when skilfully practised, is efficient at the distance of eight or ten yards, and the latter at the distance of thirty yards or upwards. The wounded whale, in the surprise and agony of the moment, makes a convulsive effort to escape. Then is the moment of danger. The boat is subjected to the most violent blows from its head or its fins, but particularly from its ponderous tail, which sometimes sweeps the air with such tremendous fury, that both boat and men are exposed to one common destruction.

The head of the whale is avoided, because it cannot be penetrated with the harpoon; but any part of the body between the head and tail will admit of the full length of the instrument, without danger of obstruction. The harpoon, therefore, is always struck into the back, and generally well forward towards the fins, thus affording the chance, when it happens to drag and plough along the back, of retaining its hold during a longer time than when struck in closer to the tail.

The moment that the wounded whale disappears, or leaves the boat, a jack or flag, elevated on a staff, is displayed, on sight of which those on watch in the ship give the alarm, by stamping on the deck, accompanied by a simultaneous and continued shout of "a fall!"* The sleeping crew, roused by the sound, jump from their beds, rush upon deck, with their clothes tied by a string in their hands, and crowd into the boats, at a temperature of zero. They generally contrive to dress themselves, in part at least, as the boats are lowered down; but sometimes they push off in the state in which they rise from their beds, row away towards the "fast boat"—that is, the boat attached by its harpoon and line to the whale—and have no opportunity to clothe themselves for a length of time afterwards.

The first effort of a "fast fish," or whale that has been struck, is to escape from the boat by sinking under water. After this, it pursues its course directly downwards, or reappears at a little distance, and swims with great celerity, near the surface of the water, towards any neighbouring ice among which it may attain an imaginary shelter; or it returns instantly to the surface, and gives evidence of its agony by the most convulsive throes, in which its fins and tail are alternately displayed in the air, and dashed into the water with tremendous violence. The former behaviour, however —that is, to dive towards the bottom of the sea—is so frequent, in comparison of any other, that it may be considered as the general conduct of a fast fish.

A whale struck near the edge of any large sheet of ice, and passing underneath it, will sometimes run the whole of the lines out of the boat in the space of eight or ten minutes of time. This being the case, when the fast boat is at a distance, both from the ship and from any other boat, it frequently happens that the lines are all withdrawn before assistance arrives, and, with the fish, entirely lost. In some cases, however, they are recovered. To retard, therefore, as much as possible the flight of the whale, it is usual for the harpooner who strikes it to cast one, two, or more turns of line round a kind of post called a bollard, which is fixed within ten or twelve inches of the stern of the boat for the purpose. Such is the friction of the line when running round the bollard, that it frequently envelopes the harpooner in smoke; and if the wood were not repeatedly wetted, would probably set fire to the boat. During the capture of one whale, a groove is sometimes cut in the bollard, near an inch in depth; and were it not for a plate of brass, iron, or a block of lignum vitæ, which covers the top of the stem where the line passes over, it is apprehended that the action of the line on the material of the boat would cut it down to the water's edge in the course of one season of successful fishing. The approaching distress of a boat, for want of line, is indicated by the elevation of an oar, in the way of a mast, to which is added a second, a third, or even a fourth, in proportion to the nature of the exigency. The utmost care and attention are requisite on the part of every person in the boat when the lines are running out; fatal consequences having been sometimes produced by the most trifling neglect. When the line happens "to run foul," and cannot be cleared on the instant, it sometimes draws the boat under water; on which, if no auxiliary boat or convenient piece of ice be at hand, the crew are plunged into the sea, and are obliged to trust to the buoyancy of their oars, or to their skill in swimming, for supporting themselves on the surface. To provide against such an accident, as well as to be ready to furnish an additional supply of lines, it is usual, when boats are sent in pursuit, for two to go out in company, and when a whale has been struck, for the first assisting boat which approaches to join the fast boat, and to stay by it until the fish reappears. The other boats likewise make towards the one carrying a flag, and surround it at various distances, awaiting the appearance of the wounded whale.

The average stay under water of a wounded whale, which steadily descends after being struck, according to the most usual conduct of the animal, is about thirty minutes. The longest I ever observed was fifty-six minutes; but in shallow water, I have been informed, it has sometimes been known to remain an hour and a-half at the bottom after being struck, and yet has returned to the surface alive. The greater the velocity, the more considerable the distance to which it descends, and the longer the time it remains under water, so much greater in proportion is the extent of its exhaustion, and the consequent facility of accomplishing its capture. Immediately on its reappearing, the assisting boats make for the place with their utmost speed, and as they reach it, each harpooner plunges his harpoon into its back, to the amount of three, four, or more, according to the size of the whale and the nature of the situation. Most frequently, however, it descends for a few minutes after receiving the second harpoon, and obliges the other boats to await its return to the surface before any further attack can be made. It is afterwards actively plied with lances, which are thrust into its body, aiming at its vitals. At length, when exhausted by numerous wounds and the loss of blood, which flows from the huge animal in copious streams, it indicates the approach of its dissolution by discharging from its blow-holes a mixture of blood along with the air and mucus which it usually expires, and finally jets of blood alone. The sea, to a great extent around, is dyed with its blood, and the ice, boats, and men are sometimes drenched with the same. Its track is likewise marked by a broad pellicle of oil, which exudes from its wounds. Its final capture is sometimes preceded by a convulsive struggle, in which its tail reared, whirled, and violently jerked in the air, resounds to the distance of miles. In dying, it turns on its back or on its side, which joyful circumstance is announced by the capturers with the striking of their flags, accompanied by three lively huzzas!'

The writer of this animated description points out how remarkably nature seems to assist man in the capture of the whale. By no efforts of its human assailants could the strength of the creature be so far reduced as to permit of its destruction, were it not that its descent, through fright, to a depth of 700 or 800 fathoms, must subject its body to the exhausting pressure of more than 200,000 tons of superincumbent water! It is through this cause, rather than from the wounds the whale has received, that it comes to the surface in so helpless a state of exhaustion. The space of time in which different individuals are captured and killed varies considerably, and in part, for the same reason. Large whales have been sometimes killed in twenty minutes, while in other instances the animal costs his assailants a struggle of sixteen hours' duration, and in some cases much more, and may escape from them after all. The average time, under favourable circumstances, is one hour; but two or three hours are no uncommon period for the contest to last, even in favourable circumstances. Two harpoons usually despatch a whale of middling size, and its movements may commonly be restrained within the limits of 600 fathoms of line. On the career or flight of a first-size whale no check can be placed, until its own exertions exhaust its powers. On the other hand, the ease with which some whales are subdued, and the slightness of the entanglement by which they are taken, have often

* The word "fall," as well as many others used in the fishery, is derived from the Dutch language. In the original it is written *val*, implying jump, drop, fall, and is considered expressive of the conduct of the sailors when manning the boats, on an occasion requiring extreme despatch.

been the cause of agreeable surprise to fishers—the accidental coil of a harpoon line round the body, or even the mere grasping of one between the jaws, having been known to alarm the animal so much, that it exhausted itself almost as speedily as though regularly struck by the harpoon.

The whale-fishing is apt to be impeded, as may readily be imagined, by the great masses of ice everywhere abounding in the northern seas. The usual course of proceedings in open water has been described; in different circumstances, different plans must be adopted. *Pack-fishing* is the name given to the chase of the whale on the borders of close packs of drift-ice. The animal loves to shelter his vast bulk under the ice of these frozen masses, and when struck, usually flies to them for refuge, thus endangering the lines and lives of the whalemen. The common method of providing against such contingencies is either to strike the fish with two harpoons from different boats at the same moment, or to affix the line of a second boat to that of the one from which the whale has been harpooned, so that the strength of two lines is brought into play against the fish. Sometimes, when a fish gets entangled in the drift-ice, the adventurous seamen climb over it, and lance the animal from that perilous station. Altogether, pack-fishing is troublesome and dangerous, and were it not that the largest whales very frequently resort to such situations, whalers would seldom attempt to fish there.

On the other hand, *field-fishing*, as it is called, or fishing on the edges of those wide connected plains of ice termed fields, is one of the most productive of all the modes of fishing prosecuted in the Greenland seas. When the weather is tolerably mild, it is also a pretty secure mode. The most marked of the advantages held out by field-fishing is the curtailment of the range of the whale's movements. When harpooned, it commonly descends obliquely beneath the field, and, being unable to rise through the ice, is forced to return to the edge, or nearly to the spot where it made the plunge. Thus the ship's boats, if stationed along the margin of the field, can at once harpoon it a second time, and despatch it. In open water, the whale, by rising at a spot far apart from where it dived, gains time to breathe freely and recruit its strength, and so either breaks away altogether, or greatly protracts the struggle. For this reason, six boats at a field will do the work of twelve in open sea. Two or more fish are frequently taken at a field at one time, and on a particular occasion six fish were actually captured at once by the seven boats of a single ship. Even in such weather as renders fishing impracticable elsewhere, field-fishing can be prosecuted with success. But there are disadvantages also attendant on this mode. The movements of fields of ice are so rapid, various, and unaccountable, and their powers of doing mischief so unlimited, that the utmost prudence and skill cannot entirely secure vessels lying in their vicinity from the risk of severe damage or total destruction. Small fields or floes are especially dangerous, particularly if they contain small cracks or holes in the centre of them. The chance of a sudden movement in such floes is much greater than in the case of the large fields; and moreover, after being struck, the whale generally makes for the apertures in the ice, and there breathes freely, rendering it necessary for the men to cross the field on foot, and despatch their prey with the lance. Even when they succeed in doing this, there is no way of getting out the whale but by sinking it, and dragging it from below the ice, at the great risk of pulling out the harpoon altogether; or by cutting the blubber away, and transporting it over the surface of the floe piece by piece. These operations are attended with vast labour and loss of time.

If whalers could choose their own ground for fishing, many of them would probably prefer a position among open, navigable drift-ice, where the force of the sea is broken, and heavy swells prevented from affecting the vessel. This kind of fishing is called *open pack-fishing*, and is held to be advantageous for the capture of whales. Where the ice is crowded, however, and affords room only for boats to pass through it, the chase becomes difficult and hazardous. Still, as the fishers must take the seas as they find them, fishing is often conducted in this situation of things. Success depends on the boats being spread widely, on the incessant watchfulness of the harpooners, and on their occasionally taking the benefit of a mass of ice, from the elevation of which the fish may sometimes be seen blowing in the interspaces. Celerity in rowing, and the highest degree of activity in all the proceedings, can alone secure success in open pack-fishing.

Whalers must also be prepared to meet and combat all the difficulties attending the prosecution of their employment in *storms* and *fogs*. When a gale occurs during a chase, and after a fish has been harpooned, fishers are often obliged to cut the lines, and let their prize go. Sometimes this takes place even when the fish is killed; and it is worthy of remark, that a whale so abandoned becomes the lawful prize of the ship that first gets hold of it, though this may occur in the face of the original captors. But it is common enough for whalers during a storm to keep a fish secured by a hawser to the ship, and to retain it thus till the return of moderate weather. Few whalers venture to commence fishing while a storm exists, and it is a matter of equal difficulty and uncertainty to fish during a fog. The mist on such occasions is so thick, that it is impossible to see objects, however large, above 100 or 150 yards off; and when a boat is led away by the chase to such a distance that a bell or a horn cannot be heard, its situation becomes very perilous.

Captain Scoresby gives an interesting account of the plan pursued by himself in *bay-ice fishing*. Being locked up with his ship in a field of thin bay-ice, that was unfit in many places to bear a man's weight, he placed a number of boats in various openings which existed a short way from the vessel. When a whale came to those apertures to breathe, it was struck, and the men endeavoured to drown it, when it darted below the ice, by keeping a steady strain on the line. If this plan failed, Captain Scoresby planted his feet in a pair of ice-shoes, formed simply of thin deal-boards, to the centre of which the feet were tied, and then he boldly crossed the thin ice to the point where, by the direction of the line, he knew the fish would rise. In three instances he was fortunate enough to see the whale through the ice, and to plunge his harpoon into its body, after which he used his lance, till in each case the fish was killed. The fish actually rose once or twice beneath the very spot where he stood, and broke through the ice with its head. He was lucky enough to escape all injury, however, though the ice in most places could not have borne the weight of a boy standing in common shoes.

Of course, in all these various ways of fishing, circumstances now and then occur which set at defiance all ordinary rules. The whale, for example, when struck near the margin of a small floe, is usually held in restraint, and killed by the use of the lines from at most *two* boats; but instances are known where the lines of three and even four boats have been insufficient. In 1812, the *Resolution* of Whitby ran out nearly six miles of lines before the final capture of a middle-sized fish. Nor does the harpoon always produce a fatal loss of blood, even after the lapse of a considerable period. An Aberdeen whaler struck a fish, which got off in consequence of a storm occurring, and rendering it necessary to cut the lines. Next day the same fish was struck, and again got off; and on the third day the identical whale was harpooned and captured.

Having killed a fish, the first operation performed by the sailors is to pierce two holes in its tail, and to lash it to a boat. The fins are also roped to the body, and then the whole of the boats, joined in a line, unite their efforts in towing it to the ship. Here it is placed with its side parallel to that of the vessel, and is arranged for the operation of *flensing*. In consequence of its enormous weight, it cannot be raised altogether out of the water. Only about one-fifth part of its body is brought above the surface, and here it is firmly secured by ropes, with the abdomen uppermost. Men, armed with spurs on their feet to prevent slipping, then leap on the body, and begin to divide the fat and skin into separate pieces or compartments by means of blubber knives or spades. A hook called a spec-tackle, which hangs from a capstern or winch on deck, is attached to each piece of fat, and draws it upwards as it is flayed off. Pieces weighing from half a ton to a ton are taken up at a time in this manner, and are cut on deck into smaller pieces, which are then cast down into the main hatches and stowed away. On the blubber being removed from one part, the whale is turned partially round by the ropes and windlass, and this cutting and turning are repeated until the whalebone and blubber have all been removed. The stripped carcass is then allowed to sink. A British whaling-crew will usually flense a common-sized whale in four or five hours. The operation is followed, when the flens-gut, or blubber-box, under hatches is filled with blubber, by another process which is termed *making-off*, from its being the finishing process. The blubber is brought on deck, separated from the skin and fibrous or muscular structure, cut into pieces of a few inches in size, and finally introduced into casks through the bung-hole.

The instinctive fear of being enclosed in the ice during the cold seasons, and of finding no apertures for respiration, appears to be the reason for the descent of the whales into the open and more southerly seas. In the month of July, when the ice becomes broken, the cetaceous tribes again enter the arctic waters, and are unassailable by fishers. The whalers, with a lesser or greater amount of cargo, or perhaps, if they have been very unlucky, with what is emphatically called a *clean* ship, are then obliged to return home to their respective ports, where the blubber is separated from its refuse, and converted into oil by boiling, and the whalebone scraped, cleaned, and dried for sale. These operations require no special description, the names of the processes sufficiently indicating their character. The greatest cargo ever borne to the shores of Britain by a whaling vessel was that brought from Spitzbergen by Captain Souter of the Resolution of Peterhead, in the year 1814. It consisted of 44 whales, which produced 299 tons of oil, value, reckoned at £32 per ton, the average price of that year, £9568; and when to this sum is added the value of the whalebone, and the bounty, the freight would appear to have reached £11,000. When oil rose to £60 per ton, smaller cargoes, in several instances, amounted to an equal value. In 1813, the Scoresbys, father and son, respectively brought home cargoes which produced £11,000. Captain Scoresby, senior, in the course of 28 voyages, captured the immense number of 498 whales, the oil and whalebone of which amounted in value to above £150,000. But few cargoes produce such sums, it must be allowed, as £11,000, and few men have such a career of activity to look back upon as Captain Scoresby.

Statistics of the Greenland Whale-Fishery.

In the years 1814, 1815, 1816, and 1817, 392 vessels sailed from England, and 194 from Scotland, for the whale-fishery. Of these, the port of Hull, which has long taken the precedence in this trade, sent out not less than 229 vessels, while London, Aberdeen, Leith, and Whitby, the next in proportion, sent out respectively 77, 55, 40, and 39. The total number of whales killed by British ships in the same years was 5030. They yielded 54,508 tons of oil, and 2697 tons of whalebone. The average to each ship was 8·6 whales, 93 tons of oil, and 4·6 tons of whalebone. By comparison with the following more recent years, the progressive condition of the trade will be seen. In 1821, when the number was greatest, there were 159 ships, of 50,709 tons, and with 7385 men, engaged in the service; in 1824, 111 ships, of 35,013 tons, and 4640 men. In 1829, a great falling off had taken place, the ships numbering only 89, of 28,812 tons. During the years consequent upon that period, a still greater decline took place in the number of employed whale-ships. In 1832, there were only 81 engaged in the trade. In 1837, the number was reduced to 52; and in 1842 to 18. This unfortunate change—for every declension in commerce, generally speaking, must be held a misfortune—merits some attention.

The decline of the British northern whale-fisheries appears to be owing to three principal causes. In the first place, the introduction of gas into universal use of late years in the island has materially lessened the demand for whale-oil and the necessity for its supply. In the second place, the former fishing-fields around Spitzbergen have been greatly exhausted, and whalers have been under the necessity of venturing into more perilous latitudes for the objects of their pursuit. The third cause is in a measure a corollary of the preceding one. In consequence of entering the broken ice of Davis' Straits and other similar seas, a loss of life and property has taken place of late years so extensive, and alarming, that mercantile men have become unwilling to risk their capital, and seamen their existence, in such ill-fated expeditions. The great increase of danger is shown by the fate of the fishing-vessels during the last few years, as compared with the results of former ones. Of 586 ships sent out in 1814, 1815, 1816, 1817, only 8 were lost. In 1819, out of 63 ships sent to Davis' Straits, 10 were lost; in 1821, out of 79, 11 were lost; in 1822, out of 60, 7 were lost; and in 1830, not less than 19 out of 91 were lost. The mischief has progressively increased. In 1837, the Davis' Straits whale-fleet lost several of its number, and many vessels were locked up in the ice through the winter, to the loss of the greater part of their crews, and at the cost of almost unparalleled sufferings to the petty remnants of them which escaped with life. And while the perils of the trade have thus largely increased, the profits, owing to the greater difficulty of finding whales, have suffered a corresponding decrease. In 1830, 21 out of the 87 vessels sent out to Davis' Straits returned *clean*; not a fish was taken by them. In the most of the years that have followed, the majority of the whalers have returned with comparatively paltry freights, and many without a pound of blubber or of bone.

The declension and apparent approaching extinction of the northern whale-fishing, which has so long been an important pillar of our commercial greatness, could not but excite uneasiness and regret in the minds of many persons who have opportunities of making observations on the subject. Accordingly, we find that various plans have been proposed for the revival of this branch of the trade of Britain. Although we conceive that the substitution of gas for oil is one important cause of the decreased ardour for whaling enterprises, and a cause, besides, neither to be deplored nor capable of remedy, and although it also appears to us that the exhaustion of the old whaling fields is another source of the evils complained of, and one only to be affected by time, yet there might, we believe, be plans adopted which would help at once to restore the lucrative character of the whale-fishery, and to alleviate, or entirely prevent, the misfortunes which have attended its prosecution of late years. The most rational scheme which we have yet seen proposed is to establish a settlement of active and enterprising whale-fishers on some favourable spot in the vicinity of Davis' Straits, and to employ only so many large vessels as may be necessary to carry out provisions to the colony, and fetch home the oil, blubber, whalebone, and other articles which may be thought worth importing. The practicability of carrying such a plan into effect, and the advantages likely to result from it, are the only two points that fall to be noticed here. The testimony of recent travellers, as well as of seamen who have been compelled to winter in the high latitudes, goes to prove the practicability of establishing and maintaining there an efficient colony. Captain Ross's remark, that 'the temperature of sensation is more relative than is imagined, the body soon contriving to find a new and much lower scale of comfortable or endurable heat,' has been completely verified by all who have visited the Polar regions. The attention now paid to the quality of ship provisions, and the improved methods of preserving them, have not only put a stop to the inroads of scurvy, but have tended materially to increase the comfort of those who choose to lengthen their stay in cold countries. Nor would they be dependent altogether on the supplies carried with them, or procured from the mother country. The musk ox, the reindeer, the white bear, the hare, and a number of other quadrupeds, would afford them at once sport and a valuable addition to their means of sustenance. Birds, too, and fresh fish of various kinds, would not be wanting to give variety to their repasts; while lobsters, mussels, and other shell-fish, could be had as abundantly as at home. To avoid all risks of famine, it would be proper to have always in the settlement provisions for two years; although it could hardly ever happen that the settlers would be so completely shut up as to be inaccessible during the whole of the summer months.

The advantages of having a numerous body of fishers on the spot, instead of sending them out annually, can easily be made apparent. 1*st*, There would be a saving of outlaid capital. For some time past, the ships sent from Great Britain to Davis' Straits may have averaged 100 each year; and we believe we speak within limits when we assert that the oil and whalebone which they have brought home might easily have been carried by one-fifth of the number. Suppose a permanent colony of 4000 fishers were established at Davis' Straits, and twenty of the 100 vessels employed in the carrying trade, the other 80 vessels might at once be withdrawn, making a saving of outlaid capital to the extent of at least £320,000. In this calculation we take merely the cost of the ships, as the boats, harpoons, casks, and other apparatus, and the provisions included in the outfit, would all be required in the settlement. 2*d*, The fishery would have a better chance of being successful. At present it sometimes happens that vessels cannot get into the proper fishing station till the season is so far advanced that they are under the necessity of returning home without lowering their boats, and this difficulty arises not from the want of open sea within the Straits, but from accumulations of ice drifted from the north extremity of Baffin's Bay to the Labrador coast. A settlement of fishers wintering inside, would in most cases make a good fishing before the British ships had penetrated far up the Straits.

The Sperm-Whale-Fishery.

There is no occasion for describing the vessels or apparatus employed in the sperm-fishery, these being similar, in every essential point, to those already described; with this exception, that the ships are always found and provisioned for a period of three years—the period of their general absence from England. Timid as it is, the cachalot often causes such peril by its convulsive efforts to escape, as render its capture not less exciting than that of the mysticetus. Young bulls, in particular, frequently give a world of trouble to their pursuers, and sometimes turn upon them with unbounded fury, intent on mischief, and effecting it both with teeth and tail. The South Sea whalers, like their northern brethren, have their particular cries and watchwords in the prosecution of the chase. When a whale is seen by the man at the look-out, the cry bursts from his lips, 'There she spouts!' Instantly the captain starts on deck, with the responsive exclamation, 'Where away?' An answer is scarcely needed, for all on board soon perceive the huge animal, blowing regularly at intervals of ten seconds, if within a moderate distance. For a half minute the men stand gazing, and at every spout the spirited cry breaks forth from them simultaneously, 'There again!' But idleness is not long the order of the day. The boats are lowered, the men rush into them, and soon are pulling towards the monster, every boat eager to reach him first. As they approach, they see him spouting more slowly. 'Ah, he is going down!—he will be lost!'—is the exclamation. But one boat nears him. 'One more spout (says Mr Beale's animated narrative) is seen slowly curling forth—it is his last for this rising—his back is bent, his enormous tail is expected to appear every instant, but the boat shoots rapidly alongside of the gigantic creature. "Peak your oars!" exclaims the mate, and directly they are flourished in the air; the glistening harpoon is seen above the head of the harpooner; in an instant it is darted with unerring force and aim, and is buried deeply in the side of the huge animal. "It is socket up;" that is, it is buried in his flesh up to the socket, which admits the handle of the harpoon. A cheer from those in the boats, and from the seamen on board, reverberates along the still deep at the same moment.' Now the pained whale plunges violently, and lashes the sea with his tail, so that the noise can be heard for miles. Suddenly he throws up his tail in the air, and disappears. Out fly the lines, and those of another boat are attached. Eight hundred fathoms are run out, and at last the whale re-appears at the surface, somewhere in the vicinity, spouting hurriedly and agitatedly. By coiling their lines, the boatmen run rapidly up to him, and then the headsman buries his lance in the vitals of the trembling monster. 'Stern all!' is at the same moment vociferated, and the boat backs away from the side of the whale. He now becomes infuriated, and rushes at the boats, often upsetting them. The lance is again driven into his sides; his motions become wild and irregular; and after what is called the mortal flurry, he turns over on his side, suffocated most commonly by the internal flux of blood from his wounds.

As in the case of the Greenland fishery, bounties were given to the sperm-whalers up to 1821, when the trade was fairly left to private enterprise. In 1791, the sperm oil imported into Britain amounted to 1258 tons; in 1827, 5552 tons were imported; and in 1836, the amount was 7001 tons. One good whale will yield forty barrels of oil, and ten barrels of spermaceti are frequently taken from one head. About ten large barrels make a ton. Both sperm oil and spermaceti bear a high price in the market, and are of great utility in various respects. Of late years, this fishery has also fallen off; so much so, that in 1845 not a single vessel cleared out for it from a British port.' 'This decline,' says M'Culloch, 'is a consequence partly of the growing scarcity of the whales in their old haunts, and of the greater difficulty experienced in their capture; but more of the competition of the Americans, and of the colonists in New South Wales and Van Diemen's Land. The situation of the latter gives them peculiar advantages for the prosecution of the fishery, which they now carry on to a great extent, and with much spirit and success.' In 1841 there were no fewer than 193,000 tons of shipping belonging to the United States engaged in sperm-fishing.

SEAL-FISHING.

The seal tribe—*Phocidæ*—according to the classification of modern naturalists, forms the last or most lowly-organised of the Carnivorous order. The family is sufficiently distinguished from all the rest by the peculiar adaptation of the animals composing it to a marine residence. Their feet are so short, and so enveloped in the skin, that they are of little use in progression on land. In fact the seal employs them only when clambering, wriggling itself forwards along a plane surface by the action of the abdominal muscles. The intervals between the toes are occupied by membranes, so as to convert the feet into oars. The body is lengthened, and the spine very flexible, as in the Cetacea and Fishes; and the animals are covered with a short, close, glistening fur, sitting flat upon the skin. All these adaptations combine to render them able swimmers; and they pass the greatest part of their time in the water, which they only quit to bask in the sunshine, and to suckle their young. Of the two genera, the *Seals* and the *Morses*, which this family contains, the former presents the least departure from the general type of the order. It possesses all three kinds of teeth; but the canines are not particularly large, and the molars are neither adapted for shearing nor for grinding the food, but are furnished with angular points adapted to keep hold of and crush the slippery prey. The head of the seal resembles that of a dog, presenting the same mild and expressive physiognomy. These animals seem to possess considerable intelligence; they are easily tamed, and become much attached to their feeder. They subsist on fish, which they always devour in the water, closing the nostrils by a kind of valve. Seals of various species are extensively diffused through the polar regions of both hemispheres, becoming scarcer in the temperate zone. They are occasionally seen on the coast of South Britain, but are more abundant on the north of Scotland. The fur-seal of the South Seas is extremely abundant in some localities; for a period of fifty years not less than 1,200,000 skins were annually obtained from a single island. The species to which the foregoing remarks more particularly refer are—the common seal, *Phoca vitulina*, which is found from four to five feet in length; the Greenland seal, *P. Groenlandica*, about six feet in length; the bearded seal, *P. barbata*, from seven to ten feet long; and the hooded seal, which averages about eight feet long in full-grown specimens. The walrus (also called morse, sea-cow, sea-horse) resembles the seal in the general form of the body and limbs, but differs considerably in the head and teeth. The lower jaw has neither incisors nor canines, and is compressed laterally, to pass between two enormous canines or tusks, which issue from the upper one, and are directed downwards, sometimes attaining a length of two feet. These seem to be used by the animal in hooking up the sea-weeds on which it partly feeds. The morse is a very bulky creature, exceeding the largest bull in size, and generally attaining the length of twenty feet.

Seals, we have said, are gregarious, and fond of reposing on ice-fields—situations where the greatest numbers are killed. These icy haunts are termed 'seal-meadows,' and the hunters endeavour to surprise the animals while sleeping, and to intercept their retreat to the water. They attack them with muskets and bludgeons, but principally with the latter, the seal being readily despatched by a blow on the nose. They are hunted chiefly for their oil and skins—a full-grown animal yielding in spring, when they are in best condition, from eight to twelve gallons of oil, and a small one from four to six gallons. The oil, when extracted before putrefaction has commenced, is beautifully clear and transparent, free from smell, and not unpleasant to the taste. The skin, when tanned, is extensively used in the making of shoes and the like; and when dressed with the hair on, serves for the covering of trunks, &c. The walrus is also occasionally sought after, but chiefly for its ivory tusks and skin, as its carcass yields but a small proportion of oil. The seal-fishery has been long prosecuted by the Dutch, but recently, with great success, by vessels of from sixty to a hundred tons, having twenty or thirty hands on board, fitted out from the ports of Newfoundland, Nova Scotia, and the United States. Though not specially engaged in by our own fishers, British whalers always take out seal-clubs as part of their equipment, and a single ship has been known to obtain a cargo of from 400 to 500 seals, yielding nearly 100 tons of oil. Indeed of late years many of our whalers would have returned *clean*, but for the seals caught on the voyage. Seal-oil is preferred to whale-oil, and brings, accordingly, a higher price in the market.

Of the value of the seal to the inhabitants of the arctic regions, some idea may be formed from the following passage from Scoresby's 'Arctic Regions:'—'Its flesh forms their most usual food: the fat is partly dressed for eating, and partly consumed in their lamps; the liver, when fried, is esteemed even among sailors as an agreeable dish. The skin, which the Esquimaux dress by a process peculiar to themselves, is made water-proof. With the hair off, it is used as coverings instead of planks for their boats, and as outer garments for themselves; shielded with which, they can invert themselves and canoes in the water without getting their bodies wet. It serves also for coverings for their tents, and for various other purposes. The jackets and trousers made of seal-skins by the Esquimaux are in great request among our whale-fishers for preserving them from oil and wet.'

COD OR WHITE-FISHING.

Under this term is included not only the fishery of the common cod, but of haddock, whiting, ling, hake, torsk, and others—all remarkable for the excellence of their flesh, which is white, firm, separates readily into flakes, is agreeable to the taste, and wholesome. They belong to the order of soft-finned fishes, and constitute a family known by the name of *Gadidæ*, which is distinguished by the following natural characters:—A smooth oblong body, covered with small soft deciduous scales; head scaleless; eyes lateral; jaws and anterior part of the mouth furnished with several ranges of unequal pointed teeth; the gills large, seven-rayed, and opening laterally; and a small beard or barbule at the tip of the lower jaw. Almost all the species have two or three dorsal fins, one or two anal, and one distinct caudal fin; and they have a large, strong, swimming bladder. They live for the most part in the seas of cold or temperate climates; and from their size, and their tendency to congregate in particular localities, as well as from the value of their flesh, they are of first-rate importance to man. As our space will not permit us to notice individually the members of this extensive family, we shall direct attention chiefly to the cod, as the head and representative—premising that the natural habits, modes of capture, curing, and preparation, are much the same in all.

The common cod—*Gadus morrhua*—must be sufficiently well known, either in its green, pickled, or dried state, to every British reader. Its body is of moderately long shape, with the abdomen very thick and prominent; the head is large, as also are the eyes; the jaws of equal length, and the lower furnished with a single barbule. The dorsal and anal fins are rather large, the pectoral and ventral rather small; the tail of moderate size, and even at the end. As to colour, the upper part of the head, cheeks, back, and sides, are mottled and spotted with dull yellow; the belly white or silvery; the lateral line white; and the fins dusky. The animal sometimes grows to a very large size. Pennant gives an instance of one taken at Scarborough which weighed seventy-eight pounds, and measured five feet eight inches in length, and five feet in girth round the shoulders; and Mr Yarrell mentions one caught in the Bristol Channel which weighed sixty pounds. The general size, however, is much less, and the weight from about fourteen to forty pounds; and those of middling size are most esteemed for the table. 'In the seas with which Europeans are best acquainted,' says the last-mentioned naturalist, 'the cod is found universally, from Iceland very nearly as far south as Gibraltar, but does not exist in the Mediterranean. It is also found and taken in abundance as far west as the shores of Newfoundland. In this country it appears to be taken all round the coast: among the islands to the north and west of Scotland it is abundant: most extensive fisheries are carried on; and it may be traced as occurring also on the shore of almost every county in Ireland. In a natural state, the cod spawns about February; and nine millions of ova have been found in the roe of one female. Cod fish are in the greatest perfection as food from the end of October to Christmas. It may, in fact, be said of the whole family of *Gadidæ*, that they are in the best condition for the table during the cold months of the year.

The cod-fish is very voracious; a favourable circumstance for the fishermen, who experience little difficulty in taking them with almost any bait, whenever a favourable locality is ascertained. As these fish generally inhabit deep water—from twenty-five to forty, and even fifty fathoms—and feed near the ground, on various small fish, worms, crustacea, and testacea, their capture is only attempted with lines and hooks. Two sorts of lines, adapted for two very different modes of fishing, are in common use. One mode is by deep-sea lines, called *bulters*, on the Cornish coast: these are long lines, with hooks fastened at regular distances along their whole length, by shorter and smaller cords called *snoods*. The snoods are six feet long each, and placed on the long line twelve feet from each other, to prevent the hooks from becoming entangled. Near the hooks, these shorter lines, or snoods, are formed of separate threads loosely fastened together, to guard against the teeth of the fish. Some variations occur at different parts of the coast as to the number of hooks attached to the line, as well as in the length of the snood; but the distance on the long line between two snoods is always double the length of the snood itself. Buoys, buoy-ropes, and anchors or grapples, are fixed one to each end of the long line; the hooks are baited with sandlaunce, limpet, mussel, whelk, &c.; the lines are always laid, or, as it is termed, *shot* across the tide; for if the tide runs upon the end of the line, it will force the hooks together, by which the whole tide's fishing is irrecoverably lost. The lines are deposited generally about the time of slack water, between each ebb and flow, and are taken up or hauled for examination after being left about six hours, or one flood or ebb. An improvement upon this more common plan was some years ago suggested by Mr Cobb, who was sent to the Shetlands by the commissioners appointed for the improvement of the fisheries. He fixed a small piece of cork within a certain distance of the hook, about twelve inches, which suspended and floated the bait so as to prevent its falling on the ground, by which method the bait was more freely shown to the fish, by the constant and variable motion produced upon it by the tide. In the old way, the bait was frequently hid from the fish by being covered with sea-weed, or was consumed by some of the numerous star-fish and crabs that infest the ground.

The fishermen, when not engaged in shooting, hauling, or rebaiting the lines, fish with hand-lines, armed with two hooks kept apart by a strong piece of wire. Each fisherman manages two lines, holding one line in each hand; a heavy weight is attached to the lower end of the line not far from the hooks, to keep the bait down near the ground, where the fish principally feed. These two modes of line-fishing are practised to a great extent nearly all round the coast; and enormous quantities of cod, haddock, whiting, coal-fish, pollack, hake, ling, torsk, and all the various flat fish, usually called by the general name of "white fish," are taken. Of cod-fish alone, the number taken in one day is very considerable. From 400 to 550 fish have been caught on the banks of Newfoundland, in ten or eleven hours, by one man; and a master of fishing vessels trading for the London market told me that eight men, fishing under his orders off the Dogger Bank, in twenty-five fathoms water, have taken eighty score of cod-fish in one day. These are brought to Gravesend in stout cutter-rigged vessels, of eighty or one hundred tons burden, called "store boats," built for this traffic, with a large well, in which the fish are preserved alive; and of these a portion is sent up to Billingsgate market by each night-tide. Well boats, for preserving alive the fish taken at sea, came into use in this country early in the last century. They are said to have been first built at Harwich in 1712. The store boats remain as low down as Gravesend, because the water there is sufficiently mixed to keep the fish alive. If they were to come higher up, the fresh water would kill them.

'A change has lately taken place,' continues our authority, 'from the cod having shifted their ground. Formerly the Gravesend and Barking fishermen obtained few cod nearer than the Orkneys or the Dogger Bank; but for the last two or three years the supply for the London market has been obtained by going no further than the Lincolnshire and Norfolk coasts, and even between that and London, where previously very few fish could be obtained.'

As already stated, cod are largely used in a fresh state; they are also pickled green in barrels, and perhaps still more largely when split up, salted, and dried. It is impossible to arrive at anything like an accurate account of the quantity taken along our own coasts, and far less of that obtained from Newfoundland, the celebrated fisheries of which are now almost entirely in the hands of the French and Americans. The same remarks are applicable to the fisheries of haddock, ling, hake, ray, sole, turbot, and other white fish. All that we know for certain is, that vast numbers are annually taken, and consumed either fresh or dried; or, as in the case of the haddock, half-dried and smoked, under the title of *Aberdeen* or *Finnan fish*, though this mode of preparation is followed extensively at other stations. Besides their flesh, for which the cod and ling are chiefly sought after, their air-bladders, popularly called *sounds*, are prepared separately, and sold pickled. The roes, which are of large size, are also used as food, or, preserved in brine, are sold, to be employed to attract fish. Another produce is the oil extracted from the liver, which is used either for lamps, or medicinally in cases of rheumatism, consumption, &c.—cod-liver oil being now a recognised article in Materia Medica.

SALMON-FISHING.

In a previous number (43) were detailed at length the natural history of the salmon, and the various devices resorted to by the angler for its capture: we shall now direct attention to its capture as a branch of industry, involving the annual transfer in Britain of perhaps a quarter of a million sterling. The modes of fishing are extremely varied—differing according to the nature of the locality, be it sea-shore, tidal estuary, or running river. Along the shores of the open sea and estuaries the salmon is continually traversing and re-traversing during summer, and in such situations the stake-net is generally employed. This consists of a long wide-meshed net, supported on poles, which runs seaward in a straight line between high and low water-mark. From this main line various bending offsets are made, so as to form chambers or traps. As the fish push along shore, they are intercepted by the main line of net, and find their way into one or other of the traps, from which there is no retreat. Higher up the rivers sweep-nets are used, one end being made fast to the shore, and the other run rapidly out by a boat, so as to enclose any fish that may be seen ascending. As soon as a salmon is observed by the outlook, a signal is made, the net run out as described, and then dragged on shore, encircling the object of capture. The central portions of wide rivers are usually worked by fishermen in boats called *cobles*, with long sweeping seine-like nets—a laborious, but not unsuccessful process. Still higher up, in certain rivers, weirs or dams are built, with enclosed places in the dam wall called *cruives*. The fish, as they push up the stream, enter these spaces, through which the water rushes, and are prevented by a grating of peculiar contrivance from getting out. In some places stages are erected, from which fishers with bag-nets intercept the ascending salmon; and at linns or water-falls spearing is occasionally resorted to. By one or other of these methods immense numbers of salmon are annually taken—and, we wish we could add, always taken with honest, judicious care in reference to the reproduction and preservation of the species. The fish so captured are chiefly used in a fresh state, the quantity now pickled and kippered being inconsiderable.

With regard to the statistics of the salmon-fishery, it is extremely difficult to arrive at correct information; indeed beyond a few broad facts, any attempted statement is little better than guess-work. The following facts are gleaned from a somewhat rambling notice in the 'Statistical Account of the British Empire:'—'Salmon being rarely caught except in estuaries or rivers, is in most instances private property: the fisheries frequently producing a large revenue to their owners. It is found in most English rivers, but seldom in such abundance as to make fishing an object of much attention. London derives the principal part of its supply from Scotland; and Liverpool, Manchester, &c. from Ireland. The fishery in the Tweed is important and valuable. About twenty years ago it produced a rental of from £15,000 to £18,000 a year; but in the interval the decline has been such, that at present it does not yield above £4000 or £5000 a year to its proprietors. This extraordinary decline is principally owing to a nearly corresponding falling off in the catch of salmon—the exports from Berwick having sunk from 9000 or 10,000 boxes a year to 3000 or 4000. Exclusive of the Tweed, there are valuable salmon-fisheries in the Tay, Forth, Dee, Don, Findhorn, Spey, Ness, and other Scottish rivers; but they are mostly all in the same condition as those of the Tweed. There is everywhere a growing scarcity of fish, and a corresponding decline in rental. Most persons seem to think that the declining state of the salmon-fisheries is mainly owing to the prevalence of poaching, or to the destruction of the breeding-fish and fry in the upper parts of the rivers during *close-time*. On the whole, we rather incline to think that fully as much injury is done in most rivers by the *weirs*, and other obstructions placed in the way of the fish when ascending the rivers to spawn, as by anything else. The fishery has also perhaps been injured by the temptation to over-fish, caused by the high price of salmon, and in a still greater degree by the too limited duration of the close-time. The last-mentioned cause of decline is thought by many good judges to be the most powerful of the whole; and it is justly objected to the Acts for the regulation of the Scotch Fisheries, that they prolong the period for fishing too far into the spawning season. The fisheries in the north of Ireland are said to have been seriously injured by the steeping of flax in waters communicating with the rivers which salmon frequent. The fisheries in the Bann, near Coleraine, the Bulick, near Ballyshannon, the Boyne, above Drogheda, and in various other Irish rivers, are still very productive; and it is owing to this cause, as well as to the recent imports from Holland, that the price of salmon has been kept at so low a figure, notwithstanding the falling off in the supply from Scotland.

Formerly, the greater part of the salmon caught in the Tweed and other Scotch rivers was pickled or kitted, after being boiled, and sent to London under the name of 'Newcastle Salmon'—a little only being brought up fresh during the early spring months. But about 1790, the plan suggested by Mr Dempster of Dunichen, of packing salmon in boxes with coarsely-pounded ice, began to be introduced; and by this ingenious contrivance it is now brought quite fresh from the most distant parts of Scotland and Ireland. This discovery immediately raised the price of salmon in the remoter parts of the country almost to the London level, and restricted its consumption within the narrowest limits. At present, the value of the salmon (fresh and pickled) imported from Scotland into the metropolis is estimated at £150,000 a year; and the average selling price at 10d. per lb.—a price which all but debars it from the middle classes, and wholly from the bulk of the population.

HERRING-FISHING.

This well-known fish—*Clupea harengus*—is ranked by naturalists in the same family with the pilchard, sprat, shad, anchovy, and white bait. The body, which is about ten or twelve inches in length, and of a handsome, regular shape, is covered with thin roundish scales; the upper part is blue or green, according to the light, and the lower of a silvery white. The belly is carinated, but not serrated, as in the sprat—a distinction which is obvious and permanent. Owing to the gill-covers being very loose, and opening wide, the animal dies almost the instant it is taken out of the water. The herring varies considerably in size and condition, but five or six ounces may be taken as the ordinary weight. The opinion of the older naturalists, that the herring periodically migrates from the arctic seas to deposit its spawn in the warmer latitude of Britain, is rejected by modern authorities. 'The herring,' says Yarrell, 'inhabits the deep waters all round the British coasts, and approaches the shores in the months of August and September for the purpose of depositing its spawn, which takes place in October or the beginning of November. It is during the two first months that the great fishing is carried on; for after the spawning is over, it returns to deep water. The mode of fishing for herrings is by drift-nets, very similar to those employed for taking mackerel and pilchard, with a slight difference in the size of the mesh. The net is suspended by its upper edge from the drift-rope, by various shorter and smaller ropes, called "buoy ropes;" and considerable practical skill is required in the arrangement, that the net may hang with the meshes square, smooth, and even in the water, and at the proper depth; for according to the wind, tide, situation of their food, and other causes, the herrings swim at various distances from the surface. . . . The size of the boat used depends on the distance from shore at which the fishery is carried on; but whether in deep or in shallow water, the nets are only in actual use during the night. It is found that the fish strike the nets in much greater numbers when it is dark than when it is light; the darkest nights, therefore, and those in which the surface of the water is ruffled by a breeze, are considered the most favourable. It is supposed that nets stretched in the day-time alarm the fish, and cause them to quit the places where that practice is followed; it is therefore strictly forbidden.' The only other legal restriction is as to the size of the mesh, and the leaving of nets so as to foul the ground with dead fish.

Respecting the history and statistics of the herring-fishery, which is the most important to the community at large, we glean the following particulars chiefly from the 'Cyclopedia of Commerce:'—This fishery has been prosecuted on the British shores from a remote period; but its early history is involved in obscurity. The progress of the Dutch herring-fishery is well known. There is a popular saying in Holland, that 'the foundation of Amsterdam is laid on herring-bones,' in allusion to the fishery having formerly been its great staple. Under the Stadtholders this fishery was considered the right arm of the republic, and it was always entitled the 'Grand Fishery.' When in the height of its prosperity (1650), the total number of vessels which it employed, including those engaged in bringing salt and transporting the fish, was stated at 6400, and the number of mariners and fishermen at 112,000. The extraordinary progress of that people led to various measures in this country for encouraging the British fisheries. These measures assumed a variety of forms at different times, such as fishing towns built at the public expense; associations under royal patronage; the strict observance of Lent; remission of the salt duties; the importation, duty free, of foreign commodities received in exchange for fish; lotteries; collections in churches; rendering it obligatory upon victuallers to take yearly a certain quantity at 30s. a barrel; and lastly, direct bounties. These 'encouragements' all failed in communicating anything like permanent prosperity to the fishery; and some of them, particularly bounties, led to great abuses. It would exceed the limits of this article to specify the different changes which took place in the bounty system. It may be mentioned, however, that in 1820, after various modifications, an allowance of 20s. a ton, increasing under certain circumstances to 30s., was granted on all vessels from 15 to 60 tons fitted out for the shore-fishery, exclusive of a premium of 4s. per barrel on herrings cured and gutted, and 2s. 8d. per barrel on those exported. In a few years afterwards the principle of bounties was abandoned; in 1826 the export bounty was withdrawn, and the bounty of 4s. was reduced 1s.

each succeeding year until 1830, when it ceased altogether. The withdrawal of the bounties, so far from having injured the herring-fishery, has had a contrary effect. The fishermen, no longer encouraged to look to extraneous aid, and relieved from the intrusion of landsmen, who engaged for a few weeks in the fishery for the purpose of obtaining the bounty, have redoubled their exertions, and are now better clothed and fed, and more temperate than before; while in many cases they have been enabled by their industry to substitute for the small boats formerly used others of much larger dimensions, and to provide themselves with superior fishing materials. Notwithstanding the repeal of the bounties, the fishery is still under the surveillance of a 'Herring Board,' which has officers at the different fishing stations to superintend the curing department, and who affix an official brand to barrels containing a certain quality of fish.

Herrings are brought to market in three principal forms: *fresh herrings* are the condition in which they are taken from the sea; *white or pickled herrings* are merely salted and put into barrels; *red herrings* are gutted and salted, and afterwards hung and fired with the smoke of greenwood; and to these we may add the recent invention of *kippering*—that is, splitting up the fresh fish, passing it through brine, and subjecting it to a slight firing with greenwood smoke. Fresh herrings are consumed in considerable quantities during the fishing season; but it is the pickled and red herrings which form the great objects of the fishery. The *boat-fishery* is that chiefly pursued when the fishing ground is not at a great distance from shore. The *deep-sea fishery*, where the fishermen go out to sea wherever the fish are to be found, requires vessels of a larger description (from thirty to eighty tons) as the herrings are pickled and stowed on board. The vessels fitted out for this fishery commonly meet with the earliest and best herrings; and owing to the circumstance of the fish deserting certain parts of the coast which they have been accustomed to frequent, it is a more regular source of profit than the boat-fishery, though it requires larger capital. The British cured herrings, though now much better than formerly, are still inferior to the Dutch—the British fishery depending for its prosperity more on quantity than quality. The fishery is mostly on the north-east coast, particularly at Wick, Helmsdale, Fraserburgh, Peterhead, Anstruther, and Dunbar; it is also extensively pursued in the Orkney and Shetland islands; on the west coast of Scotland, which yields the famed Lochfine herrings; the Isle of Man; the Yorkshire coast; and at Yarmouth, where red herrings (Yarmouth bloaters) are largely cured for the home market. In 1844 the quantity of herrings cured (gutted and ungutted) at the different stations amounted to 665,360 barrels; and this independently of what was consumed in the fresh state. In the same year the number of boats employed amounted to 14,667; the number of fishermen and boys, 60,457; coopers, 2306; packers, gutters, &c. (chiefly women), 28,177; miscellaneous labourers, 7104; and fish-curers, 1611. Of the cured herrings, about one-half (320,000 barrels) are annually exported.

The herring-fishery of Ireland, until lately, was of very little consequence. In 1842, however, a Board of Commissioners was appointed for its improvement and regulation, and under this superintendence it is gratifying to observe a rapid and marked change. The whole coast has been divided into 28 districts, each of which is placed under a local officer; and it appears, from the reports of these officials, that in 1845 there were 19,883 vessels of all sizes, and 93,073 men and boys, wholly and partially engaged in the fishery.

PILCHARD FISHING.

The Pilchard—*Clupea pilchardus*—bears a close resemblance to the herring, not only in general appearance, but in its habits. When full grown it is about nine inches in length, is somewhat rounder and lumpier in form than the herring, and is covered with considerably larger scales. The head is rather flat, and the mouth is destitute of teeth; the back is of a bluish cast, the belly and sides silvery, and the upper angle of each of the gills is marked with a large black spot. They feed with voracity on small crustaceous animals, their stomachs being occasionally found crammed with thousands of a minute species of shrimp not larger than a flea. They are also partial to the spawn of fishes; hence the custom of the French fishermen to throw salted pea-roe about their nets to attract the shoals. They appear annually on the southern coasts of England and Ireland, where they are captured in immense quantities either by *seans* or by drift-nets. The same reason, until late years, was assigned for the periodical return of the pilchards as for that of the herring—namely, their presumed migration from the arctic seas to warmer regions for the purpose of spawning; but this opinion is now all but abandoned. Indeed it has been established beyond doubt by Mr Couch and others that the pilchard inhabits our own seas, merely forsaking the deep waters, and coming towards the shore to deposit their spawn—thus fulfilling a great law of nature in the propagation of their species, and at the same time providing multitudes of human beings with a cheap and delicious food. The following account of the English pilchard-fishery is obtained chiefly from M'Culloch and Yarrell, as furnished, we believe, by Mr Couch of Cornwall:—

It is carried on along the coasts of Cornwall and Devon, its principal seats being St Ives, Mounts Bay, and Mevagissey. The fish usually make their appearance in vast shoals in the early part of July, and disappear about the middle of October; but they sometimes reappear in large numbers in November and December. They are taken either by drift-nets or by seans; but principally by the latter. The outfit of the former consists of a number of nets, great in proportion to the wealth of the proprietor and size of the boat; but commonly about twenty, each from 15 to 18 fathoms long and 7 fathoms deep; so that a string of driving-nets will sometimes reach three-quarters of a mile. These nets are fastened to each other in length, and on to a head-line appropriated to each, along which runs a row of cork buoys; another line runs loosely along the middle of the nets, to afford additional strength, but no weights are used at the bottom. The nets are carried in common fishing-boats, some of which, as at Mounts Bay, are luggers, and most of the others have sprit-sails: the crew consists of four men and a boy. The fishery begins a little before sunset, and the nets are drawn in about two hours, to be again shot as morning approaches; for pilchards enter the nets better at these seasons. A rope from one end of the string is fastened over the quarter of the boat, and the nets are left to float with the tide, no sails being set, except rarely in very calm weather, to prevent the nets being entangled. The number of fish taken by a drift-boat in a night's fishing varies exceedingly: from 5000 to 10,000 is considered moderate: it often amounts to 20,000. For the season's fishing about 150,000 fish would be considered favourable.

The other mode—namely, fishing by sean—is more profitable and expeditious. A sean is a net varying from 200 to 300 fathoms in length, and from 10 to 14½ fathoms in depth, having cork buoys on one edge, and lead weights on the other. Three boats are attached to each sean—namely, a boat (*sean-boat*) of about fifteen tons burden for carrying the sean; another (*follower*) of about the same size, to assist in mooring it; and a smaller boat (*lurker*) for general purposes. The number of hands employed in these three boats varies from 13 to 18, but may be taken at an average of 16. When the shoals of fish come so near the shore that the water is about the depth of the sean, it is employed to encircle them; the fishermen being directed to proper places for casting the nets by persons (*huers*) stationed for that purpose on the cliffs and in the boats. The practice is to row the boat, with the sean on board, gently round the shoal; and the sean being at the same time thrown gradually into the water, assumes, by means of its buoys and weights, a vertical position—its loaded edge being at the bottom, and the other floating on the surface. Its two ends are then fastened together; and being brought into a convenient situation, it is moored by small anchors or grapnels; sometimes, however, one or two smaller seans are employed to assist in securing the fish. At low water the enclosed pilchards are taken out by a *tuck-net* and carried on shore. A single sean has been known to enclose 3000 hogsheads of fish; but it is seldom that even a third of that amount is enclosed at a time. The 'take,' in fact, depends upon so many accidental circumstances, that while one sean may catch and carry in from 1000 to 2000 hogsheads, others in the neighbourhood may not get a single fish. An instance has been known where 10,000 hogsheads have been taken in one part in a single day—thus providing the enormous multitude of 25,000,000 of living creatures drawn at once from the ocean for human sustenance. In some places the tides are so strong as to break the seans, and set the fish at liberty; and occasionally this happens from the rush and pressure of the fish themselves. When the quantity enclosed is large, it requires several days to take them out, as they must not be removed from the water in greater numbers than the curers can conveniently manage.

As soon as the fish are brought on shore they are carried to cellars or warehouses, where they are piled in large heaps, having a sufficient quantity of salt interspersed between the layers. Having remained in this state for about thirty-five days, they are, after being carefully washed and cleaned, packed in hogsheads, each containing on an average 2600 fish. They are then subject to a pressure sufficient to extract the oil, of which each hogshead yields—provided the fish be caught in summer—about three gallons; but those that are taken late in the season do not yield above half this quantity. This oil usually sells from 12 to 15 per cent. under the price of brown seal oil. The broken and refuse fish and salt are sold to the farmers, and are used as manure with excellent effect. The skimmings which float on the water in which the fish are washed are called *dregs*, and are chiefly sold as grease for machinery. Pilchards are not used in England, except in the counties in which they are taken, where about 3000 hogsheads are retained for home consumption. They are chiefly exported to Italy.

The following is a statement, perhaps nearly approaching the truth, where absolute certainty is unattainable, of the amount of property engaged in the pilchard-fishery in the year 1827, when the bounty began to be withdrawn:—Number of seans employed, 186; not employed, 130; total number of seans, 316; number of drift-boats, 368; men employed on board drift-boats, 1600; number of men employed on seans at sea, 2672; number of persons (chiefly women) on shore to whom the fishery affords direct employment, 6350; total number of persons employed in the fishery, 10,521. Cost of seans, boats, &c. employed in the fishery, £209,840; cost of drift-boats and nets, £61,400; cost of cellars for curing and other establishments on shore for carrying on the fishery, £169,175; total capital invested directly in the pilchard-fishery, £441,215. It is but right to add to this estimate, made in reference to 1827, that in 1847 Mr M'Culloch sets down the total capital as not exceeding £250,000. The outfit of a sean amounts to about £800; a string of drift-nets will cost £6 the net; and the boat from £100 to £150; but this is used throughout the year for the other purposes of fishing. The nets are supposed to last about six years, and ought of course to produce their own value within that time, together with an adequate profit; but it is the complaint of the fishermen that this is not the case. The profit of the men depends on the share of the fish, which is divided into eight parts, of which the boat has one-eighth part, the nets three, and the men four: a boy that accompanies them is rewarded with the fish that may fall into the sea as the nets are drawn, to secure which he is furnished with a bag-net at the end of a rod. The annual average produce of the Cornish pilchard-fisheries is stated at 21,000 hogsheads; in 1845 it amounted to upwards of 33,000 hogsheads. The annual export is about 17,000 hogsheads; in 1842 it exceeded 20,000.

MACKEREL FISHING.

The mackerel—*Scomber scomber*—is described as 'one of the most beautiful of fishes as regards the brilliancy of its colours, and at the same time one of the most useful as regards the food of man.' It is a native of the European and American seas, generally appearing at stated seasons in immense shoals round particular coasts. The periodical appearance of these vast shoals was formerly imputed to its migration from north to south; but many facts are opposed to this idea; and there is abundant reason to believe that it inhabits the deeper parts of the seas around our island throughout the year, and that its periodical appearance on our coasts in such vast numbers, is solely due to its seeking the shore for the purpose of depositing its spawn. The usual length of the mackerel is about fourteen inches, or varying from twelve to sixteen; but in the northern seas it is occasionally found of a larger size. Its colour on the upper parts, as far as the lateral line, is a rich deep blue, accompanied by a varying tinge of green, and marked by numerous black transverse streaks, which in the male are nearly straight, but in the female beautifully undulated. The jaws, gill-covers, and abdomen, are of a bright silvery hue, with a slight cast of gold green on the sides. The scales are small, oval, and transparent; the spurious fins or pinnules are five in number both above and below; the tail is crescent-shaped; the head is pointed, with the lower jaw projecting. Beautiful as are the colours of the mackerel when alive, no sooner is it caught than its lustre begins to disappear. It is a voracious feeder, and its growth is rapid; but it is not the largest fish that are accounted the best for the table. Those taken in May or June are considered superior in flavour to such as are caught either in early spring or in autumn. The mackerel spawns in June; and 540,000 ova are said to have been counted in one female. For mackerel roaming hither and thither through the waters of the ocean, no successful mode of capture could be adopted; but at their periodical returns to the shore millions are taken by the net, sean, or line, and yet the number caught is but a mere fraction of the countless shoals that escape.

For the following statistics in reference to the capture, &c. of this esteemed fish, we are indebted to Mr Yarrell. 'At our various fishing-towns on the coast, the mackerel season is one of great bustle and activity. The frequent departures and arrivals of boats at this time form a lively contrast to the more ordinary routine of other periods; the high price obtained for the early cargoes, and the large return gained generally from the enormous numbers of this fish sometimes captured in a single night, being the inducement to great exertions. The most common mode of fishing, and the way in which the greatest numbers are taken, is by drift-nets. The drift-net is 20 feet deep, by 120 feet long; well corked at the top, but without lead at the bottom. They are made of small fine twine, which is tanned of a reddish-brown colour, to preserve it from the action of the sea water; and it is thereby rendered much more durable. The size of the mesh is about two and a-half inches, or rather larger. Twelve, fifteen, and sometimes eighteen of these nets are attached lengthways, by tying along a thick rope, called the "drift-rope," and at the ends of each net, to each other. When arranged for depositing in the sea, a large buoy attached to the end of the drift-rope is thrown overboard, the vessel is put before the wind, and as she sails along, the rope with the nets thus attached is passed over the stern into the water till the whole of the nets are run out. The net thus deposited hangs suspended in the water perpendicularly twenty feet deep from the drift-rope, and extending from three-quarters of a mile to a mile, or even a mile and a-half—depending on the number of nets belonging to the party or company engaged in fishing together. When the whole of the nets are thus handed out, the drift-rope is shifted from the stern to the bow of the vessel, and she rides as if at anchor. The benefit gained by the boat's hanging at the end of the drift-rope is, that the net is kept strained in a straight line, which, without this pull upon it, would not be the case. The nets are shot in the evening, and sometimes hauled once during the night, at others allowed to remain in the water all night. The fish roving in the dark through the water, hang in the meshes of the net, which are large enough to admit them beyond the gill covers and pectoral fins, but not large enough to allow the thickest part of the body to pass through. Early in the morning preparations are made for hauling the nets. A capstan on the deck is manned, about which two turns of the drift-rope are taken. One man stands forward to untie the upper edge of each net from the drift-rope, which is called "casting off the lashings;" others hand in the net with the fish caught, to which one side of the vessel is devoted; the other side is occupied by the drift-rope, which is wound in by the men at the capstan. The whole of the net in, and the fish secured, the vessel runs back into harbour with her fish, or depositing them on board some other boat in company, that carries for the party to the nearest market, the fishing vessel remains at sea for next night's operations. Indeed the boats engaged in fishing are usually attended by other fast-sailing vessels, which are sent away with the fish taken. From some situations these vessels sail direct for the London market; at others they make for the nearest point from which they can obtain land-carriage for their fish. From Hastings and other fishing towns on the Sussex coast the mackerel are usually brought by vans, which travel up during the night.' It is scarcely necessary to remark, that the facilities now afforded by railways have entirely changed the aspect of affairs, and that fresh fish are now often sooner in Billingsgate than in the market-places of the ports where they are landed!

Mr Couch describes two other modes of fishing for mackerel: the one by means of a long deep net, with small meshes, by which the fish are surrounded, and then either taken from the water by baskets, or hauled direct to the land, in the manner of a ground-net; the other by means of a hook and line, called *trailing*. The latter forms a first-rate marine sport, and is thus performed:—'The mackerel will bite at any bait that is used to take the smaller kinds of fish; but preference is given to what resembles a living and active prey, which is imitated by what is termed a *lask*—a long slice cut from the side of one of its own kind, near the tail. It is found also that a slip of red leather or piece of scarlet cloth, will commonly succeed; and a scarlet coat has therefore been called a mackerel bait for a lady. The boat is placed under sail, and a smart breeze is considered favourable; hence termed a "mackerel breeze." The line is short, but weighed down with a heavy plummet; and in this manner, when these fish abound, two men will take from 500 to 1000 in a day. It is singular that the greatest number of mackerel are caught when the boat moves most rapidly, and that even then the hook is commonly swallowed. It seems that the mackerel takes its food by striking across the course of what it supposes to be its flying prey. A gloomy atmosphere greatly aids this kind of fishing.'

Mackerel-fishing being extremely uncertain and irregular, there is no possibility of arriving at anything like its annual value. It is, in fact, a lottery, as the following recorded instances will show:—In May 1807, the first Brighton boat-load of mackerel sold at Billingsgate for forty guineas per hundred—seven shillings each, reckoning six score to a hundred—the highest price ever known at that market. The next boat-load produced but thirteen guineas per hundred. Mackerel were so plentiful at Dover in 1808, that they were sold sixty for a shilling. The success of the fishery in 1821 was such, that the value of the catch of sixteen boats from Lowestoft, on the 30th of June, amounted to £5252; and it is estimated that in that season not less than £14,000 were realised by the owners and men concerned in the fishery of the Suffolk coast. In March 1833, on a Sunday, four Hastings boats brought on shore 10,800 mackerel; and the next day two boats 7000. Early in February 1834, one boat's crew from Hastings cleared £100 by the fish caught in one night; and in March of the same year they were cried through the streets of London three for a shilling. Mackerel are always consumed fresh, and the fresher the better; but the French salt them down like herrings—a practice occasionally followed by the fishers and country people of Cornwall.

CRAB AND LOBSTER FISHING.

Under this head may be included the capture of the shrimp, prawn, crab, lobster, and allied crustacea, some of which are greedily sought after by epicures, though all are indifferently nutritious and difficult of digestion. The shrimp, which looks like a lobster in miniature, is found abundantly in the shallow waters of our flat sandy coasts. It has ten feet, and its motion consists of leaps. When full-grown, it does not exceed two inches in length; the tail is as long as the body, and terminates in a spreading fan-like flap; it has no large anterior claws. During life, the body is semi-pellucid, and is scarcely distinguishable from the water. The shrimp is in great request for the table, and its capture affords employment for women and boys, who wade in the sandy shallows, pushing a sort of dredge-net before them at the end of a long pole. A more certain and profitable mode is to collect them by means of sweep-nets, drawn over the ground they frequent, by men in small boats. The prawn is less abundant, but is equally esteemed. The species sold by the fishmongers is about three inches long, of a pale-red colour, and distinguished by its long frontal serrated spine.

The common edible crab is too well known to require description. The most remarkable feature in its economy, and which indeed is common to all crustaceans, is the process of sloughing, or moulting at regular periods the entire calcareous covering or crust. As it is obvious that the hard shell, when once perfected, cannot change with the growth of the animal, it becomes necessary that it should be shed entirely. When the season of shedding arrives, the aquatic crabs generally seek the sandy shores of creeks and rivers, and having selected a place of rest, the change begins. The body seems to swell; the larger upper shell begins to separate from the breast or corslet; the muscles of the limbs soften and contract, which allows of their slipping from their cases; the parts about the head and antennæ undergo a similar change; and gradually the animal escapes from the crust, soft, helpless, and incapable of exertion or resistance. In twenty or thirty hours, however, a thin crust has again overspread its various parts and members, and in the course of a few days it is enabled to resume its wonted habits. During the moulting season, as well as during the period of spawning, crabs are worthless; at other times they are excellent. On the rocky coasts they frequent they are either drawn at ebb-tide from the holes and crevices, by means of an iron hook, or they are fished for, in four or five fathoms water, by traps or cages baited with garbage. Immense numbers are annually consumed in all our seaports.

Lobsters, which are also caught either by pots and cages, by baited nets, or, in some countries, by torch-light, with the aid of wooden forceps, stand at the head of our native crustacea, and generally bring extravagantly high prices in the market. They are usually in their best season from the middle of October to the end of May, when they commence to shed their spawn; and it is provided by an act of George II. that 'no lobsters must be taken on the coast of Scotland between 1st June and 1st September, under a penalty of £5 for each offence.' In summer they are found near the shore, but in winter they are seldom taken in less than twelve or fifteen fathoms water. A sizeable specimen weighs from one to two pounds. The consumption of lobsters in London is immense—the number annually sold at Billingsgate being reckoned at 2,000,000. The supply is derived partly from the Shetland Islands and east coast of the island as far south as the Humber, but chiefly from Norway. It has been estimated by Sir John Barrow (see Encyclopædia Britannica) that London alone pays not less than £12,000 a year to the Danes and Norwegians for lobsters!

OYSTER FISHING.

The shell-fish gathered by hand, dredged, or otherwise collected along our shores, are chiefly periwinkles, limpits, mussels, cockles, and oysters. Unless in the case of oysters, none of the others are supplied to our markets with regularity; not from want of demand, but because few direct their attention to these matters as a branch of industry. And yet if things were rightly directed, how many of the poorer classes might obtain an honest livelihood by reaping from the endless supply of shell-fish with which nature has furnished our sea-coasts! Mussels and cockles are to be found in many of our estuaries, in extensive beds of the finest quality; and at certain seasons our rocky shores are profusely studded with limpits and periwinkles. All that is needed are regularity of supply and attention to the proper season of collecting, and, we may add, a higher degree of skill in preparing them in some agreeable manner for the table.

The case is altogether different with the oyster—*Ostrea edulis*—which has been highly prized by epicures in all ages, and has accordingly furnished an important article of trade. The common oyster, which is abundant on the shores of Britain and most other countries, inhabits an unequal bivalve shell, externally of a coarse and dirty appearance, each shell being composed of laminae irregularly closed down on each other. The animal itself is of a very simple structure: on separating the valves, four rows of gills, or what are called *beards*, are seen at a little distance from the fringed edge of the mantle; the abductor muscle is situated near the centre of the body, where the heart may be observed; and the mouth lies beneath a hood formed by the union of the two edges of the mantle near the hinge. Altogether, unless on close inspection, the creature looks more like a mass of delicate animal jelly than an organised body. Though apparently dull, and stationary beyond comparison, the oyster is said to possess the power of locomotion. This is performed by suddenly closing the shells, by which the water is ejected with force sufficient to throw them backward or in a lateral direction; and thus, by a repetition of this process, considerable progress is obtained.

The principal breeding time of the oyster is in April or May, when their spawn is usually cast: this appears at first like spots of grease, which fasten upon rocks, or other hard substances that happen to be near. Very commonly they adhere to adult shells, and thus are formed the large masses called oyster-banks. In about a year and a-half the young oysters have attained a profitable size, and are then dredged up and conveyed direct to market, or are transferred to artificial pits or beds within tide reach, where they are fattened to the desired size. Though this practice of transference has been carried on from the time of the Romans downwards, it has nothing to recommend it beyond convenience, and certainty of obtaining a regular supply; for the transplanted oysters, or *exiles*, according to connoisseurs, are never found in such perfection as *natives*. As with every other article of luxury, so with oysters; certain varieties are more fashionable and popular than others. In London, the Colchester and Milton oysters are held in most esteem; Edinburgh has her 'whiskered Pandores,' and latterly Aberdour oysters; and Dublin the Carlingford and Powldoodies of Burran. The British trade in oysters is of very considerable importance, and ranks next to that in salmon and herrings. Besides the large supply obtained from our own coasts, upwards of 200,000 bushels are annually imported from Jersey, where, according to Mr Inglis, 1500 men, 1000 women and children, and 250 boats, are engaged in the fishery.

From spawn time till the end of July the oysters are said to be *sick*, or out of season; and their capture, or the removal of anything to which they adhere, is then prohibited by law. On the 4th of August Billingsgate opens with great bustle, and the supply continues till the 12th of May following. Private right in oyster-beds is protected by act of parliament; and by a convention between Britain and France, the subjects of each power enjoy the exclusive right of fishery within the distance of three geographical miles from low water-mark along the whole of their respective coasts. The oyster fishery beyond these limits is common to the subjects of both countries.

Such is a hasty outline of our British Sea-Fisheries, from which it will readily be seen that, important as some of them are, not one has reached that stage of development which the inexhaustible supply of the material and the wants of our population would lead the statistician to expect. 'That this harvest,' says Sir John Barrow, 'ripe for gathering at all seasons of the year, without the labour of tillage, without the expense of seed or manure, without the payment of rent or taxes, is inexhaustible, the extraordinary fecundity of the most valuable kinds of fish would alone afford abundant proof. To enumerate the thousands and even millions of eggs which are impregnated in the herring, the cod, the ling, and indeed in almost the whole of the esculent fishes, would give but an inadequate idea of the prodigious multitudes in which they flock to our shores; the shoals themselves must be seen, in order to convey to the mind any just idea of their aggregate mass.' And yet with all this superabundance on the one hand, and the wants of a needy population on the other, our fisheries, on the whole, are conducted in a very rude, meagre, and imperfect manner. Not only are more skilful modes of capture necessary, but a heavier and more efficient equipment, a different style of vessel, the application of steam-power instead of sails, and the adoption of deep-sea fishing in preference to a paltry and uncertain creeping along shore, are all indispensable to the advancement of this branch of industry. Nor is this advancement to be gained by any pampering or bounties on the part of government; these have hitherto miserably failed, and must ever do so. What is wanted is a liberal outlay of capital, in the expectation of a certain and liberal remuneration; and there need be no hope of any important change in the present system until parties, calculating upon a full supply and increasing demand, enter the field with the necessary means. Regularity and cheapness, which can only be obtained by the adoption of a better system, are sure to increase the demand, and all the more readily now that railways have opened up a facility of transport which may be said to place our seaport and inland towns on an equal footing as regards a fresh and abundant supply of our maritime produce. Already is railway transport beginning to lower prices and increase demand; placing fresh fish within the reach of such towns as Birmingham and Manchester, for example, at a fourth of the rates formerly charged. A new era, indeed, seems to be dawning upon our fisheries, and fishmongers of capital are directing attention to other apparatus, vessels, and modes than those now in general operation. Sir John Barrow has estimated the annual value of our fisheries, foreign and domestic, at eight millions; Mr M'Culloch thinks half that sum to be nearer the mark; but whether four millions or eight millions, there cannot be the shadow of a doubt that either amount is far below what they might be made to produce under a more skilful and efficient system.

PRESERVATION OF HEALTH.

A HUMAN being, supposing him to be soundly constituted at first, will continue in health till he reaches old age, provided that certain conditions are observed, and no injurious accident shall befall. This is a proposition so well supported by extensive observation of facts, that it may be regarded as an established axiom. It becomes, therefore, important to ascertain what are the conditions essential to health, that, by their observance, we may preserve for ourselves what is justly esteemed as the greatest of earthly blessings, and dwell for our naturally appointed time upon the earth. A general acquaintance with these conditions may be easily attained by all, and to render them obedience is much more within the power of individuals than is commonly supposed.

The leading conditions essential to health are:—1. A constant supply of pure air; 2. A sufficiency of nourishing food, rightly taken; 3. Cleanliness; 4. A sufficiency of exercise to the various organs of the system; 5. A proper temperature; 6. A sufficiency of cheerful and innocent enjoyments; and, 7. Exemption from harassing cares. These conditions we shall now treat in succession, taking as our guides the most recent and eminent of physiological authorities.

AIR.

The common air is a fluid composed mainly of two gases, in certain proportions; namely, 20 parts of oxygen and 80 of nitrogen in 100, with a very minute addition of carbonic acid gas. (See CHEMISTRY, p. 295.) Such is air in its pure and normal state, and such is the state in which we require it for respiration. When it is loaded with any admixture of a different kind, or its natural proportions are in anyway deranged, it cannot be breathed without producing injurious results. We also require what is apt to appear a large quantity of this element of healthy existence. The lungs of a healthy full-grown man will inhale the bulk of twenty cubic inches at every inspiration, and he will use no less than fifty-seven hogsheads in twenty-four hours. And not only is this large quantity necessary, but the air that surrounds us must be in free circulation, in order that what we expire may be speedily carried away, and allowed to commingle with the atmosphere, which is subject to never-ceasing causes tending to its restoration and renewal.

Now there are various circumstances which tend to surround us at times with vitiated air, and which must accordingly be guarded against. That first calling for attention is the miasma or noxious quality imparted to the atmosphere in certain districts by stagnant water and decaying vegetable matter. It is now generally acknowledged that this noxious quality is, in reality, a subtile poison, which acts on the human system through the medium of the lungs, producing fevers and other epidemics. A noted instance of its acting on a great scale is presented in the Campagna di Roma, where a large surface is retained in a marshy state. The exhalations arising from that territory at certain seasons of the year, obliges the inhabitants of the adjacent districts of the city to desert their homes, and escape its pernicious influence. All marshes, and low damp grounds of every kind, produce more or less miasma, and it is consequently dangerous to live upon or near them. Slightly-elevated ground, with a free exposure to light and air, should accordingly in all cases be chosen for the sites of both single houses and towns. Tanks and collections of water of every kind are dangerous beneath or near a house, because, unless their contents be constantly in a state of change, which is rarely the case, their tendency is to send up exhalations of a noxious kind. Some years ago, Viscount Milton—a youth of great promise, and who had recently become a husband and father—died of a fever which was traced to the opening of an old reservoir of water underneath the country-house in which he dwelt. More recently, a similar but more extensively fatal tragedy took place at a farmhouse in the south of Scotland. Not only did the farmer, his wife, and a female servant sink under a malignant fever, but a son and daughter, and several other servants, narrowly escaped with their lives, and only by removing from the house. It was observed in this case that removal produced instantaneous improvement of health, but a return to the devoted dwelling at once renewed the ailment. On proper investigation, it was found that immediately behind the house was a kind of mill-pond, into which every kind of refuse was thrown, or allowed to discharge itself; and that this collection of putrid matter had not been once cleared out for a long series of years, no one dreaming of any harm from it. The momentous consequences from a cause so trifling, and the consideration that they might have been warded off by only a little knowledge of natural causes, furnish melancholy matter for reflection. Many analogous cases, which might be referred to, demonstrate that we are yet but in the infancy of an understanding of the subject of aërial poisons.

Putrid matter of all kinds is another conspicuous source of noxious effluvia. The filth collected in ill-regulated towns—ill-managed drains—collections of decaying animal substances placed too near or within private dwellings—are notable for their effects in vitiating the atmosphere and generating disease in those exposed to them. (See No. 30.) In this case also it is a poison, diffused abroad through the air, which acts so injuriously on the human frame. This was probably the main cause of the plagues which devastated European cities during the middle ages. In those days there were no adequate provisions for public cleaning, and the consequence was, that masses of filth were suffered to accumulate. The noxious air diffused by these means through the narrow streets and confined dwellings would tend to the most fatal effects. In old drains there is generated a gas (sulphuretted hydrogen) which is calculated to produce dreadful consequences in those exposed to its inhalation. It has lately been discovered that it is the presence of this gas, arising from the shores, river deltas, and mangrove jungle of tropical Africa, which causes the peculiar unhealthiness of that region. It is ascertained that small animals, such as birds, die when the air they breathe contains one fifteen-hundredth part of sulphuretted hydrogen, and that an infusion six times greater will kill a horse. It follows that we can scarcely attach too much importance to measures for cleaning and improving the sewerage of cities. There are as yet no large towns in Britain kept in a state so clean as is desirable for the welfare of their inhabitants; nor will they be so till the measures now in agitation for improved modes of construction, for adequate supplies of pure water, and for thorough scavengering and sewerage be adopted.

The human subject tends to vitiate the atmosphere for itself, by the effect which it produces on the air which is breathed. Our breath, when we draw it in, consists of the ingredients formerly mentioned, but it is in a very different state when we part with it. On passing into our lungs, the oxygen, forming the lesser ingredient, enters into combination with the carbon of the venous blood (or blood which has already performed its round through the body); in this process about two-fifths of the oxygen is abstracted and sent into the blood, only the remaining three-fifths being expired along with the nitrogen nearly as it was before.

In place of the oxygen consumed, there is expired an equal volume of carbonic acid gas, such gas being a result of the process of combination just alluded to. Now carbonic acid gas, in a larger proportion than that in which it is found in the atmosphere, is noxious. The volume of it expired by the lungs, if free to mingle with the air at large, will do no harm; but if breathed out into a close room, it will render the air unfit for being again breathed. Suppose an individual to be shut up in an air-tight box; each breath he emits throws a certain quantity of carbonic acid gas into the air filling the box; the air is thus vitiated, and every successive inspiration is composed of worse and worse materials, till at length the oxygen is so much exhausted, that it is insufficient for the support of life. He would then be sensible of a great difficulty in breathing, and in a little time longer he would die.

Most rooms in which human beings live are not strictly close. The chimney and the chinks of the door and windows generally allow of a communication to a certain extent with the outer air, so that it rarely happens that great immediate inconvenience is experienced in ordinary apartments from want of fresh air. But it is at the same time quite certain that in all ordinary apartments where human beings are assembled, the air unavoidably becomes *considerably vitiated;* for in such a situation there cannot be a sufficiently ready or copious supply of oxygen to make up for that which has been consumed, and the carbonic acid gas will be constantly accumulating. This is particularly the case in bedchambers, and in theatres, assembly-rooms, churches, and schools. An extreme case was that of the celebrated Black Hole of Calcutta, where a hundred and forty-six persons were confined for a night in a room eighteen feet square with two small windows. Here the oxygen, scarcely sufficient for the healthy supply of one person, was called upon to support a large number. The unfortunate prisoners found themselves in a state of unheard-of suffering, and in the morning all were dead but twenty-three, some of whom afterwards sunk under putrid fever, brought on by breathing so long a tainted atmosphere.

Although the vitiation of the air in ordinary apartments and places of public assembly does not generally excite much attention, it nevertheless exercises a certain unfavourable influence on health in all the degrees in which it exists. Perhaps it is in bedrooms that most harm is done. These are generally smaller than other rooms, and they are usually kept close during the whole night. The result of sleeping in such a room is very injurious. A common fire, from the draught which it produces, is very serviceable in ventilating rooms, but it is at best a defective means of doing so. The draught which it creates generally sweeps along near the floor between the door and the fire, leaving all above the level of the chimney-piece unpurified. Yet scarcely any other arrangement is anywhere made for the purpose of changing the air in ordinary apartments. To open the window is a plan occasionally resorted to, but it is not always agreeable in our climate, and sometimes it produces bad consequences of a different kind.

It would nevertheless be easy to produce an effective draught from any room in which a fire is kept. It is only necessary to make an aperture into the flue, near the ceiling of the room, and insert therein a tin tube, with a valve at the exterior, capable of opening inwards, but closing when at rest, or when a draught is sent the contrary way. The draught produced by the fire in the flue would cause a constant flow of air out of the upper *part* of the room (where most vitiated); and the valve would be an effectual protection against back-smoke, should there be the least tendency to it. This plan was adopted in Buckingham Palace. It could be applied to any existing house at a mere trifle of expense. A more effectual plan, and one which operates when there is no fire in the room, is to establish a tin tube, of two or three inches diameter, out of each apartment to be ventilated, causing them all to meet in one general tube, the extremity of which passes into some active flue—for example, that of the kitchen, which is rarely cold. Thus there might be a constant passing of fresh air into and through every room of a large house, so that it would be at all times as healthy in this respect as the open fields. At the same time the supply might, by means of graduated valves, be regulated to any degree which might be deemed agreeable. (For various modes of ventilation, see No. 23.)

FOOD.

The second requisite for the preservation of health is—a sufficiency of nutritious food.

Organic bodies, in which are included vegetables as well as animals, are constituted (as explained under PHYSIOLOGY) upon the principle of *a continual waste of substance supplied by continual nutrition.*

The Nutritive System of animals, from apparently the humblest of these to the highest, comprehends an *alimentary tube* or *cavity*, into which food is received, and from which, after undergoing certain changes, it is diffused by means of smaller vessels throughout the whole structure. In the form of this tube, and in the other apparatus connected with the taking of food, there are in different animals varieties of structure, all of which are respectively in conformity with peculiarities in the quality and amount of food which the particular animals are designed to take. The harmony to be observed in these arrangements is remarkably significant of that Creative Design to be traced in all things.

Man designed to live on a Mixed Diet.

Some animals are formed to live upon vegetable substances alone; others are calculated to live upon the flesh of other animals. Herbivorous animals, as the former are called, have generally a long and complicated alimentary tube, because the nutritious part of such food, being comparatively small in proportion to the whole bulk, requires a greater space in which to be extracted and absorbed into the system. The sheep, for example, has a series of intestines twenty-seven times the length of its body. For the opposite reasons, carnivorous or flesh-devouring animals—as the feline tribe of quadrupeds and the rapacious birds—have generally a short intestinal canal. The former class of animals are furnished with teeth, calculated, by their broad and flat surfaces, as well as by the lateral movement of the jaws in which they are set, to mince down the herbage and grain eaten by them. But the carnivorous animals, with wide-opening jaws, have long and sharp fangs to seize and tear their prey. These peculiarities of structure mark sufficiently the designs of nature with respect to the kinds of food required by the two different classes of animals for their support.

The human intestinal canal being of medium length, and the human teeth being a mixture of the two kinds, it necessarily follows that man was designed to eat both vegetable and animal food. As no animal can live agreeably or healthy except in conformity with the laws of its constitution, it follows that man will not thrive unless with a mixture of animal and vegetable food. The followers of Pythagoras argued, from the cruelty of putting animals to death, that it was proper to live on vegetables alone; and eccentric persons of modern times have acted upon this rule. But the ordinances of Nature speak a different language; and if we have any faith in these, we cannot for a moment doubt that a mixture of animal food is necessary for our wellbeing. On the other hand, we cannot dispense with vegetable food without injurious consequences. In that case, we place in a medium alimentary canal a kind of food which is calculated for a short one, thus violating an arrangement of the most important nature. A balance between the two kinds of food is what we should observe, if we would desire to live a natural and healthy life.

Rules connected with Eating.

In order fully to understand how to eat, what to eat, and how to conduct ourselves after eating, it is necessary that we should be acquainted in some measure with the *process of nutrition*—that curious series of operations by which food is received and assimilated by our system, in order to make good the deficiency produced by waste.

Food is first received into the mouth, and there the operations in question may be said to commence. It is there to be chewed (or masticated) and mixed with saliva, preparatorily to its being swallowed or sent into the stomach. Even in this introductory stage there are certain rules to be observed. Strange as it may appear, to know *how to eat* is physiologically a matter of very considerable importance.

Many persons, thinking it all a matter of indifference, or perhaps unduly anxious to despatch their meals, eat very fast. If we are to believe the accounts of travellers, the whole of the mercantile classes in the United States of America eat hurriedly, seldom taking more than ten minutes to breakfast, and a quarter of an hour to dinner. They tumble their meat precipitately into their mouths, and swallow it almost without mastication. This is contrary to an express law of nature, as may be very easily demonstrated.

Food, on being received into the mouth, has two processes to undergo, both very necessary to digestion. It has to be masticated, or chewed down, and also to receive an admixture of saliva. The saliva is a fluid arising from certain glands in and near the mouth, and approaching in character to the gastric juice afterwards to be described. Unless food be well broken down or masticated, and also well mixed up with the salivary fluid, it will be difficult of digestion. The stomach is then called upon to perform, besides its own proper function, that which properly belongs to the teeth and saliva, and it is thus overburdened often in a very serious manner. The pains of indigestion are the immediate consequence, and more remote injuries are likely to follow.

The importance of the saliva has been shown in a striking manner on several occasions when food was received into the stomach otherwise than through the mouth. A gentleman, who, in consequence of a stricture in the gullet, had his food introduced by an aperture into that tube, used to suffer severely from indigestion. It is recorded of a criminal, who, having cut his throat in prison without fatal consequences, required to get his food introduced by means of a tube inserted by the mouth, that every time he was fed there was an effusion of saliva to the amount of from six to eight ounces. We cannot suppose that a fluid of a peculiar character would have been prepared in such quantity, when water would serve as well merely to moisten the food, if it had not been designed to act an important part in the business of nutrition.

With regard to mastication, the evidence of its importance is still more decided. A few years ago, a young Canadian, named Alexis St Martin, had a hole made by a shot into his stomach, which healed without becoming closed. It was therefore possible to observe the whole operations of the stomach with the eye. His medical attendant, Dr Beaumont, by these means ascertained that when a piece of solid food was introduced, the gastric juice acted merely on its outside. It was only when the food was comminuted, or made *small*, that this fluid could fully perform its function. When the stomach finds itself totally unable to digest a solid piece of food, it either rejects it by vomiting, or passes it on into the *gut*, where it produces an irritating effect, and is apt to occasion an attack of cholic or flatulency. It must therefore be concluded that *a deliberate mastication of our food is conducive to health, and that fast eating is injurious, and sometimes even dangerous.*

The food, having been properly masticated, is by the action of the tongue thrown into the gullet. It then descends into the stomach, not so much by its own gravity, as by its being urged along by the contractions and motions of the gullet itself. The stomach may be considered as an expansion of the gullet, and the chief part of the alimentary canal. It is, in fact, a membranous pouch or bag, very similar in shape to a bagpipe, having two openings, the one by which the food is admitted, the other that by which it is passed onward. It is into the greater curvature of the bag that the gullet enters; it is at its lesser that it opens into that adjoining portion of the canal into which the half-digested mass is next propelled.

When food has been introduced, the two orifices close, and that which we may term the second stage in the process of digestion commences. The mass, already saturated with saliva, and so broken down as to expose all its particles to the action of the gastric juice, is now submitted to the action of that fluid, which, during digestion, is freely secreted by the vessels of the stomach. The most remarkable quality of this juice is its solvent power, which is prodigious.

The food exposed to this dissolving agency is converted into a soft, gray, pulpy mass, called *chyme*, which, by the muscular contraction of the stomach, is urged on into the adjoining part of the alimentary canal, called the *duodenum*. This is generally completed in the space of from half an hour to two or three hours; the period varying according to the nature and volume of the food taken, and the degree of mastication and insalivation it has undergone.

In the duodenum, the chyme becomes intimately mixed and incorporated with the bile and pancreatic juices; also with a fluid secreted by the mucous follicles of the intestine itself. The bile is a greenish, bitter, and somewhat viscid fluid, secreted by the liver, which occupies a considerable space on the right side of the body immediately under the ribs. From this organ the bile, after a portion of it has passed up into the adjacent gall-bladder, descends through a small duct, about the size of a goose-quill, into the duodenum. The chyme, when mixed with these fluids, undergoes a change in its appearance: it assumes a yellow colour and bitter taste, owing to the predominance of the bile in the mass; but its character varies according to the nature of the food that has been taken. Fatty matters, tendons, cartilages, white of eggs, &c. are not so readily converted into chyme as fibrous or fleshy, cheesy, and gelatinous substances. The chyme, having undergone the changes adverted to, is urged by the peristaltic motion of the intestines onwards through the alimentary canal. This curious motion of the intestines is caused by the contraction of the muscular coat which enters into their structure, and one of the principal uses ascribed to the bile is that of stimulating them to this motion. If the peristaltic motion be diminished, owing to a deficiency of bile, then the progress of digestion is retarded, and the intestines become constipated. In such cases, calomel, the blue pill, and other medicines, are administered for the purpose of stimulating the liver to secrete the biliary fluid, that it may quicken, by its stimulating properties, the peristaltic action.

The preceding, however, is not the only use of the bile: it also assists in separating the nutritious from the non-nutritious portion of the alimentary mass, for the chyme now presents a mixture of a fluid termed *chyle*, which is in reality the nutritious portion eliminated from the food. The chyme thus mixed with chyle arrives in the small intestines; on the walls of which a series of exquisitely delicate vessels ramify in every direction. These vessels absorb or take up the chyle, leaving the rest of the mass to be ejected from the body. The chyle, thus taken up, is carried into little bodies or glands, where it is still further elaborated, acquiring additional nutritious properties; after which corresponding vessels, emerging from these glands, carry along the fluid to a comparatively large vessel, called the thoracic duct, which ascends in the abdomen along the side of the backbone, and pours it into that side of the heart to which the blood that has already circulated through the body returns. Here the chyle is intimately mixed with the blood, which fluid is now propelled into the lungs, where it undergoes, from being exposed to the action of the air we breathe, the changes necessary to render it again fit for circulation. It is in the lungs, therefore, that the process of digestion is completed:

the blood has now acquired those nutritient properties from which it secretes the new particles of matter adapted to supply the waste of the different textures of the body. (See ANIMAL PHYSIOLOGY, p. 200.)

When food is received into the stomach, the secretion of the gastric juice immediately commences; and when a full meal has been taken, this secretion generally lasts for about an hour. It is a law of vital action, that when any living organ is called into play, there is immediately an increased flow of blood and nervous energy towards it. The stomach, while secreting the bile, displays this phenomenon, and the consequence is that the blood and nervous energy are called away from other organs.' This is the cause of that chilliness at the extremities which we often feel after eating heartily. So great is the demand which the stomach thus makes upon the rest of the system, that during and for some time after a meal, we are not in a condition to take strong exercise of any kind. Both body and mind are inactive and languid. They are so simply because that which supports muscular and mental activity is concentrated for the time upon the organs of digestion. This is an arrangement of nature which a regard to health requires that we should not interfere with. *We should indulge in the muscular and mental repose which is demanded; and this should last for not much less than an hour after every regular meal.* In that time the secretion of bile is nearly finished; the new nutriment begins to tell upon the general circulation; and we are again fit for active exertion. The consequence of not observing this rule is often very hurtful. Strong exercise, or mental application, during or immediately after a meal, diverts the flow of nervous energy and of blood to the stomach, and the process of digestion is necessarily retarded or stopped. Confusion and obstruction are thus introduced into the system, and a tendency to the terrible calamity of dyspepsia is perhaps established.

For the same reason that repose is required after a meal, it is necessary in some measure for a little while before. At the moment when we have concluded a severe muscular task—such, for example, as a long walk—the flow of nervous energy and of circulation is strongly directed to the muscular system. It requires some time to allow this flow to stop and subside; and till this takes place, it is not proper to bring the stomach into exercise, as the demand which it makes when filled would not in that case be answered. In like manner also, if we be engaged in close mental application, the nervous energy and circulation being in that case directed to the brain, it is not right all at once to call another and distant organ into play; some time is required to allow of the energy and circulation being prepared to take the new direction. It may therefore be laid down as a maxim, that *a short period of repose, or at least of very light occupation, should be allowed before every meal.*

It is remarkable that these rules, although the natural reasons for them were not perhaps well known, have long been followed with regard to animals upon which man sets a value, while as yet their application to the human constitution is thought of only by a few. Those intrusted with horses and dogs will not allow them to feed immediately after exercise; nor will they allow them to be subjected to exercise for some time after feeding. Experience has also instructed veteran soldiers not to dine the instant that a long march has been concluded, but to wait coolly till ample time has been allowed for all the proper preparations.

Although strong mental and muscular exercise should be avoided before, during, and immediately after a meal, there can be no objection to the light and lively chat which is generally indulged in where several are met to eat together. On the contrary, it is believed that jocund conversation is useful towards the process of nutrition. Dr Combe, in one of his invaluable works, 'The Physiology of Digestion,' observes as follows:—'The necessary churning or agitation of the food is, from the peculiar situation of the stomach, greatly assisted by the play of the diaphragm and abdominal muscles during inspiration and expiration; and the diminution of the vivacity and extent of the respiratory movement which always attends despondency and grief, is one source of the enfeebled digestion which notoriously accompanies depression of mind. The same cause also leads necessarily to an unfavourable condition of the blood itself, which in its turn weakens digestion in common with every other function; but the muscular or mechanical influence is that which at present chiefly concerns us. On the other hand, the active and energetic respiration attendant on cheerfulness and buoyancy of spirits adds to the power of digestion, both by aiding the motions of the stomach and by imparting to it a more richly-constituted blood. If to those causes be added the increase of nervous stimulus which pleasing emotions occasion in the stomach (as in the muscles and organs of secretion generally), we shall have no difficulty in perceiving why digestion goes on so well in parties where there is much jocularity and mirth. "Laughter," says Professor Hufeland of Berlin, "is one of the greatest helps to digestion with which I am acquainted; and the custom prevalent among our forefathers, of exciting it at table by jesters and buffoons, was founded on [or rather, accidentally in harmony with?] true medical principles. In a word, endeavour to have cheerful and merry companions at your meals: what nourishment one receives amidst mirth and jollity will certainly produce good and light blood."'

Kinds of Food.

It has been shown, by a reference to the structure of the human intestinal canal, that our food is designed to be a mixture of animal and vegetable substances. There is, it is to be remarked, a power of adaptation in nature, by which individuals may be enabled for a considerable time to live healthily on one or the other kind exclusively or nearly so. The above is nevertheless the general rule, to which it is safest to adhere. It has been found, for instance, that field-labourers, including ploughmen, will live healthily for many years on a diet chiefly farinaceous—that is, composed of the farina of grain. But it is to be feared that the food in this case, though apparently sufficient for health, is only so apparently; and that the constitution, being all the time not supported as it ought to be, breaks down prematurely in a great proportion of instances. It has been said again that the Irish labouring classes are a remarkably robust race, although their food consists almost exclusively of potatoes. The fact is overlooked, that the Irish eat a quantity of potatoes so enormous, as could not fail to make up in some measure for the want of animal diet. It was found by the Poor-Law Commissioners, that the greater number of the peasantry of Ireland, women as well as men, take at their two daily meals in general about nine pounds weight of this aliment! Such a case is rather to be ranked amongst instances of extraordinary adaptations to a particular variety of food, than as a proof that an unmixed potato diet is healthy.

Climate has a remarkable effect in modifying the rule as to the mixture and amount of animal and vegetable food. The former has most of a stimulating quality, and this quality is greater in beef, and flesh in general, than in fowl or fish. Now the inhabitants of torrid countries are, in their ordinary condition, least in need of stimulus: hence they find a simple diet of rice and sago sufficient for them. Those, on the contrary, who dwell in cold countries need much stimulus; hence they can devour vast quantities of flesh and blubber, with scarcely any mixture of vegetable food.

Inquiries with respect to the comparative digestibility of different kinds of food, are perhaps chiefly of consequence to those in whom health has already been lost. To the sound and healthy it is comparatively of little consequence what kind of food is taken, provided that some variation is observed, and no excess committed as to quantity. Within the range of fish, flesh, and fowl, there is ample scope for a safe choice. There is scarcely any of the familiar aliments of these kinds but, if plainly dressed, will digest in from two to four hours, and prove perfectly healthy. One rule alone has been pretty well ascertained with respect to animal foods, that they are the more digestible the more minute and tender the fibre may be. They contain more nutriment in a given bulk than vegetable matters, and hence their less need for length of intestine to digest them. Yet it is worthy of notice, that between the chyle produced from animal and that from vegetable food no essential distinction can be observed.

Tendon, suet, and oily matters in general, are considerably less digestible than the ordinary fibre; and these are aliments which should be taken sparingly. Pickling, from its effect in hardening the fibre, diminishes the digestibility of meat. Dressed shell-fish, cheese, and some other animal foods, are avoided by many as not sufficiently digestible.

Farinaceous foods of all kinds—wheat, oaten, and barley bread, oaten porridge, sago, arrow-root, tapioca, and potatoes—are highly suitable to the human constitution. They generally require under two hours for digestion, or about half the time of a full mixed meal. The cottage children of Scotland, reared exclusively upon oaten porridge and bread, with potatoes and milk, may be cited as a remarkable example of a class of human beings possessing in an uncommon degree the blessing of health. Green vegetables and fruit, however softened by dressing, are less digestible, and less healthy as a diet. One important consideration here occurs: there is need for a certain bulk in our ordinary food. Receiving nutriment in a condensed form, and in a small space, will not serve the purpose. This is because the organs of digestion are calculated for receiving our food nearly in the condition in which nature presents it—namely, in a considerable bulk with regard to the proportion of its nutritious properties. The same law applies with respect to the lower animals. When a horse is fed upon corn alone, it does not thrive. Nature did not contemplate that all horses should readily obtain a corn diet, but looked chiefly to grass and hay for their support. She therefore prepared the organs for the reception of something of considerable volume; and when a food of less volume is persisted in, her law is violated, and fatal consequences ensue. Civilised man is apt to pay little attention to this rule in his own case. Consulting taste alone, he is apt to refine his food overmuch, and reject what it were better for him to take. The present writer is much inclined to doubt the propriety of grinding off the coarse exterior of wheaten grain. It does not seem by any means likely that nature calculated the human alimentary cavity for the use of the white interior of the grain, exclusive of all the rest, which consists of very different but not less necessary chemical constituents. Wheat forms so large a part of our daily food, that if this be the case, we unquestionably make a departure of a very important kind from the laws of health. Experience is favourable to this view, for the effect of coarse brown bread in relaxing seems only comparable to that of white bread in constipating the bowels.

Quantity of Food—Number and Times of Meals.

With respect to the amount of food necessary for health, it is difficult to lay down any rule, as different quantities are safe with different individuals, according to their sex, age, activity of life, and some other conditions. There is a general and probably well-founded opinion, that most persons who have the means eat too much, and thereby injure their health. This may be true, and yet it may not be easy to assign to such persons a limit beyond which they ought not to go.

The best authorities are obliged to refer the matter to our own sensations. Dr Beaumont, for example, says that we should not eat till the mind has a sense of *satiety*, for appetite may exceed the power of digestion, and generally does so, particularly in invalids; but to a point previous to that, which 'may be known by the pleasurable sensations of *perfect satisfaction, ease, and quiescence of body and mind*.'

The number and times of meals are other questions as yet undetermined. As the digestion of a meal rarely requires more than four hours, and the waking part of a day is about sixteen, it seems unavoidable that at least three meals be taken, though it may be proper that one, if not two of these, be comparatively of a light nature. Breakfast, dinner, and tea as a light meal, may be considered as a safe, if not a very accurate prescription for the daily food of a healthy person. Certainly four good meals a day is too much. No experiments, as far as we are aware, have been made with regard to the total amount of solids which a healthy person in active life may safely take in a day. It has been found, however, that confined criminals and paupers are healthiest when the daily solids are not much either above or below twenty-four ounces.* Of course, in active life there must be need for a larger allowance, but only to a small extent. We may thus arrive at a tolerably clear conviction of the reality of that excess which is said to be generally indulged in; for certainly most grown people who have the means, not excepting many who pursue very sedentary lives, eat *much more* than twenty-four ounces.

The interval between rising and breakfast ought not to be great, and no severe exercise or taskwork of any kind should be undergone during this interval. There is a general prepossession to the contrary, arising probably from the feeling of freedom and lightness which most people feel at that period of the day, and which seems to them as indicating a preparedness for exertion. But this feeling, perhaps, only arises from a sense of relief from that oppression of food under which much of the rest of the day is spent. It is quite inconsistent with all we know of the physiology of aliment, to suppose that the body is capable of much exertion when the stomach has been for several hours quite empty. We have known many persons take long walks before breakfast, under an impression that they were doing something extremely favourable to health. Others we have known go through three hours of mental taskwork at the same period, believing that they were gaining so much time. But the only observable result was, to subtract from the powers of exertion in the middle and latter part of the day. In so far as the practice was contrary to nature, it would likewise of course produce permanent injury. Only a short saunter in the open air, or a very brief application to business or taskwork, can be safely indulged in before breakfast.

With regard to the time for either breakfast or dinner, nothing can be said with scientific authority. Dr Combe, who is by no means disposed to take lax or indulgent views with regard to dietary matters, while favourable to an early dinner hour, allows that he has himself changed his hours for both breakfast and dinner, from comparatively early to comparatively late periods, without any perceptible inconvenience. In rural life, it is found convenient to dine not long after the middle of the day; but in cities, where it is necessary to have a long uninterrupted space in the middle of the day for business, a late dinner hour is scarcely avoidable. In such a case a slight lunch serves to keep the strength from sinking; and if dinner is taken not less than five or six hours before bed-time, it is not easy to see how any injurious consequences should follow. The changes that have taken place in meal hours from old times are more apparent than real. The present substantial lunch of fashionable life occurs nearly at the same hour as the Elizabethan dinner, and the present dinner is in all respects, except name, the same as the supper of those times. The only thing which the physiologist would much insist on is, that between the two principal meals of the day there should be no long fasts. If the interval be above seven hours, a biscuit should be taken after four of the seven hours have elapsed. When the

* See two papers on food, in Nos. 366 and 368 of 'Chambers's Edinburgh Journal,' old series.

interval amounts to nine hours, the lunch should be a little more substantial, but not of animal food, particularly if any has been taken at breakfast. A glass of wine is often added to a biscuit lunch, or wine alone is taken; but neither of these practices can be commended. While a small quantity of bread or biscuit gives real strength, and is quite sufficient for the occasion, wine only gives a stimulus, serving for the time, but making the case worse afterwards.

Variety of Food.

A judicious variation of food is not only useful, but important. There are, it is true, some aliments, such as bread, which cannot be varied, and which no one ever wishes to be so. But apart from one or two articles, a certain variation or rotation is much to be desired, and will prove favourable to health. There is a common prepossession respecting *one dish*, which is more spoken of than acted upon. In reality there is no virtue in this practice, excepting that, if rigidly adhered to, it makes excess nearly impossible, no one being able to eat to satiety of one kind of food. There would be a benefit from both a daily variation of food and eating of more than one dish at a meal, *if moderation were in both cases to be strictly observed;* for the relish to be thus obtained is useful, as promotive of the flow of nervous energy to the stomach, exactly in the same manner as cheerfulness is useful. The policy which would make food in anyway unpleasant to the taste is a most mistaken one; for to eat with languor, or against inclination, or with any degree of disgust, is to lose much of the benefit of eating. On the other hand, to cook dishes highly, and provoke appetite by artificial means, are equally reprehensible. Propriety lies in the mean between the two extremes.

Beverages.

The body containing a vast amount of fluids, which are undergoing a perpetual waste, there is a necessity for an occasional supply of liquor of some kind, as well as of solid aliment. It remains to be considered what is required in the character or nature of this liquor, to make it serve as a beverage consistently with the preservation of health.

It is scarcely necessary to remark how men in all ages, and almost all climes, have indulged in liquors containing a large infusion of alcohol, or how widespread in our own society is the custom of drinking considerable quantities of wine, spirits, and beer, both at meals and on other occasions. Against habits so inveterate it is apt to appear like fanaticism to make any decided objection; yet the investigator of the laws which regulate health is bound to consider, above all things, how any particular habit bears upon the human constitution, and to state what is the result of his inquiries, however irreconcilable it may be with popular prejudice or practice.

'The primary effect of all distilled and fermented liquors,' says Dr Combe, 'is to *stimulate the nervous system and quicken the circulation.*' They may thus be said to have a larger measure of the effect which animal food has upon the system. It is therefore the less surprising that those tropical nations which live most on farinaceous diet are also found to be those which have the least propensity to the drinking of ardent spirits; while those northern nations which live most on animal food have the exactly contrary inclination with respect to liquor, the Scandinavian tribes being notoriously the greatest sots that have ever been known. Dr Combe admits that in some conditions of the system, when the natural stimulus is defective, it may be proper to take an artificial supply in the form of ardent and fermented liquors. 'There are,' he says, 'many constitutions so inherently defective in energy, as to derive benefit from a moderate daily allowance of wine; and there are many situations in which even the healthiest derive additional security from its occasional use. If, for example, a healthy person is exposed to unusual and continued exertion in the open air, or to the influence of anxious and depressing watchfulness, a moderate quantity of wine with his food may become the means of warding off actual disease, and enabling him to bear up uninjured, where without it he would have given way.' But Dr Combe at the same time declares, in the most decided language, that when the digestion is good, and the system in full vigour, the bodily energy is easily sustained by nutritious food, and 'artificial stimulant *only increases the wasting of the natural strength.*' Nearly all physicians, indeed, concur in representing ardent liquors as unfavourable to the health of the healthy, and as being, in their excess, highly injurious. Even the specious defence which has been set up for their use, on the ground that they would not have been given to man if they had not been designed for general use, has been shown to be ill-founded, seeing that *vinous fermentation*, from which they are derived, is not a healthy condition of vegetable matter, but a stage in its progress to decay. Upon the whole, there can be little doubt that these liquors are deleterious in our ordinary healthy condition; and that pure water, toast-water, milk, whey, and other simple and unexciting beverages, would be preferable (the first being the most natural), if we could only consent to deny ourselves further indulgence.

CLEANLINESS.

To keep the body in a cleanly condition is the third important requisite for the preservation of health. This becomes necessary, in consequence of a very important natural process which is constantly going on near and upon the surface of the body.

The process in question is that of *perspiration*. The matter here concerned is a watery secretion, produced by glands near the surface of the body, and sent up through the skin by channels imperceptibly minute and wonderfully numerous. From two to six pounds of this secretion is believed to exude through these channels or *pores* in the course of twenty-four hours, being in fact the chief form taken by what is called the waste of the system, the remainder passing off by the bowels, kidneys, and lungs. To promote the free egress of this fluid is of the utmost importance to health; for when it is suppressed, disease is apt to fall upon some of the other organs concerned in the discharge of waste.

One of the most notable checks which perspiration experiences is that produced by a current of cold air upon the skin, in which case the pores instantly contract and close, and the individual is seized with some ailment either in one of the other organs of waste, whichever is in him the weakest, or in the internal lining of some part of the body, all of which is sympathetic with the condition of the skin. A result of the nature of that last described is usually recognised as a cold or catarrh. We are not at present called on particularly to notice such effects of checked perspiration, but shall allude to others of a less perceptible, though not less dangerous nature.

The fluid alluded to is composed, besides water, of certain salts and animal matters, which, being solid, do not pass away in vapour, as does the watery part of the compound, but rest on the surface where they have been discharged. There, if not removed by some artificial means, they form a layer of hard stuff, and unavoidably impede the egress of the current perspiration. By cleanliness is merely meant the taking proper means to prevent this or any other extraneous matter from accumulating on the surface, to the production of certain hurtful consequences.

Ablution or washing is the best means of attaining this end; and accordingly it is well for us to wash or bathe the body frequently. Many leave by far the greater part of their bodies unwashed, except perhaps on rare occasions, thinking it enough if the parts exposed to common view be in decent trim. If the object of cleaning were solely to preserve fair appearances, this might be sufficient; but the great end, it must be clearly seen, is to keep the skin in a fit state for its peculiar and very important functions. Frequent change of the clothing next to the skin is of course a great aid to cleanliness, and may partly be esteemed as a substitute for bathing, seeing that the clothes absorb much of the impurities, and, when changed, may be said to carry these off. But still this will not serve the end nearly so well as frequent ablution of the whole person. Any one will be convinced of this who goes into a bath, and uses the flesh-brush in cleansing his body. The quantity of scurf and impurity which he will then remove, from a body which has changes of linen even once a day, will surprise him.

Considering the importance of personal cleanliness for health, it becomes a great duty of municipal rulers to afford every encouragement in their power to the establishment of public baths for the middle and working classes, and to extend and protect all existing facilities for washing clothes, as well as for private supplies of water. Baths should neither be very cold nor very warm, but in an agreeable medium; and they should never be taken within three hours of a meal. Nature may be said to make a strong pleading for their more general use, in the remarkably pleasing feeling which is experienced in the skin after ablution.

EXERCISE.

The constitution of external nature shows that man was destined for an active existence, as without labour scarcely any of the gifts of Providence are to be made available. In perfect harmony with this character of the material world, he has been furnished with a muscular and mental system, constructed on the principle of being fitted for exertion, and requiring exertion for a continued healthy existence. Formed as he is, it is not possible for him to abstain from exertion without very hurtful consequences.

Muscular Exercise.

With regard to merely bodily exercise, it is to be observed, in the first place, that we have no fewer than four hundred muscles, each designed to serve some particular end in locomotion, or in operating upon external objects. A sound state of body depends very much upon each of these muscles being brought into action in proper circumstances, and to a suitable extent. There is even a law, operating within a certain range, by which each muscle will gain *in strength and soundness* by being brought into a proper degree of activity.

The process of waste and renovation may be said to be always going on in the body, but it does not go on with permanent steadiness, unless the muscular system be exercised. Whenever one of the organs is put into exertion, this process becomes active, and the two operations of which it consists maintain a due proportion to each other. A greater flow of blood and of nervous energy is sent to the organ, and this continues as long as it is kept in activity. When one state of action follows close upon another, the renovating part of the process rather exceeds the waste, and an accretion of new substance, as well as an addition of fresh power, takes place. On the contrary, when an organ is little exercised, the process of renovation goes on languidly, and to a less extent than that of waste, and the parts consequently become flabby, shrunken, and weak. Even the bones are subject to the same laws. If these be duly exercised in their business of administering to motion, the vessels which pervade them are fed more actively with blood, and they increase in dimensions, solidity, and strength. If they be little exercised, the stimulus required for the supply of blood to them becomes insufficient; imperfect nutrition takes place; and the consequences are debility, softness, and unfitness for their office. Bones may be so much softened by inaction, as to become susceptible of being cut by a knife. In a less degree, the same cause will produce languor and bad health.

It is of the utmost importance to observe that the exercise of any particular limb does little besides improving the strength of that limb; and that, in order to increase our general strength, the whole frame must be brought into exercise. The blacksmith, by wielding his hammer, increases the muscular volume and strength of his right arm only, or if the rest of his body derives any advantage from his exercise, it is through the general movement which the wielding of a hammer occasions. One whose profession consists in dancing or leaping, for the same reason, chiefly improves the muscles of his legs. The right hands of most persons, by being more frequently employed than the left, become sensibly larger as well as stronger. A still more striking illustration of the principle is to be found in a personal peculiarity which has been remarked in the inhabitants of Paris. Owing to the uneven nature of the pavement of that city, the people are obliged to walk in a tripping manner on the front of their feet; a movement which calls the muscles of the calves of the legs into strong exertion. It is accordingly remarked that a larger proportion of the people of Paris are distinguished by an uncommon bulk in this part of their persons than in other cities.

In order, then, to maintain in a sound state the energies which nature has given us, and, still more particularly, to increase their amount, *we must exercise them.* If we desire to have a strong limb, we must exercise that limb; if we desire that the whole of our frame should be sound and strong, we must exercise the whole of our frame. It is mainly by these means that health and strength are to be preserved and improved. There are rules, however, for the application of these laws of our being.

1. That bodily exercise may be truly advantageous, the parts must be in a state of sufficient health to endure the exertion. A system weakened by disease or long inaction must be exercised very sparingly, and brought on to greater efforts very gradually, otherwise the usual effects of over-exercise will follow. In no case must exercise be carried beyond what the parts are capable of bearing with ease, otherwise a loss of energy, instead of a gain, will be the consequence.

2. Exercise, to be efficacious even in a healthy subject, must be excited, sustained, and directed by that nervous stimulus which gives the muscles the principal part of their strength, and contributes so much to the nutrition of parts in a state of activity. To explain this, it must be mentioned that to produce motion requires the co-operation of the muscular fibre with two sets of nerves, one of which conveys the command of the brain to the muscle, and causes its contraction, while the other conveys back to the brain the peculiar sense of the state of the muscle, by which we judge of the fitness of the degree of contraction which has been produced to accomplish the end desired, and which is obviously an indispensable piece of information to the mind in regulating the movements of the body. The nervous stimulus thus created, will enable a muscle in the living frame to bear the weight of a hundred pounds, while, if detached, it would be torn asunder by one of ten. It is what causes men in danger, or in the pursuit of some eagerly-desired object, to perform such extraordinary feats of strength and activity. In order, then, to obtain the advantage of this powerful agent, *we must be interested in what we are doing.* A sport that calls up the mental energy, a walk towards a place which we are anxious to reach, or even an exercise which we engage in through a desire of invigorating our health and strength, will prove beneficial, when more of actual motion, performed languidly, may be nearly ineffectual.

3. The waste occasioned by exercise must be duly replaced by food; as, if there be any deficiency in that important requisite, the blood will soon cease to give that invigoration to the parts upon which increased health and strength depend.

Kinds of Bodily Exercise.

Exercise is usually considered as of two kinds—active and passive. The active consists in walking, running, leaping, riding, fencing, rowing, skating, swimming, dancing, and various exercises, such as those with the poles, ropes, &c. prescribed in gymnastic institutions. The passive consists in carriage riding, sailing, friction, swinging, &c. (For various modes of agreeable recreation, see articles on IN-DOOR and OUT-DOOR AMUSEMENTS—Volume II.)

Walking is perhaps the readiest mode of taking exercise, and the one most extensively resorted to. If it brought the upper part of the body as thoroughly into exertion as the lower, it would be perfect, for it is gentle and safe with nearly all except the much debilitated. To render it the more effectual in the upper part of the body, it were well to walk at all times, when convenient, *singly*, and allow the arms and trunk free play. It is best to walk with a companion, or for some definite object, as the flow of nervous energy will be by these means promoted, and the exercise be rendered, as has been already explained, the more serviceable.

Very long or rapid walks should not be attempted by individuals of sedentary habits, nor by weakly persons. Their frames are totally unprepared for such violent exertion. When a person who has been long confined at still employments finds himself at liberty to indulge his inclination for a ramble of a few days in the country, he should begin with slow and short marches, and be content therewith till his body is hardened for greater efforts. This is a rule followed in the army with respect to regiments which are about to undertake long marches. Every summer many youths, from ignorance, do themselves great injury, by undertaking pedestrian excursions much beyond their strength. Jaded to the last degree, and incapable of enjoying anything presented to their observation, they nevertheless persist in making out some appointed number of miles per day, never once thinking of the outrage they are committing upon themselves, and only looking to the glory of executing their task, the only pleasure they find in the journey. Serious consequences—consumption not unfrequently—follow such ill-advised and senseless efforts.

With respect to very violent walking, Dr Johnson records some effects from it, of a remarkable nature, as occurring in his own case. 'In my own person,' says he, 'I had some years ago a very severe and alarming instance of the bad effects of too great muscular action, occasioned by a habit of walking very fast. After a day and night of unusual fatigue and rapid pedestrian exertion, together with considerable mental anxiety, I was suddenly seized with an intermission of the pulse at irregular periods. During each intermission, I felt the heart give a kind of struggle, as it were, and strike with great violence against the ribs, accompanied by a peculiar and most distressing sensation in the cardiac region, which I cannot describe.' These symptoms became aggravated, and lasted for eight weeks, 'during which time,' he continues, 'I used gentle horse-exercise, and kept, when at home, in a horizontal position. At length the heart gradually lost its morbid irritability, and at the end of fourteen or fifteen weeks I could walk as well as ever.'

Running is an exercise which is intermediate between walking and leaping; it consists, in fact, of a series of leaps performed in progression from one foot to another, and the degree of its rapidity bears a constant proportion to the length of the individual and successive leaps. During this exercise the individual is obliged to take long inspirations, and make slow expirations; the air-cells of the lungs are thereby distended, and the action of the heart being at the same time increased, and the circulation through the lungs much accelerated, a sense of oppression is felt on the chest, which is often exceedingly painful; when the violent action is discontinued, the heart palpitates with intermitting strokes, in the endeavour to recover its natural equilibrium of motion. Although this and other gymnastic exercises, such as leaping, wrestling, throwing heavy weights, &c. may, when judiciously had recourse to, invigorate the body, yet from apprehension of the evils and accidents which may be so occasioned, young persons ought not to be permitted to engage extensively in such exercises, except under the care of some one well acquainted with gymnastics.

Fencing is, of all active exercises, that which is the most commendable, inasmuch as it throws open the chest, and at the same time calls into action the muscles both of the upper and lower extremities. Add to this that it improves very much the carriage of the body; for which reason it may be reckoned a branch of polite education. The salutary effects of the other exercises which are taught in gymnastic institutions—such as exercise with the ropes, poles, pulleys, &c.—in increasing the strength of the body, will be seen by consulting Mr Roland's Treatise on Gymnastics, where will be found a table showing the amount of the increasing growth and strength of the body in a given time during the employment of these exercises.

Dancing is exhilarating and healthful, and seems to be almost the only active exercise which the despotic laws of conventionality permit young ladies to enjoy. We can scarcely consider modern quadrilles, elegant though they be, as exercise, seeing that they differ little from the most common walking movements. But country dances, reels, and hornpipes, are genuine exercise, and their less refinement may be considered as amply compensated by the superior benefit which they are calculated to confer upon health.

Riding is generally classed among the passive exercises, but in reality it is one which involves much action of the whole frame, and as such is very useful. Pursued solitarily, it has the drawback of being somewhat dull; but when two or three ride in company, a sufficient flow of the nervous energy may be obtained.

The amount of bodily exercise which should be taken must vary according to the habits, strength, and general health of the individual. It was an aphorism of Boerhaave, that every person should take at least two hours' exercise in the day, and this may be regarded as a good general rule.

Mental Exercise.

Having thus explained the laws and regulations by which exercise may be serviceable to the physical system, we shall proceed to show that the same rules hold good respecting the mental faculties. These, as is generally allowed, however immaterial in one sense, are connected organically with the brain—a portion of the animal system nourished by the same blood, and regulated by the same vital laws, as the muscles, bones, and nerves. As, by disuse, muscle becomes emaciated, bone softens, blood-vessels are obliterated, and nerves lose their natural structure, so by disuse does the brain fall out of its proper state, and create misery to its possessor; and as, by over-exertion, the waste of the animal system exceeds the supply, and debility and unsoundness are produced, so by over-exertion are the functions of the brain liable to be deranged and destroyed. The processes are physiologically the same, and the effects bear an exact relation to each other. As with the bodily powers, the mental are to be increased in magnitude and energy by a degree of exercise measured with a just regard to their ordinary health and native or habitual energies. Corresponding, moreover, to the influence which the mind has in giving the nervous stimulus so useful in bodily exercise, is the dependence of the mind upon the body for supplies of healthy nutriment. And, in like manner with the bodily functions, each mental faculty is only to be strengthened by the exercise of itself in particular. Every part of our intellectual and moral nature stands, in this respect, exactly in the same situation with the blacksmith's right arm and the lower limbs of the inhabitants of Paris: each must be exercised for its own sake.

The fatal effects of the disuse of the mental faculties are strikingly observable in persons who have the misfortune to be solitarily confined, many of whom become insane, or at least weak in their intellects. It is also observable in the deaf and blind, among whom, from the non-employment of a number of the faculties, weakness of mind and idiocy are more prevalent than among other people. This is indeed a frequent predisposing cause of every form of nervous disease.

The loss of power and health of mind from imperfect or partial exercise of the faculties, is frequently observable in the country clergy, in retired merchants, in annuitants, in the clerks of public offices, and in tradesmen whose professions comprehend a very limited range of objects. There is no class, however, in whom the evil is more widely observable than in those females who, either from ignorance of the laws of exercise, or from inveterate habit, spend their lives in unbroken seclusion, and in the performance of a limited range of duties. All motive is there wanting. No immediate object of solicitude ever presents itself. Fixing their thoughts entirely on themselves, and constantly brooding over a few narrow and trivial ideas, they at length approach a state little removed from insanity, or are only saved from that, perhaps, by the false and deluding relief afforded by stimulating liquors. In general, the education of such persons has given them only a few *accomplishments*, calculated to afford employment to one or two of the minor powers of the mind, while all that could have engaged the reflecting powers has been omitted. Education, if properly conducted, would go far to prevent these evils.

On the other hand, excessive exercise of the brain, by propelling too much blood to it, and unduly distending the vessels, is equally injurious with its disuse. And not only are fatal effects to be apprehended from undue mental taskwork, but also from that constant *stretch* of the mind which attends an unduly anxious and watchful disposition. The ancients had some notion of the impropriety of an incessant exertion of the mind, and rebuked it by their well-known proverb—*Apollo does not keep his bow always bent.* But they had comparatively little experience of the oppressive mental labours endured by large portions of modern society. Irrational, and in some respects dangerous, as many of the habits of our ancestors were, it is questionable if they suffered so much from these causes as their successors do from virtuous but overtasking exertion. To maintain what each man conceives to be a creditable place in society, now requires such close and vigorous exertions, that more, we verily believe, perish in the performance of duties in themselves laudable, than formerly sank under fox-hunting, toast-drinking, and the gout.

It is in large cities that this unintentional kind of self-destruction is most conspicuously exemplified. And it is in London, above all other places, that the frenzy is to be observed in its most glaring forms. To spend nine hours at a time in business, without food or relaxation, is not only not uncommon, but an almost universal practice, among the citizens of London: from a breakfast at eight to a chop at five, they are never, to use an expressive phrase, *off the stretch.* Upon a stomach enfeebled by exhaustion, they then lay the load of a full meal, which perfect leisure would hardly enable them to digest. But far from waiting to digest it, they have no sooner laid down knife and fork, than away they must once more rush to business—not perhaps willingly, for nature tells them that it would be agreeable to rest; but then—but then business *must* be attended to. If nature were to punish the daily transgression by the nightly suffering, we should find few who, for the sake of pecuniary gain, would thus expose themselves to misery. But unfortunately she runs long accounts with her children, and, like a cheating attorney, seldom renders her bill till the whole subject of litigation has been eaten up. Paralysis at fifty comes like the mesne process upon the victim of commercial enthusiasm,* and either hurries him off to that prison from which there is no liberation, or leaves him for a few years organically alive to *enjoy* the fruits of his labours. A life thus spent is a mere fragment of what it ought to be. The means of obtaining pleasure have swallowed up the end. The glorious face of nature, with all its sublime and beautiful alternations; the delights of social life; the pleasures arising from the exercise of the finer feelings and the cultivation of the intellect; all that higher class of gratifications which Nature has designed a moderate degree of labour to place within the reach of *all* her creatures, have been lost to such a man.

The absurdity of an ignorance or weakness of this kind is perhaps still more striking when it occurs in individuals who make the acquisition of knowledge the chief aim of life. As the world is at present situated, it is possible to acquire learning upon almost every subject, and an infinite amount of knowledge, useful and otherwise, without even by chance lighting upon a knowledge of the most indispensable observances necessary for the preservation of a sound mind in a sound body. Half of the multiform languages of Asia may be mastered, while the prodigy who boasts so much learning knows not that to sit a whole day within doors at close study is detrimental to health; or, if he knows so much, deliberately prefers the course which leads to ruin. Leyden, an enthusiast of this order, was ill with a fever and liver complaint at Mysore, and yet continued to study ten hours a day. He eventually sank, in his thirty-sixth year, under the consequences of spending some time in an ill-ventilated library, which a slight acquaintance with one of the most familiar of the sciences would have warned him against entering. Alexander Nicoll, a recent professor of Hebrew at Oxford, of whom it was said that he might have walked to the wall of China without the aid of an interpreter, died at the same age, partly through the effects of that intense study which so effectually, but so uselessly, had gained him distinction. Dr Alexander Murray, a similar prodigy, died in his thirty-eighth year of over-severe study; making the third of a set of men remarkable for the same wonderful attainments, and natives of the same country, who, within a space of twenty years, fell victims to their ignorance of the laws of mental exercise. In 1807, Sir Humphry Davy prosecuted his inquiry into the alkaline metals with such inordinate eagerness, that, through excitement and fatigue, he contracted a dangerous fever, which he, in ignorance of the human physiology, ascribed to contagion caught in experimenting on the fumigation of hospitals. His physician was at no loss to trace it to his habits of study, which were such as would have soon worn out a frame much more robust. Davy at this time spent all the earlier part of the day in his laboratory, surrounded by persons of every rank, whose admiration of his experiments added to his excitement. 'Individuals of the highest distinction,' says Paris in his biographical sketch of Sir Humphry, 'contended for the honour of his company to dinner, and he did not possess sufficient resolution to resist the gratification thus afforded, though it generally happened that his pursuits in the laboratory were not suspended until the appointed dinner hour had passed. On his return in the evening, he resumed his chemical labours, and commonly continued them till three or four in the morning, and yet the servants of the establishment not unfrequently found that he had risen before them.' Overtasked nature at length yielded under his exertions, and it was with the greatest difficulty that he was restored to health. Excessive application is known to have in like manner thrown Boerhaave into a species of delirium for six weeks, and to have on one occasion given a severe shock to the health of Newton. It unquestionably cut short the days of Sir Walter Scott, and also of the celebrated Weber, whose mournful exclamation in the midst of his numerous engagements can never be forgotten—'Would that I were a tailor, for then I should have a Sunday's holiday!'

The premature extinction of early prodigies of genius is generally traceable to the same cause. We read that, while all other children played, they remained at home to study; and then we learn that they perished in the

* Of the frequent occurrence of premature paralysis, in consequence of the mode of life above described, we are assured by a metropolitan physician of the greatest eminence.

bed, and balked the hopes of all their admiring friends. The ignorant wonder is of course always the greater when life is broken short in the midst of honourable undertakings. We wonder at the inscrutable decrees which permit the idle and dissolute to live, and remove the ardent benefactor of his kind, the hope of parents, the virtuous, and the self-devoted; never reflecting that the highest moral and intellectual qualities avail nothing in repairing or warding off a decided injury to the physical system, which is regulated by laws of a different, but of as imperative a nature. The conduct of the Portuguese sailors in a storm, when, instead of working the vessel properly, they employ themselves in paying vows to their saints, is just as rational as most of the notions which prevail on this subject in the most enlightened circles of British society.

It ought to be universally known that the uses of our intellectual nature are not to be properly realised without a just regard to the laws of that perishable frame with which it is connected; that, in cultivating the mind, we must neither overtask nor undertask the body, neither push it to too great a speed, nor leave it neglected; and that notwithstanding this intimate connection and mutual dependence, the highest merits on the part of the mind will not compensate for muscles mistreated, or soothe a nervous system which severe study has tortured into insanity. To come to detail—it ought to be impressed on all, that to spend more than a moderate number of hours in mental exercise, diminishes insensibly the powers of future application, and tends to abbreviate life; that no mental exercise should be attempted immediately after meals, as the processes of thought and of digestion cannot be safely prosecuted together; and that without a due share of exercise to the whole of the mental faculties, there can be no soundness in any, while the whole corporeal system will give way beneath a severe pressure upon any one in particular. These are truths completely established with physiologists, and upon which it is undeniable that a great portion of human happiness depends.

Repose a condition demanded by Exercise.

Exercise demands occasional periods of repose, and, in particular, that a certain part of every twenty-four hours be spent in sleep. After having been engaged in daily occupations for fourteen or sixteen hours, a general feeling of fatigue and weakness is induced; the motions of the body become difficult, the senses confused, the power of volition or will suspended, and the rest of the mental faculties, becoming more and more inactive, sink at length into a state of unconsciousness. The sense of sight first ceases to act by the closing of the eyelids; then the senses of taste and smell become dormant; and then those of hearing and touch. The muscles also dispose themselves with a certain reference to ease of position, those of the limbs having grown indolent before those that support the head, and those that support the head before those of the trunk. In proportion as these phenomena proceed, the respiration becomes slower and more deep, the circulation diminishes in impetus, the blood proceeds in great quantity towards the head, and all the functions of the internal organs become retarded. In this state, shut out, as it were, from the external world, the mind still retains part of its wonted activity, deprived, however, of the guidance of judgment and the power of *distinct* recollection; in consequence of which it does not perceive the monstrous incongruities of the imagery which sweeps before it, and takes but imperfect cognisance of the time which elapses.

It may be laid down as an axiom, that the more uninterrupted sleep is, the more refreshing and salutary will be its effects; for, during this period, the body undoubtedly acquires an accession of nervous energy, which restlessness, however induced, must disturb; and therefore the state of the body before going to sleep, the kind of bed, and the manner of clothing, require especial attention. As the functions of the body are performed more slowly during our sleeping than our waking hours, a full meal or supper, taken immediately before going to bed, imposes a load on the stomach which it is not in a condition to digest, and the unpleasant consequence of oppressive and harassing dreams is almost certain to ensue. When the sleeper lies upon his back, the heart pressing, while pulsating, on the lungs, gives rise to a sense of intolerable oppression on the chest, which seems to bear down upon the whole body, so that in this painful state not a muscle will obey the impulse of the will, and every effort to move appears to be altogether unavailing. This constitutes *incubus* or *nightmare*; and it may be observed that, as acidity on the stomach, or indigestion, gives rise to such dreams, so all dreams of this disturbed character are converse indications of indigestion; for which reason the great physiologist Haller considered dreaming to be a symptom of disease. It is certain that the dreams of healthy persons are the lightest and most evanescent.

The kind of bed on which we repose requires attention. Some are advocates for soft, others for hard beds; hence some accustom themselves to featherbeds, others to mattresses. The only difference between a soft and a hard bed is this—that the weight of the body in a soft bed presses on a larger surface than on a hard bed, and thereby a greater degree of comfort is enjoyed. Parents err in fancying that a very hard bed contributes to harden the constitution of their children; for which reason they lay them down on mattresses, or beds with boarded bottoms. A bed for young children cannot be too soft, provided the child does not sink into it in such a manner that the surrounding parts of the bed bend over and cover the body. The too great hardness of beds, says Dr Darwin, frequently proves injurious to the shape of infants, by causing them to rest on too few parts at a time; it also causes their sleep to be uneasy and unrefreshing. The universal analogy derived from other animals evinces the truth of this doctrine, both in respect to the softness and due degree of warmth of their beds. Birds line the nests of their young with feathers; the eider duck and the rabbit pluck the down from their own breasts to increase the softness of the beds of their tender offspring, and brood over them with their wings, or clasp them to their bosoms for the sake of warmth. For this reason, it is better that delicate children should sleep with a bedfellow than alone; for in this case, if any part of the body becomes cold, the child instinctively places that part in contact with the warmer body of its companion. So, also, it is better for a new-born infant to sleep with its mother in winter, or with its nurse, than in a solitary crib by the bedside.

When in bed, the head should be always higher than the feet, and those subject to palpitation of the heart should lie with their heads considerably higher. Night-clothes should never consist of more than a chemise or shirt of cotton or linen, with a flannel shirt beneath. It is also highly improper to sleep in a bed overloaded with clothes; the body is thereby heated, and feverishness and restlessness induced. Accordingly, persons who complain of sleeplessness should look to the quantity of their bed-clothing; for the unnecessary addition of a single blanket may be the sole cause of the annoyance. It is also imprudent to lie with the head entirely within the bed-clothes; for in this case the same air which has been already breathed must be again and again inhaled. For the same reason, the curtains should not be drawn closely round the bed. Washing the face and hands, and brushing the teeth, before going to bed, will be found to contribute materially to comfort. Whatever be the time chosen for sleep, it is evident that no person can with impunity convert day into night. Eight o'clock for children, and eleven for adults, may be recommended as good hours for retiring to rest. It is well known that children require more sleep than adults; and more sleep is requisite in winter than in summer. The average duration of sleep which may be recommended for adults is *eight* hours; but much depends upon habit, and many persons require only six. It is scarcely necessary to observe that, on rising in the morning, the strictest attention should be paid to washing the face, neck, and hands; the mouth and teeth should also be well cleansed. The most simple powder for the teeth is finely-pounded charcoal, a little of which will clear away all impurities, destroy any fœtor, and preserve the teeth. On leaving the bedroom, the windows should be opened, and the clothes of the bed turned down, in order that the exhalations of the body during sleep may be dissipated. If, instead of this, the bed be made immediately after we have risen, these exhalations are again folded up with the clothes—a practice which is not consonant either with cleanliness or with health.

TEMPERATURE.

The fifth important requisite for health is, that the body be kept in a temperature suitable to it.

The degree of heat indicated by 60 degrees of Fahrenheit's thermometer, or that of a temperate summer day, is what the human body finds it agreeable to be exposed to when in a state of inactivity. In air much colder, the body experiences an unpleasant sensation, unless some warm clothing be worn, or a pretty active exercise be indulged in. When, either by natural or artificial means, the body is kept in a suitable state of warmth, the functions of the circulation and perspiration in the skin go on healthily; it is red, in consequence of the blood being urged into the capillaries or minute vessels near the surface; it is also soft and moist, from the action of the glands for secreting the waste fluid and its free egress through the pores. This is a condition of great comfort; and the appearance of those who enjoy it conveys to others the notion that they are in good health. When, on the contrary, there is a much lower temperature, the functions of the vessels connected with the skin are apt to be considerably deranged. The vessels, in these circumstances, contract; the blood is driven inwards, where it sometimes occasions diseases of a dangerous nature; the perspiration also, being prevented from passing out by its usual channels, catarrhal complaints ensue, sometimes ending in consumption.

It is of the more importance to make these facts generally known, as a notion prevails that exposure to a painful degree of cold tends to induce hardiness of constitution and to promote health. Undoubtedly there may be harm from an opposite extreme, and we know well that excessive clothing and living in overheated apartments are detrimental to health. But safety lies in a medium between the two extremes. There is a degree of warmth which is both agreeable and healthy, and which it is desirable to have around us as constantly as possible—generally from 54 to 60 degrees Fahrenheit.

There is no period of life at which warmth is of more consequence than in infancy. In a very young babe, the circulation is almost altogether confined to the surface, the internal organs being as yet in a very weak state. In such circumstances, to plunge the child into cold water, from an idea of making it hardy, as is customary in some countries, and among ignorant persons in our own, is the height of cruelty and folly; for the unavoidable consequence is, that the blood is thrown in upon the internal organs, and inflammation, bowel-complaints, croup, or convulsions, are very apt to ensue. A baby requires to be kept at a temperature above what is suitable to a grown person; it should be warmly, but not heavily clothed; the room where it is kept should be maintained at a good, but not oppressive heat; and it should never be put into other than tepid water. It should not be exposed to the open air for some days after its birth.

At all periods of life, it is most desirable to avoid exposure to very low temperatures, especially for any considerable length of time. To sit long in cold school-rooms or work-rooms, with the whole body, and especially the feet, in a chilled condition, is very unfavourable to the health of young people. It is not possible that a condition so adverse to the healthy action of the cutaneous vessels should not lead, if long persisted in, to very bad consequences. Those who are compelled to be sedentary, should make it their endeavour to obtain a sufficiently high temperature, either by warming their apartments sufficiently, or thickening their clothing. Common fires, though delightful from their cheerful look, are confessedly very inadequate, in most circumstances, to heat large work-rooms, school-rooms, or even the larger class of sitting-rooms; not to speak of the great objection which has been made to them on the score of economy, three-fourths of their heat being sent off through the chimney. It is most desirable that some means in which the public could have confidence were devised for thoroughly, and at the same time healthily, warming large apartments. Stoves enclosed in large iron-plate cases (Arnott's stoves), pipes of hot water or of steam, and blasts of heated air, are amongst the most conspicuous plans tried within the last few years. But none of these plans seems to have succeeded in obtaining the hearty approbation of the public, chiefly, we suspect, from their not being accompanied by what is peculiarly necessary where they are in operation—a means of ventilation. We can speak from some experience in favour of the plan of large steam-tubes, accompanied by a ventilating process; and have very little doubt that, with the latter requisite, this and several other of the recently-suggested modes of heating might be found to serve the desired end. It is certainly of great consequence that some plan should be generally consented upon for warming the large rooms in which scholars and workpeople spend so much time, as the chilliness there so generally experienced is a fatal underminer of the human constitution. (See HEATING, No. 29.)

Clothing should be in proportion to the temperature of the climate and the season of the year; and where there are such abrupt transitions from heat to cold as in our own country, it is not safe ever to go very thinly clad, as we may in that case be exposed to a sudden chill before we can effect the proper change of dress. Very fatal effects often result to ladies from incautiously stepping out of heated rooms in the imperfect clothing which they ludicrously style *full-dress*: all such injuries might be avoided by putting on a sufficiency of shawls or cloaks, and allowing themselves a little time in the lobby to cool. The under-clothing in this country should be invariably of flannel, which is remarkably well calculated to preserve uniformity of temperature, as well as to produce a healthy irritation in the skin. While the value of comfortable clothing is fully acknowledged, we should never lose sight of the value of exercise for keeping up a kindly glow upon the surface, and for the support of a high tone of general health. Any one who, neglecting this, should live constantly in a warm apartment, or only go out of doors muffled up in a mass of clothing, would speedily suffer from a relaxed state of the system, and become so susceptible of damage from the slightest change of temperature in the atmosphere, that the most dangerous consequences might be apprehended.

Wet clothes applied to any part of the body, when it is in an inactive state, have an instantaneous effect in reducing the temperature, this being an unavoidable effect of the process of evaporation which then takes place. Hence it is extremely dangerous to sit upon damp ground, or to remain at rest for a single minute with wetted feet, or any other part of the body invested in damp garments. Dampness in the house in which we live has the same effect, and is equally dangerous. The chill produced by the evaporation from the wetted surface checks the perspiration, and sends the blood inwards to the vital parts, where it tends to produce inflammatory disease. Few persons seem to be aware of these truths. We find young men heedlessly getting their feet wet, and sitting with them in that condition, thereby incurring the most deadly peril. Young women commit a similar folly when they walk out in thin shoes in a wet or cold day. Exposure to wet, damp, or cold, is of comparatively little moment when the body, by a course of exercise or training, has been prepared to endure these conditions. Thus a person brought up delicately, or much within doors, would be killed by that which would have little or no effect on a ploughman. It is therefore worthy of being suggested as a line of policy, that no one should accustom him or herself to a pampered or too delicate mode of life. Every one should, if possible, go out daily, both in good and bad weather, with clothing corresponding to the nature of the weather, and in this way strengthen and harden the constitution to endure all ordinary and reasonable exposure. It is important, however, to note, that even the hardiest persons are never safe from the effects of wet clothes and other modes of exposure to a reduced temperature. No complaint is more common among out-of-door labourers, and also poor people in damp lodgings, than rheumatism. This is an affection produced solely by a violation of the natural law which demands that the body should not be chilled. Rheumatism is produced alike from exposure to a shower or to a draught of cold air when the body is warm, and from sitting with the feet on a cold stone or clay floor; the only difference, perhaps, being, that the rheumatism is in one case in the shoulders and in the other in the legs. Let us therefore impress on all the propriety of avoiding chills, the effects of which may be much more fatal than a simple attack of rheumatism. When rheumatism has been contracted, the best remedy for its expulsion, if adopted in time, is friction of the part; if well rubbed before a fire with flour of mustard, so as to cause a counter irritation on the surface, the internal complaint may be expelled.

Errors in Dress.

This is perhaps the most appropriate place in which to introduce some remarks upon errors in dress. The integuments which nature calls upon us to put on for the sake of warmth, are too often made the means of inflicting serious injury, either through ignorance, fashion, or caprice. It is therefore necessary, in a treatise on the preservation of health, to advert in emphatic terms to this subject.

It is scarcely too much to say that there is no part of the human frame, from the sole of the foot to the crown of the head, which has not been, and is not at this moment, mistreated by fashion. We laugh at the Chinese ladies, who have their feet constrained by iron moulds into mere bulbous appendages to the limbs; but we never reflect that, amongst ourselves, errors only inferior in degree are constantly committed. The foot naturally spreads out, fan-like, from the heel to the toes. But instead of having our shoes formed in the same triangular shape, they are made in a lozenge form, truncated at the front, the toes being thus perverted from their radiating arrangement into one exactly the opposite; so that they become crushed under one another, and deprived of a great part of that muscular power by which they were designed to propel our bodies in walking. In the greater height usually given to the heels of shoes, another important deviation from nature is committed. When the heel is raised above the level of the ball of the foot, a complete derangement takes place in the muscles of locomotion; the power of the limb is impaired; and the whole body is thrown off its equipoise. It is impossible, in such circumstances, to exercise the body as it ought to be. The foot is also forced or plugged down into the narrow front of the shoe, where the toes become liable to the grievance of corns. Thus the free healthy play of the various parts of the body is further diminished. From the uneasiness and constraint experienced in the feet, sympathetic affections of a dangerous kind often assail the stomach and chest; as hemorrhage, apoplexy, and consumption. Low-heeled shoes, with a sufficiency of room for the toes, would completely prevent all such consequences.

An improved taste in the male sex has long since abolished the coarse and self-annoying absurdity of leathern small-clothes; but it is still too common to impede the circulation and the play of the muscles by tight apparel, especially in the regions of the stomach and neck. The immediate effect of these injudicious appliances is much inconvenience: the remote result is a diminution of the general strength and health. But all the errors of the male sex sink into insignificance when compared with one to which the fair are liable. In the construction of the human chest, nature has provided ample room for several important viscera, the functions of which cannot be in any degree disturbed without a wrong being inflicted upon the whole system. Here reside the heart, the lungs, the liver, and the stomach. Fine ladies may affect to shut their mind's eye to the existence of such things; but the daintiest of their emotions depend upon the right state of those very viscera, without which they could no more think, speak, and act, than they could cast languishing looks without eyes, or melt our hearts by witching minstrelsy without a tongue and fingers. In the natural state, the external figure at this place tapers gently downwards. The waist of the Venus de Medici is of that form, and its perfect elegance was never challenged. But the women of the ordinary world have set up for themselves a different standard of beauty. A fine waist, in their estimation, is one which tapers rapidly below the arms, and is not above two-thirds of the natural girth. It must also be strictly round, although the waist of nature verges upon the oval. In order to reduce themselves to the desired shape and space, almost all the unmarried, and not a few of those who are otherwise, brace themselves in a greater or less degree with corsets, which no doubt produce the requisite roundness and slenderness, but at the expense of all the internal organs upon which health depends. The false ribs are pressed inwards; the respiratory and circulatory systems are crushed and thrust out of their proper place; the alimentary system is deranged; and even upon the exterior of the person, deformities of the most glaring kind, such as humped shoulders and curved spines, are produced. Custom to a certain extent enables the victim to endure the inconvenience; there are even some who feel so little trouble from it, as to deny that any harm ensues from tight-lacing. But a violation so excessive cannot be otherwise than mischievous. We have seen a young lady's sash which measured exactly twenty-two inches, showing that the chest to which it was applied had been reduced to a diameter (allowing for clothes) of little more than seven inches!

All who are aware of the internal organs at that part of the body, know very well that it is impossible for these to exist in their natural condition within so small a space. Bruised, impeded, and disordered, they must of course be, and accordingly cannot fail to become a source of dreadful suffering to the wretched being who outrages them. Palpitations, flushings, dyspepsia, determination of blood to the head, and consumption, are among the evils which physicians enumerate as flowing from this sacrifice to vanity. Another of a moral kind is acknowledged to be of by no means infrequent occurrence: in order to soothe the painful sensations produced by the constraint, spirituous liquors and cordials are resorted to, and thus habits of the most degrading nature are formed. Another evil still, respecting which a hint may be sufficient, is the unfitting of the system for the duties of a mother. How many domestic afflictions, which are submitted to in a spirit of resignation, as the unavoidable decrees of Providence; how many of the saddest scenes which this world ever presents—gentle and tender girls pining away under the eyes of hopeless parents—beloved wives torn from the arms of husbands and children at the very moment when prolonged life was most needful—must be owing to a cause too trivial and unworthy to be mentioned in the same sentence with its so dire effects! No doubt, it is well to submit meekly to such afflictions; but while they are ascribed in all humility to a Providence which is upon the whole only another term for Mercy and Justice, let us not be blind to the fact, that they accrue through violations committed by ourselves upon laws established by Providence for our happiness, and might have been avoided by a different course of conduct.

The fashion of tight-lacing obviously owes its origin to a desire on the part of the ladies to attract admiration. It is of little importance to point out that they are quite wrong in their calculations as to the effect; but we would press upon the guilty parties, and all interested in their welfare, that tight-lacing is a practice which cannot be long persisted in without the most disastrous consequences. It is painful to reflect that parents, so far from discouraging the practice, are so ignorant as often to force it upon their children. We have heard of a young lady whose mother stood over her every morning with the engine of torture in her hand, and notwithstanding many remonstrative tears, obliged her to submit to be laced so tightly as almost to stop the power of breathing. The result is, that the unfortunate victim is now severely afflicted with asthma, and has fallen into a state of low health. As a general rule, it cannot be too strongly impressed upon those who have the care of young persons, that all clothing should sit lightly upon the figure, so as to allow of the full play of every part of the system.

INNOCENT ENJOYMENTS.

A sufficiency of innocent enjoyments has been set down as the sixth requisite towards the preservation of health. It may seem almost superfluous to treat this part of the subject, since the disposition to take amusement is one by no means generally wanting. A regard, however, for the completeness of our little treatise, induces us to make a few remarks on it; and we are not satisfied that there is not a considerable number of persons to whom an injunction to take innocent enjoyments is needful. There may be some advantage, therefore, in seeing the matter placed on something like a philosophical basis.

No physiological doctrine seems more entitled to faith and regard, than that a harmonious exercise, in moderation, of all parts of the system, including the organs of the mental faculties, is necessary for health. It is proved by the very craving which we experience, after a long task, or a long perseverance in some particular habits, for something which will engage a different set of faculties. There is nothing which will pleasingly engage our thoughts for any considerable length of time. Something inferior will invariably be preferred, if it only be new. Now the duties by which men in general earn their subsistence, are in all cases of such a nature as only to call into exercise a part of their mental and bodily system. Something is required at once to soothe and compensate us for the drudgery of our current labours, and to bring into exercise those parts of our muscular frame and intellect which professional duty has left unoccupied. To begin with a humble illustration: how delightful to a tailor, after long exercising his fingers and arms alone at his business, to enter into some athletic sport upon the village-green, by which his limbs also will be exercised! After a lawyer has fagged for a day at a brief, how delightful to be able, by the reading of a new novel or play, to call up another set of the intellectual powers! In these changes from grave to light occupation there is at once repose given to the tasked faculty, and the gratification of employment given to others which have been pining for want of something to do. It so happens that, from the sentient nerves being mixed with those which direct the operations of all our organs, each organ has a sense of enjoyment in being rightly exercised. Even the stomach has, from this cause, a gratification when its functions are going on well, and this altogether independent of any pleasure we may have had in eating the meal upon which it is now employed. An organ left long unoccupied is thus somewhat like a child in a family which its parents have been overlooking. It craves to be noticed like the rest, and when the desired notice at length comes, it experiences a high degree of satisfaction. In short, variation of occupation and pursuit, for the purpose of keeping all the parts of the system in harmonious exercise and in healthy tone, is one of the most important principles concerned in the preservation of health.

There are several powers of the mind which must have been designed for the express purpose of creating and receiving amusement, and the existence of which therefore shows that amusement has a place in the right economy of human life. The imitative arts in general—music, fiction, drollery of all kinds—spring directly from primitive faculties of the mind; and when we see the pleasure they give in society, we cannot doubt that they are things naturally required by man, and in which it is quite legitimate for him to indulge within moderate bounds and in circumstances compatible with innocence. These things are doubtless designed to alleviate the burdens of life and beguile us of its cares. They furnish something like a different sphere of existence, into which we may enter and temporarily lose the sense of all that harasses us in the ordinary one. The *joculator*—under which name our ancestors associated the poet, tale-teller, and mimic, and which we may apply equally extensively to the poet, novelist, artist, and player—is therefore a most useful functionary in society. We say nothing on the present occasion of the refinement to be derived, in addition, from communion with the productions of the higher class of such minds.

Amongst amusements, *reading* takes a most distinguished place; for there is none which may be more readily or more innocently indulged in, and fortunately, in our own country, it is one which may now be enjoyed by all. It is unquestionably the chief of in-door amusements; and few scenes are calculated to awaken more agreeable feelings in a well-constituted mind, than a family group assembled in their parlour, to hear some one of their number reading a pleasant book. Ever honoured be the great masters of fiction, who have allowed us, by these means, to pass from common life, for a time, into 'the tale of Troy divine,' the story of 'the gentle lady married to the Moor,' the tear-compelling fate of Ravenswood, and all the other numberless suppositions of things done, and persons who spoke and acted, which we feel to be more real than much of even the life that is passing around us!

Next to reading stands *music*, a means of enjoyment of which only a few comparatively, in our country, take advantage, but which might easily be made much more extensively available, and probably will be so in the course of a few years. Connected intimately with music is *dancing*, which is not only a cheerful amusement, but a positive and direct means of bodily exercise. A family musical or dancing scene, like a family reading scene, is a thing beautiful to look upon. There is a prejudice against both in some minds, on account of their being liable to abuse; but the abuses of both arise very much from their not being extensively or freely indulged in. Were music the general accomplishment which it might easily be made, it would not only be indulged in on all occasions with simplicity and innocence, but it would supplant coarser and more clandestine amusements. Dancing is the nightly amusement of the French peasantry, and it has never been pretended that these people are less virtuous than the corresponding class in our own country. *Theatrical representations* it might be more difficult to place on such a footing as to secure the unhesitating approbation of the good; but certainly if this were done, they might prove highly serviceable in furnishing amusement.

In the class of amusements we must reckon meetings or promenades in ornamental grounds, excursions into the country, and little tours, all of which are highly commendable in those who are able to indulge in them. The entertainment of little parties of friends, and the going out to entertainments given by them in return, are other means of amusement common in society, and which may be moderately indulged in with much advantage. In short, whatever gives a pleasant variation to the monotony of life, without leading the mind away from duty or corrupting the manners, ought to be indulged in as freely as circumstances will permit. The mind returns from such diversions with renewed tone and power, and neither the time nor the expense is lost in the long-run. It is the more necessary to impress these maxims, as many well-meaning persons, alarmed perhaps at the occasional abuse of such enjoyments, repudiate them nearly altogether, and thereby lower the tone of their health, both as respects the body and the mind. It is particularly distressing to see such persons exercising a control over the young, and denying to their unfortunate protégés an element of life not much less pressingly necessary than the air they breathe. (See IN-DOOR AMUSEMENTS.)

Dr Southwood Smith, in his excellent work 'The Philosophy of Health,' has pointed out that pleasure is the ordinary, and pain in all cases an extraordinary, result of the action of our organs. 'There are,' he says, 'many cases in which pleasure is manifestly given for its own sake; but in no case is the excitement of pain gratuitous.' Pain is always a punishment; and, when it reaches a certain extreme, it is destructive of what feels it. But 'all such action of the organs as is productive of pleasure is conducive to the perpetuation of life. There is a close connection between happiness and longevity. Enjoyment is not only the end of life, but it is the only condition of life which is compatible with a protracted term of existence. The happier a human being is, the longer he lives; the more he suffers, the sooner he dies: to add to enjoyment is to lengthen life; to inflict pain is to shorten the duration of existence.' It may fairly be presumed, then, that a certain amount of enjoyment in life is necessary for health, and that when the quantity actually secured is much below that point, unhealthy conditions must ensue. If, for example, poverty or embarrassed circumstances press so severely upon a cautious and conscientious man as to leave him scarcely a moment's comfort from one year to another, he cannot fail to sink in health. If married to a female of bad temper, or who afflicts him by bad habits, and if, from these causes, he rarely enjoys a moment of happiness, so also must his health fail. In short, to be placed in any such circumstances as constitute a bar against nearly all enjoyments, must prove injurious, and tend to the shortening of life.

Enjoyments are of many kinds. Some are sensual, as the taking of agreeable food; others are intellectual, as agreeable music, reading, &c.; others are moral, as the exercise of philanthropy, the religious feelings, &c.; and some are sympathetic, and consist in the exercise of the affections, and the reflection of that gratification which we have endeavoured to impart to others. We may consider as such all things over and above the plainest unrelished fare, and the supply of water, air, and a barely sufficient temperature. These are usually considered as strictly the necessaries of life, the others being the comforts or luxuries. The distinction is not quite correct. The first class are certainly immediately necessary to the support of life; that is to say, they are hourly, daily necessary. But more or less of what are called the comforts of life are also necessary, if we would preserve health. The only difference is, that the want of them would not tell in so short a time as the want of the so-called necessaries. If a human being be shut up in a cell, and allowed only a sufficiency of unrelished and unvaried food, with air and water, the want of all the enjoyments of life, sensual, intellectual, moral, and sympathetic, will in a certain time make him utterly miserable; the health of body and mind will give way; and if the experiment be sufficiently protracted, he will perish. The ignorance which prevails on this point has led to the trial of what is called the *silent system* in prisons, which is now about to be abandoned as utterly irreconcilable with humanity. It were well if more knowledge prevailed on the subject, for, from erroneous ideas of what is necessary for healthy life, many deprive themselves or others of things which, when we take the element of time into account, are as essential to health as the supply of the air we breathe. There is, in some enthusiastic minds, a spirit of asceticism and self-mortification which would give up all the enjoyments of life together. Such persons rarely fail to reduce their own health, if they do not also exercise some unhappy control to the same effect over their fellow-creatures. While self-denial for moral purposes is always admirable, and over-indulgence of every kind saps the vigour and fortitude of the human character, it should be ever kept in view that there is great danger in reducing the allowance of comforts and indulgences too low. Very rigid views of what is necessary for the support of life usually prevail, wherever the affluent have to dictate a style of living for the poor. The tendency there is, to reduce allowances as nearly as possible to what may be called the *immediate necessaries;* for it does not seem just or right that paupers, adults or children, should enjoy any species of gratification. But these are short-sighted views. The health of these unfortunate persons requires something more, and this something would be granted by an enlightened humanity. We have a strong manifestation of this need in the eagerness with which paupers generally desire allowances of tea or tobacco, or indeed the least variation of their diet. The craving for these luxuries is not so much, what it is generally thought solely to be, the result of bad habits long indulged in, as it is the expression of a want in the personal economy—a want which, by one means or another, must be supplied, or injurious consequences will ensue.

Exemption from Harassing Cares.

It is little more than a repetition of doctrines already laid down, that, for the due preservation of health, a human being requires an exemption from acute distress of mind and harassing cares.

Mental distress and anxiety operate through the brain upon the condition of the whole body, and, when long protracted, effectually undermine the health. 'It is impossible,' says Dr S. Smith, 'to maintain the physical processes in a natural and vigorous condition if the mind be in a state of suffering. Every one must have observed the altered appearance of persons who have sustained calamity. A misfortune, that struck to the heart, happened to a person a year ago: observe him some time afterwards—he is wasted, worn, the miserable shadow of himself; inquire about him at the distance of a few months—he is no more.' It is Dr Smith's opinion that the nearest cause of many suicides is not strictly a desire to escape from a state of suffering, but some disease, probably inflammation of the brain, brought on by distress of mind. 'By a certain amount and intensity of misery, life may be suddenly destroyed; by a smaller amount and intensity, it may be slowly worn out and exhausted. The state of the mind affects the physical condition; the continuance of life is wholly dependent on the physical condition; it follows that, in the degree in which the state of the mind is capable of affecting the physical condition, it is capable of influencing the duration of life.'

Depression of mind, besides its immediate effect on the nervous system, deranges the respiration, and mars the proper oxygenation and circulation of the blood. A diminished vitality is the consequence, often leading to pulmonary consumption. An excessive agitation and alarm of the selfish feelings, such as takes place in some minds on the approach of an epidemic, affects the whole system in such a way as—to use an expressive phrase of Dr Combe—'places it on the brink of disease;' and hence the notoriously great liability of persons in this state of alarm and apprehension to fall victims to the malady when it comes. It has been remarked that an army in a high state of confidence and cheerfulness after a victory, has a much smaller proportion of sick than in the opposite circumstances, or even in its ordinary condition. The usual proportion of sick in a garrison quartered, during peace, in a healthy country, is five per cent.; during a campaign, when there is more anxiety of mind, it is ten; in the event of defeat, although the circumstances be otherwise not unfavourable, the proportion rises to a much higher amount. It is a very instructive fact, that in a large detachment of the French army cantoned in Bavaria immediately after the battle of Austerlitz, the proportion of sick was little more than one per cent.

GENERAL OBSERVATIONS.

The fundamental principle of every effort to improve and preserve health has been thus stated :—' Man, as an organised being, is subject to organic laws, as much as the inanimate bodies which surround him are to laws mechanical and chemical; and we can as little escape the consequences of neglect or violation of these natural laws, which affect organic life through the air we breathe, the food we eat, and the exercise we take, as a stone projected from the hand, or a shot from the mouth of a cannon, can place itself beyond the bounds of gravitation.' To this it may be added, that ' all human science, all the arts of civilised man, consist of discoveries made by us of the laws impressed upon nature by the Author of the universe, and the applications of these laws to the conditions—which are laws also—in which man and the particular bodies and substances around him, are placed; nor, it is manifest, should any science concern us more than that which relates to the conditions on which organic life is held by each individual.'

The preceding sections are but explanations, such as we have been able to afford, of the conditions under which the organic frame of man exists, and the agencies, internal and external, which operate upon it, for the maintenance of health or the introduction of disease. It must be evident, where there is a conviction of the truth of the fundamental doctrine, that individuals and societies have their health very much at their own disposal; that a careful avoidance, on the one hand, of what is noxious, and a judicious attention to what is beneficial, are what are chiefly necessary for the preservation of the human frame in health to old age; and that premature deaths, over and above those which result from unforeseen casualties, instead of being, as supposed by the untutored mind, a mysterious and irreversible decree of Providence, are simply the natural effect of our own violation of laws which Providence has appointed for our welfare. It might still be objected that human nature is such, that the due obedience and observance of those natural ordinances are not to be expected; so that the vast quantity of disease, and the great number of premature deaths, which afflict our present state of being, are equally to be regarded as things immutable, and therefore to be tranquilly submitted to. But this view would be not less a mistaken one; for there is no fact more clearly ascertained, than that disease and premature death are not, and never have been, fixed at any given amount, but yield constantly to the power of any new conditions which man may be able to introduce. Regarding clear views on this subject as of great importance, we shall here enter a little into detail.

The object is, we apprehend, to show that sickness and mortality vary both in place and in time, according to physical and organic conditions.

Inquiries into these subjects were not made in ancient times; but during the last two hundred years, such facts have been recorded as enable us to ascertain that in that space of time, with regard to nearly the whole of Europe, there has been a gradual improvement in health and life, in proportion to improved conditions. In Sweden, for instance, between 1756 and 1763, the annual mortality was, for males, 1 in 33½, for females, 1 in 35¾; whereas in the year 1800 it had diminished to 1 in 34¾ for males, and 1 in 37⅓ for females. From mortuary tables preserved with considerable accuracy at Geneva, it appears that at the time of the Reformation, one-half of the children born died within the sixth year; in the seventeenth century, not until the twelfth year; in the eighteenth century, not until the twenty-seventh year; consequently, in the space of about three centuries, the probability that a child born in Geneva would arrive at maturity has increased fivefold. In London, in the year 1606, the annual deaths were 1 in 14½, or 7 per cent. of the population; and in plague years during that century it reached 25 in 100, or every fourth man, woman, and child! *In 1838, it was only 1 in 35½.* Knowing that, at the former period, the city was dense, and ill-cleaned, and that the habits of the people were not then what they are now, we cannot doubt that this diminution of mortality to less than one-half is owing to the improved conditions in which human beings now live in the metropolis. Between the years 1730 and 1750, 74 of every 100 children born in London died before they were six years of age; but in more recent times, only 31 and a fraction out of every 100 die under the same age—that is to say, the deaths of children in London were then more than twice as numerous as they are now. About a century ago, the mortality of the children received into the London hospitals was of astonishing amount. Though the fact seems scarcely credible, we believe there is no good reason to doubt that, of the 2800 annually received, 2690, or *twenty-three in every twenty-four*, died before they were a year old. It was at length seen that this mortality was the effect of overcrowding, impure air, and imperfect aliment; and after an act of parliament had been procured to compel the officers to send the infants to nurse in the country, only 450 out of 2800 died in the first year. It has been ascertained that, during the last century, about a third has been added to the average expectation of life—that is to say, an individual now has as good a chance of living forty years, as he had a hundred years ago of living thirty. To what can such a fact be owing but to the diminution of the causes of disease in the improved conditions of the people?

The facts ascertained with regard to differences of mortality in different places are equally striking. A remarkable instance of the effect of marshes upon health is cited by M. Villermé. Formerly, the district of Vareggio in Tuscany was in this condition, and its few miserable inhabitants were every year visited by severe agues. In 1741, floodgates were erected to keep out the sea, the marsh was dried up, and ague appeared no more. Vareggio subsequently became a populous and healthy district. The Isle of Ely is a marshy district in the east of England, and it was ascertained that of 10,000 deaths which occurred in it between the years 1813 and 1830, no fewer than 4732 were of children under ten years of age; the proportion of deaths of children under ten in all the other agricultural districts of England being only 3505, or as about 3 to 4 of the former number. Of 10,000 deaths between ten years and extreme old age in the same period, there were, of persons between ten and forty, 3712 in the Isle of Ely, and only 3142 in drier districts. There are some remarkable discrepancies of mortality in different counties of England. While the proportion of annual deaths in every hundred persons under six years of age is, for the whole of England and Wales, about five and a-third, the proportion in Suffolk is three and a-half, in Warwick six, in Middlesex eight and a-third. Suffolk is an agricultural county; Warwick contains Birmingham and some other large towns; and the metropolis is situated in Middlesex: can we resist concluding that the pure air and constant exercise which children obtain in the country are the immediate means of prolonging their lives; while the narrow accommodations, impure air, and limited exercise to be had in large towns have exactly the contrary effect? In the general population of England, 443 in 1000 die under ten years of age; but in Manchester and Salford the number is a third larger, or 602. Here, the miserable circumstances of many of the humbler classes in Manchester—above eighteen thousand of them, for one thing, living *in cellars*—must be considered as the immediate cause of the disproportioned mortality. While the general mortality of London is, as stated, 1 annually in 35½, there are great differences with respect to different districts. In Camberwell, an open suburban district, it is 1 in 52; in Hackney, a similar district, 1 in 54; but in the huddled district of St George's, Southwark, it is 1 in 30; and in the still more dense and miserable region of Whitechapel, so much as 1 in 26, or exactly double the mortality of Camberwell.

A curious investigation has been made in London to ascertain the effect of density of population upon health. In a large district, where the population is so dense that there is only 35 square yards for each person, the annual mortality is 3428; in another district of the same population, where each individual has an allowance of 119 square yards, the mortality sinks to 2786; in a third, where there are 189 square yards to each person, the mortality is only 2289, or under two-thirds of what it is in the closest of the three districts. It was also found that in the three districts the mortality from typhus fever was, respectively—as we go from the roomiest to the most confined—131, 181, and 349. The proportion of sickness and mortality which the poor suffer in comparison with the rich is thus placed in a striking point of view. Precisely similar results have been discovered in Paris. M. Villermé has there ascertained that the deaths in some poor arrondissements are just double what they are in the rich. He states that, taking the whole of the French population, human life is protracted twelve and a-half years among the wealthy beyond its duration among the poor; consequently, in the one class, a child, newly born, has a probability of living forty-two and a-half years; in the other, only thirty years.

Taking the whole of the above facts into account, we must see that not only do health and longevity depend expressly on laws the operation of which we can understand, but man has it in his power to modify to a great extent the circumstances in which he lives, with a view to the promotion of his organic wellbeing and preservation. We see that the draining of a marsh banishes the ague, that a change from city to country air diminishes mortality, and that the greater comforts possessed by the affluent secure them longer life than the poor. It may not immediately be in the power of every one to change his circumstances from the unhealthy to the healthy; but it is a great matter to know that the object is within human power, for then at least an encouragement is held out to induce each individual to make every possible effort to put himself, and to contribute to putting society in general, into more salubrious conditions.

The object may be said to depend partly upon individual and partly upon social efforts. Every person has some control over the quantity and quality of the food he eats, the condition of the air he breathes, and the exercise, repose, and recreation which are demanded by his muscular and nervous system, according to the principles laid down in this and similar treatises; as also some power to refrain from injurious excesses, and to avoid the various external agencies of a detrimental kind which constantly beset him.* Let him act as he ought to do in these respects, and he will reap an immediate reward in that pleasurable state of consciousness which attends a healthy existence. But some of the most important requisites for health depend on public measures. The amount of the necessaries and comforts of life to be obtained by the great mass of the operative classes in all countries, depends very much upon regulations which may have been made with regard to *production* and *exchange*, as also those which may have been made for instructing and morally elevating and sustaining the bulk of the people. It unfortunately happens, in most countries, that while the bearing of certain acts upon individual happiness is fully seen and provided for, those which affect the condition of communities are imperfectly understood; so that measures destructively injurious to millions will be blindly enforced and defended by those who would severely punish the slightest wrong inflicted by one man upon another.

Measures for improving general conditions, with respect to air and exercise, are perhaps more readily practicable; yet here also the bearing of active principles upon great masses is so dimly seen, that, not to speak of more positive difficulties, it is usually long before proper sanitary regulations are made. The cleaning police of most cities is certainly improved considerably within the last fifty years; yet it is still far from being what it ought to be, while drainage continues to be extremely defective, and ventilation and means of innocent and healthful recreation can scarcely be said to be thought of. Some facts elicited by recent parliamentary inquiry, with regard to several of our principal cities, are of a most startling kind.

Dr Arnott, when examined as to the prevalence of fever in Bethnal Green, Whitechapel, Wapping, and certain other districts in the metropolis, attributed them directly to the dirty and neglected state of these localities, instancing—'Houses, courts, and alleys without privies, without covered drains, and with only open surface gutters, so ill-made, that the fluid in many cases was stagnant; large open ditches containing stagnant liquid filth; houses dirty beyond description, as if never washed or swept, and extremely crowded with inhabitants; heaps of refuse and rubbish, vegetable and animal remains, at the bottom of close courts and in corners.' [The amount of noxious matter which is allowed to collect in London is far beyond what most of its inhabitants have any conception of, as is the case with most other conditions chiefly affecting the poor.] In Manchester, 18,300 persons, or one-twelfth of the whole working population, live beneath the level of the ground, with an insufficiency of both light and air. In that town the dwellings of labourers are often situated in narrow courts, and back to back, so as to prevent ventilation; the drains are far from sufficient; and till recently there was not in the town one free space in which the people could enjoy the slightest recreation. In Liverpool, 39,000 persons live in cellars, dark, damp, confined, ill-ventilated, and dirty. The class next above, to the number of 80,000, inhabit houses built around small courts, closely pent up, back to back, with only one entrance to each, and usually a receptacle for refuse in the centre; an arrangement which appears as if it had been expressly calculated to keep health low and mortality high. In Leeds a similar style of building obtains, with a similar train of circumstances—'no effective drainage, inspection, or system of paving or cleansing.' The greater part of this town was described in 1839 as 'in a most filthy condition, demanding an immediate remedy.' It was mentioned, that in a certain dirty yard there was a house which for many years had been the seat of disease of a very malignant character: three years ago, the attention of the commissioners of police was directed to the extremely imperfect drainage of the surface-water: at that time a better escape for the refuse-water was provided; and since that period, says the reporter, 'I believe *we have not had a single case of fever from that particular locality.*'

Narrow alleys and close courts, with wet filth constantly exhaling within them, and containing a densely-huddled and extremely poor population, exist in Edinburgh, where, however, an exposure to high winds makes the evil less pestilential. In Glasgow, a comparatively level city, the same peculiarity exists to perhaps a greater extent than in any other British city. This, added to the miserably insufficient succour extended to the poor, and the influx of migratory Irish, renders Glasgow at present one of the unhealthiest cities in Europe; the mortality of the year 1837 being 1 in 24½, and the number of fever cases for the five years before 1839 at an average of 11,118 per annum. Here also we have a most notable instance (See No. 29, p. 460) of the counteractive power of a single sanitary principle; for a house containing about five hundred poor inhabitants, having been ventilated by a draught from each room in 1832, fever, which had previously never been absent from that dwelling, was nearly banished, only four cases occurring in the ensuing eight years, though fever raged during that period in all the other districts of the city occupied by the poorer classes.

FOOD—BEVERAGES.

Having shown in the preceding sheet that man is destined to subsist on a mixed diet—that is, partly on vegetable and partly on animal food—we shall now proceed to describe the specific characters of the more common alimentary substances, in as far as these have been determined by science and experience. In so doing, we shall consider their natural history and production, their chemical composition, their relative alimentary value, and the like, leaving their culinary preparation for the subject of a separate treatise. Before doing so, however, it will be necessary to establish a clear conception of the functions which food has to perform in the animal economy.

Chemical research has shown that the food of man is composed of organic matter, water, and mineral ingredients. The mineral ingredients are required to form the skeleton or solid framework; the watery fluid is necessary to the due performance of the vital functions; whilst the organic matter supplies at once the heat and nourishment of the system. Every one knows how indispensable animal heat is to the preservation of life and health; and this heat is produced, according to the researches of Liebig and others, by the consumption of a certain portion of the food, much in the same way as fuel produces heat by being burned. The elements of this portion of our food are hence termed *calorifiant or respiratory*, because it is chiefly in respiration that they, after having undergone various changes in the body, are brought in contact with the oxygen of the atmosphere in the lungs and capillary vessels all over the body; and by the chemical changes thence resulting (see Animal Physiology), heat is given out, and the warmth of the body maintained. Animal heat is thus generated by a combination of the carbon and hydrogen of a portion of the food with the oxygen of the inspired air—heat always being given out by such chemical changes, and compounds of carbonic acid and water being the result, which are given off by the lungs and skin as waste matter. The elements of the other portion of our food are termed *nutritive*, because they supply the waste and growth of the fabric. Every thought of the mind, every act of the body, produces changes in our systems, from the living and healthy particles of which they are composed, to dead and waste particles, which, being no longer of use, are either burned by the slow combustion already described, or carried off as excrementitious matter; and it is the province of these elements of nutrition, by going to form blood, to renew the parts where such waste has been produced. The leading ingredient in the nutritive portion is nitrogen or azote, hence the terms nitrogenous or azotised are equivalent to nutritive.

From the preceding statements, it must be evident that all wholesome dietary must contain both a *heat-forming* and a *flesh-forming* principle; and that, according as we live in a hot climate or cold climate, take much exercise or remain sedentary, so must we have recourse to food which will supply the elements which our bodies most stand in need of. It is the province of chemistry to determine the constituents of human food, to point out the excess or defect of the principle we are in search of; and thus attempts have recently been made to classify substances according to their capabilities of supplying heat, flesh, and bone. For example, 100 pounds of

Beans yield	31	flesh,	51½	heat,	3½	bone,	14	water.
Wheat ...	21	...	62	...	2½	...	14½	...
Oats ...	18	...	68	...	3	...	16	...
Potatoes ...	2	...	25	...	1	...	72	...
Turnips ...	1	...	9	...	1	...	89	...

If these results be correct, oats, for example, form a less flesh-forming diet than wheat; but they yield a larger amount of heating principle, at the same time that they are more favourable to the growth of bone. With a view to exhibit the relative value of substances as flesh-formers or heat-formers, chemists are also in the habit of tabulating their researches thus:—

Milk, . . .	1	of nutrition to	2	of heat.
Beans, . . .	1	...	2½	...
Oatmeal, . .	1	...	5	...
Wheat-flour,	1	...	8	...
Potatoes, . .	1	...	9	...
Turnips, . .	1	...	11	...

Or they may simply state the per centage of the principle they are in search of, as—

Beanmeal	contains	23½	per cent.	albuminous or	nutritive matter.
Oatmeal	...	23½	...	...	...
Flour	...	11¼	...	...	...
Potatoes	...	2¼	...	...	...
Turnips	...	1¼	...	...	...

In whatever way the results may be stated, it is necessary that they be obtained with accuracy; and it is equally necessary that the condition of the body as to health or disease, rest or exercise, shelter or exposure to cold, should be also ascertained, so that by the adoption of a proper diet any defect may be supplied or excess corrected. On this point man has yet made little true scientific progress. Where he has arrived at the truth, it has been chiefly by a long process of trial and error; and it is only now that he is beginning to apply the lights of science to guide and direct him. In describing the various articles of food—vegetable and animal—we can therefore only refer to very general results: accurate and detailed experiments being yet in many instances altogether wanting. To Baron Liebig, Boussingault, Mulder, and other continental chemists; to our own countrymen Sir H. Davy, Professor Johnston, Drs Thomson, Pereira, and Playfair, are we indebted for most of those researches on food which bid fair to introduce a system of dietetics, if not altogether new, at least more strictly in accordance with sound reason and economy. It must not be supposed, however, that substances which yield to the chemist the largest amount of nutritive matter, are in every case the most nutritious and wholesome. The fact is, they may contain other principles which greatly impair their digestibility, or they may be unfitted for peculiar states and conditions of health; or, what is also possible, they may be obnoxious to certain constitutions, unless administered along with the necessary correctives. Due allowance must ever be made for such exceptions; and all that we can reasonably expect of the chemist or physician, is a statement of results as applicable to healthy or normal conditions.

FOOD.

The aliment of man consists of solid and liquid substances; hence such popular distinctions as 'meats and drinks,' 'food and beverages'—the one calculated to allay the cravings of hunger, and to afford the body substantial support; the other simply to allay the sense of thirst. Such distinctions, however, are more popularly convenient than scientifically correct: milk, for example, though liquid, being the sole support of the young mammal, and affording, moreover, more substantial nourishment to every portion of the fabric than any solid substance whatever; while starch, though solid, yields little or nothing that can administer to the growth of the living tissues. Adopting, however, the common distinction of 'food and beverages,' as in some measure convenient, we shall treat the former under the three heads *vegetable*, *animal*, and *mineral*—remarking that it is chiefly the vegetable and animal kingdoms (and especially the vegetable) from which man derives the greater portion of his solid sustenance. In the dietary of tropical countries the vegetable element generally prevails over the animal; in temperate regions the proportion is more equable; while in the colder latitudes the flesh of animals may be said to be the staple of existence.

VEGETABLE FOOD.

Vegetable food, wherever employed, is consumed partly in a green and succulent state either cooked or uncooked; partly in a ripe condition—as fruits, nuts, and the like; and partly when dried and artificially prepared—as the various bread-corns. In whatever condition or form vegetable substances may be used, they consist essentially of the same elements—carbon, hydrogen, oxygen, and nitrogen, with a small proportion of solid inorganic matter. These are usually termed *ultimate* elements, from which the living vegetable elaborates certain *proximate* principles for the construction of its own peculiar fabric. These principles are—starch or fecula, gluten, vegetable albumen, sugar or the saccharine principle, gum or mucilage, lignin or woody fibre, vegetable jelly or pectin, fixed and volatile oils, wax, resin, balsams, gum-resins, camphor, tannin, colouring matter, acids, and alkalies. Of these the most abundant are starch, gluten, albumen, sugar, and gum; these constitute the principal ingredients in all esculent vegetables; and it may be remarked, that starch and gluten are the most nutritious—starch yielding carbon, or heat-forming, and gluten nitrogen, or flesh-forming principle. It may also be observed, that some of these proximate principles are convertible or nearly allied: thus starch can be converted into sugar by the processes of vitality and fermentation; and albumen differs from gluten only in containing a less amount of nitrogen. According to the prevalence of these respective principles, writers on dietetics have proposed certain classifications of vegetable food, such as the starchy or amylaceous, the saccharine, mucilaginous, oily, acid, alkaline, and so forth. Others, again, finding that many plants yield several principles in equal abundance, and that it is impossible to draw such distinctions without leading to misconceptions, abandon this classification, and merely treat of the parts consumed, as the seeds, roots, fruits, leaves, and the like. Any rigid division of this kind is also liable to objection, since the seeds of a plant may be wholesome, while its roots are poisonous; or its leaves may be worthless, while its fruit is valuable; or it may contain a deleterious principle when raw, and yet be exceedingly wholesome and agreeable when boiled or roasted. Abandoning, therefore, all such distinctions as apt to mislead, unless accompanied by more detailed explanations than our limits will allow, we shall treat of vegetables chiefly in the order of their importance.

One of the most abundant sources of vegetable food is the cereals, or bread-corns—wheat, rye, barley, oats, millet, and maize—all of which belong to the natural order *Gramineæ*, or grain-bearing plants. All of these grow in a similar manner; all yield starch, gluten, and a certain amount of phosphates; and all have been cultivated and improved by the inhabitants of different countries from time immemorial. They are commonly spoken of as *farinaceous foods*; their elements of *nutrition* being albumen, fibrine, gluten, and mucine; and their elements of *respiration*, starch (principally), sugar, and gum.

Wheat (*Triticum*), of which there are numerous varieties, justly stands at the head of the cereals. It is now grown largely in all civilised countries, and forms a principal portion of human food. The grain, freed from its bran or husk, is usually ground to a fine *flour*, and in this state is used in the manufacture of bread, pastry, maccaroni, vermicelli, semolina, and other preparations. It consists, as already stated, of starch, gluten, sugar, gum, certain phosphates, and water; and these ingredients are found to vary not only with the soil in which the corn is grown, but according to the climate or latitude—that of southern Europe yielding from two to six per cent. more gluten than that grown in the north. It is for this reason that Italian flour is so well fitted for the manufacture of maccaroni; and why bakers often prefer a mixture of wheats in the composition of their loaves. The following are given as analyses of different wheats and wheat flours:—

	French Wheat.	Odessa Hard Wheat.	Odessa Soft Wheat.	First Flour.	Second Flour.
Starch,	71·49	56·50	62·00	71·2	67·78
Gluten,	10·96	14·55	12·00	10·3	9·02
Sugar,	4·72	8·48	7·56	4·8	4·80
Gum,	3·32	4·90	5·80	3·6	4·60
Bran,	...	2·30	1·20	...	2·00
Water,	10·00	12·00	10·00	8·0	12·00

Bread is the most important article of consumption prepared from the flour of wheat, and may be fermented or unfermented:—

1. Common *fermented or loaf-bread* consists of wheat flour, salt, water, and either yeast or leaven (old dough already in a state of fermentation). To these bakers very generally add potatoes and alum—the former to assist the process of fermentation, and render the bread lighter, the latter to augment its whiteness and firmness. As to the addition of potatoes, there can be no objection beyond the substitution of an article containing less nutritive matter than pure flour; but as to alum, it is highly objectionable, and its use by bakers is accordingly prohibited by law. The rationale of the fermenting process is this:—'The yeast or leaven causes the flour to undergo the vinous fermentation, by which carbonic acid and alcohol are formed. The carbonic acid is prevented from escaping by the tenacity of the dough, which, becoming distended with gas, swells up, and acquires a vesicular structure, forming a kind of spongy mass. In this way, therefore, are produced the vesicles or eyes, which give to ordinary loaf-bread its well-known lightness and elasticity. If the vinous fermentation be not checked in due time by *baking*, the dough becomes sour; and for this purpose the mass, after being formed into loaves, is exposed in an oven to an elevated temperature, which puts a period to the fermentation, expands the carbonic acid, expels the alcohol formed, and drives off all the water capable of being removed by the degree of heat employed. On weighing bread taken from the oven, it is found to be twenty-eight or thirty per cent. heavier than the flour used in its preparation.' 'In the formation of wheaten bread,' says Sir H. Davy, 'more than one quarter of the elements of water combine with the flour; more water is consolidated in the formation of bread from barley, and still more in that from oats; but the gluten in wheat being in much larger quantity than in other grain, seems to form a combination with the starch and water, which renders wheaten bread more digestible than other species of bread.' From pretty accurate experiments, it has been found that the proportion of nutritive to the heat-forming principle in loaf-bread is as 1 to 7 and upwards: in milk, the natural food of all young mammalia, the proportion is as 1 to 2, from which it will be seen that bread alone, though popularly termed 'the staff of life,' is incapable of supporting a prolonged existence.

With regard to the other common forms of fermented bread, Dr Pereira in his valuable Treatise on Food has the following remarks:—'The *fine bread* prepared from flour only is the most nutritive and digestible. *Brown bread* made from wheaten meal, which contains bran, is laxative, and is used with effect by persons troubled with habitual constipation, as well as by those labouring under diabetes. *Hot Rolls* are indigestible, and unfit for dyspeptics and invalids; indeed all kinds of new bread are injurious. Rolls, both English and French, are made with a much larger proportion of yeast than is employed in ordinary bread. The different kinds of *fancy breads* are less adapted for the use of invalids, and of those who suffer from a tender stomach, than the common loaf-bread. *Compressed bread*—that is, bread which has been submitted to compression by the hydraulic press—becomes dry and hard, and may be kept for an almost indefinite period; it requires to be granulated before being used. *Rusks*, and *Tops and Bottoms*, are both made with wheat flour, butter, sugar, and milk, and a considerable quantity of yeast to give them lightness. Notwithstanding that they are frequently employed as infants' food, it is obvious that they are objectionable, on the double ground of containing butter and of being fermented.'

2. *Unfermented* or *unleavened bread* is prepared in two forms—either heavy and compact, or light and spongy. The former condition is that in which all the varieties of biscuits appear—the main ingredient in these being flour worked into dough with hot or cold water. *Sea biscuits*, so largely employed in the victualling of the navy, are composed of wheaten flour and a little bran: they are hard and heavy, and are difficult of mastication. *Biscuit powder* is not of course liable to this objection, and being prepared for use with hot water, is reckoned fair food for infants. The *captains' biscuits* of the ships are generally made of fine flour with a small proportion of butter; the so-called *Abernethy biscuits* are made variously by different bakers—most of whom add a little yeast, and flavour with caraway-seeds. In the numerous *fancy biscuits* now used, butter, milk, sugar, and the like, are indispensable ingredients; and for this reason little definite or favourable can be asserted of their dietetic properties.

The other form of unfermented bread is that in which, by the use of effervescing compounds, it is rendered light and spongy, and made to resemble ordinary loaf-bread. Numerous receipts have been given, and several patents taken out, for the manufacture of this species of bread, but all of them may be readily comprehended from a description of the original method. It is well understood, that if we take muriatic acid and carbonate of soda, and mingle them in due proportions, an effervescence will take place, carbonic acid is disengaged, and common salt (muriate of soda) is formed. Now if we take the soda and muriatic acid, and knead them as rapidly as possible with dough, an internal action will go on, the carbonic acid gas will raise the mass, the salt formed will season it, and if properly baked, a light, sweet, and nutritious bread will be the result. Such is the rationale of all the unfermented breads now so largely in vogue; though of course various bakers have adopted various ingredients, and hit upon different modes of applying them. Wheaten flour 7 lbs., carbonate of soda 350 to 500 grains, water $2\frac{3}{4}$ pints, and muriatic acid 420 to 560 grains, are said to form an excellent bread. A still finer and sweeter bread is said to be prepared from the following proportions:—Flour, 1 lb.; supercarbonate of soda, 40 grains; cold water, half a pint, or as much as may be sufficient; muriatic acid, 50 drops; and powdered loaf-sugar, a teaspoonful. According to Dr Robert Thomson of Glasgow, a good method of making unfermented bread is—to take of flour, 4 lbs.; supercarbonate of soda, 320 grains; muriatic acid, 6 fluid drachms; common salt, 300 grains; and 35 ounces of water by measure. The soda is first mingled with the flour very intimately; the salt is dissolved in the water and added to the acid—the whole being then rapidly mixed, as in common baking. The bread may be either baked in tins or formed like cottage loaves, and should be kept from one to two hours in the oven. Should it appear yellow, it is a proof that the soda has been in excess, and indicates the propriety of adding a little more acid—the acid varying somewhat in strength.

As to the merits of fermented and unfermented bread, medical testimony is in favour of the superior wholesomeness of the latter; at the same time that it is not so liable to become stale or sour. It has also the advantage in point of economy, there being no loss of nutritive principle through the destructive process of fermentation. 'The result of my experiments,' says Dr Thomson, 'upon the bread produced by the action of muriatic acid upon carbonate of soda, has been that in a sack of flour there was a difference in favour of the unfermented bread to the amount of 30 lbs. 13 ounces; or, in round numbers, a sack of flour would produce 107 loaves of unfermented bread, and only 100 of fermented bread of the same weight. Hence it appears that in the sack of flour by the common process of baking, 7 loaves, or $6\frac{1}{2}$ per cent. of the flour, are driven off into the air and lost. An important question now arises from the consideration of the result of this experiment: Does the loss arise entirely from the decomposition of sugar, or is any other element of the flour attacked? It appears from a mean of eight analyses of wheat flour from different parts of Europe by Vauquelin, that the quantity of sugar in flour amounts to 5·61 per cent. But it is obvious that, as the quantity lost by baking exceeded this amount by nearly one per cent., the loss cannot be accounted for by the removal merely of the ready-formed sugar in the flour. We must either ascribe this extra loss to the conversion of a portion of the gum of the flour into sugar, and its decomposition by means of the ferment—which is highly probable—or we must attribute it to the action of the yeast upon another element of the flour; and if we admit that yeast is generated during the fermentation of the dough, then the conclusion is inevitable that, besides the gum and sugar, the gluten (the nutritive principle) of the flour has also been affected.'

Among unfermented preparations from wheat flour may be classed a large variety of *cakes*, *pastry*, and *pudding*. From the amount of butter, lard, eggs, fruit, seasoning, &c. which they generally contain, they form a most indigestible kind of food, totally unfit for children, invalids, and those having a tendency to dyspepsia. 'All pastry,' remarks Dr Paris, 'is an abomination; and I verily believe that one-half at least of the cases of indigestion which occur after dinner parties may be traced to this cause.' While these remarks apply to ordinary bakers' cakes, pastry, suet pudding, and the like, there are certain light cakes, baked and boiled bread-puddings, which are not only agreeable, but wholesome and nutritious. The Italian preparations *maccaroni*, *vermicelli*, and *Cagliari paste*, consist of the finest wheat flour. The two former have their well-known forms given to them by forcing the tenacious paste through a number of holes in a metallic plate; the latter is pressed into the form of stars, rings, Maltese crosses, and the like. The nutritive qualities of all these preparations, according to Pereira, are identical with wheat; and when plainly cooked, as by boiling (maccaroni and vermicelli soup), they are easily digestible. *Semolina*, *mannacroup*, *&c.* are granular preparations of the finest wheat deprived of bran. They possess of course all the nutritious properties of wheat, and are very agreeable, light, and well fitted for children and invalids. The same remark applies to the so-called *farinaceous foods* of the druggist, which are either pure wheat flour subjected to some heating process which bursts the starch granules, or admixtures of wheat flour with that of barley or oats.

Barley (*Hordeum*), of which there are several varieties cultivated in the British islands, is one of the cereals found all over the temperate regions of the northern hemisphere—some of the varieties coming to profitable maturity even within the limits of the polar circle. As a staple of human food in northern countries, it is used in various forms: thus, freed from their husks by milling, the grains form *pot barley*, used for making broth; still more thoroughly freed from husky matter, and rounded and polished in the mill, they constitute *pearl barley*, used also in broth, and sometimes boiled in water and eaten as rice with milk; the common pot barley, ground to flour, forms the *barley-meal* of the Scotch; and from pearl barley similarly treated is obtained the *patent barley* of the shops. In any of these forms barley forms a wholesome and nutritious food; and it is much to be wished that it were consumed more in the solid state, and less in the liquid which is now so largely distilled from it.

The composition of barley has been variously stated. According to Einhof, the ripe grains yield 70 parts meal, $18\frac{3}{4}$ husky matter, and $11\frac{1}{4}$ water; and the meal so obtained consists of 67·18 starch, 4·62 gum, 5·21 sugar, 3·52 gluten, 1·15 albumen, 0·24 phosphate of lime with albumen, 7·29 fibrous matter (lignin, gluten, and starch), 9·37 moisture, and 1·42 loss. In 100 parts Norfolk barley, Sir H. Davy found 79 starch, 6 gluten, 7 saccharine matter, and 8 husk. Proust, Vauquelin, and others, have subjected this grain to analysis with very nearly the same results; and Dr Thomson adds that the gluten of barley is partially soluble in cold water, as is shown in the steeping of the grain for malting; but it coagulates in 120° or 130°, and falls down in gray-coloured flocks. He also extracted from the husks of barley a small quantity of an oily matter, of an asparagus green colour, and taste resembling that of spirits from raw grain, to which no doubt the flavour of whisky is owing. He likewise found in the specimens he analysed some nitrate of soda capable of crystallisation. From these data it will be seen that barley contains less nutritive matter than wheat, and that this matter is differently composed—that is, it has more mucilage, only about a third of the quantity of gluten, as much sugar, and nearly the same proportion of starch. On the other hand, it is lighter and less stimulating, and has the advantage of having no tendency to induce constipation; so that some persons who are habitually costive, derive advantage from the use of barley-meal cakes and porridge. We say cakes, for in consequence of the small quantity of gluten it contains, it is incapable of undergoing the panary fermentation, so as to form a light spongy loaf like flour from wheat. The barley *bannocks* or *scones* of northern countries are formed by kneading the meal thoroughly with water and a little salt, flattening the dough into cakes rather thin than otherwise, and toasting the same either on a hot iron plate or before a clear brisk fire. When new and properly made, bread of this kind is sweet and palatable; and though somewhat more difficult of digestion than wheaten bread, possesses the advantages already mentioned. *Barley water*, or a decoction of pearl barley, is reputed a soft and lubricating beverage, slightly nutritive, very easy of digestion, and recommended, with the addition of nitre, in cases of fever and inflammation. The Pharmacopœias give the following directions for its preparation:—Take two ounces and a-half of pearl barley; first wash away with water the foreign matters adhering to the seeds, then add half a pint of water, and boil for a little while. This liquid being then thrown away, pour on them four pints (imperial) of boiling water; boil down to two pints, and strain. It is frequently flavoured with sugar, and sometimes with slices of lemon-peel. *Compound barley water* is prepared by boiling together two pints of barley water, a pint of water, two ounces and a-half of sliced figs, half an ounce of liquorice root sliced and bruised, and two ounces and a-half of raisins. This composition is boiled down to two pints, and strained. It is said to be emollient, demulcent, and slightly aperient.

The Oat (*Avena*), of which there are also a number of varieties cultivated in Britain, is one of the hardiest of our cereals. It can be grown with advantage where neither wheat nor barley will ripen; and indeed thrives best under a cold climate like that of Scotland, if the soil on which it is planted be sufficiently dry. It cannot be cultivated in the south of Europe, and is altogether a staple for the inhabitants of high northern regions. The entire grain is largely used as food for horses; freed of the husk, it forms *groats* or *grits*, and these, when crushed, are termed *Embden groats*, and when ground to flour, *prepared groats*. In one or other of these forms oats are pretty extensively used as human food; but more largely as *oatmeal*, which is prepared by grinding the kiln-dried groats to various degrees of fineness, according to taste. This meal is not so white as wheaten flour, and has a peculiar agreeable odour, but somewhat bitterish taste. In various districts of the country it is used for making bread, porridge, puddings, and other preparations.

According to Sir H. Davy, 1000 parts of oats yielded 641 starch, 87 gluten, and 15 saccharine matter. Vogel found in 100 parts of the entire seeds 66 meal and 34 husky matter; and the meal so obtained to consist of 59 starch, 8·25 sugar and bitter matter, 4·30 gray albuminous matter, 2 fatty oil, 2·50 gum, and 23·95 husk, mixture, and loss. Dr Christison's analysis yielded 72·6 starch, 5·8 saccharo-mucilaginous extract, 3·2 albumen, 11·3 lignin (bran), a trace of oily-resinous matter, and 6·6 moisture. From these data it would appear that oats are inferior in point of nutrition to wheat, though, according to Boussingault, the difference is but small. Whatever may be the opinion of chemists, experience proves that they form a substantial nutritive article of diet, since many of the labouring classes in Scotland, in Lancashire, Derbyshire, Northumberland, and other parts of England and Wales, subsist chiefly upon bread, pottage, and other oaten preparations. Oaten food, according to Pereira, is apt to disagree with those having a tendency to dyspepsia: in other words, it is apt to become acescent on the stomach, and oat-bread, in particular, to occasion heartburn. With good digestive organs, however, and a proper amount of vigorous exercise, no inconveniences of the kind are experienced. *Porridge* or *stir-about*, which is composed of oatmeal, water, and a little salt, when well boiled, is one of the best forms in which oaten food can be taken, and eaten with milk, constitutes a capital breakfast. *Gruel* is described by the last-quoted authority 'a mild, nutritious, and, in most cases, an easily-digested article of food in chronic diseases, and in the convalescence from acute maladies. In some irritable conditions of the stomach, it is occasionally retained when many other foods are rejected; yet it is less demulcent than barley-water.' 'Unless gruel be very thin,' says Dr A. T. Thomson, 'it can scarcely be regarded as a diluent; and when thick, it is too heating an aliment for patients labouring under febrile symptoms.' On account of the nitrogenous principle which it contains, it is of course more nourishing than the starchy preparations (arrowroot, sago, tapioca, &c.) frequently employed in the sick chamber. It may be prepared either from oatmeal or ground groats (Robinson's, for example), and may be sweetened with sugar, acidulated with lemon-juice, or spiced. Butter should never be added in the case of the dyspeptic, or where the stomach is tender. *Oaten-cake*, unless made with scalding water, and well-fired, is apt to be heavy and heating; and as oatmeal contains too little gluten to undergo the panary fermentation, Dr R. Thomson recommends a loaf of equal parts of finely-sifted oatmeal and Canadian flour, which those who have tried it consider a great improvement on the hard dry oat-cakes, so much used by the peasantry in some parts of the country.

Rye (*Secale cereale*), though cultivated to some extent on the light sandy soils of our country, can scarcely be considered as one of the staples of British consumption. The small amount grown, however, generally meets with a ready market, partly for distillation, and partly for the making of a light spongy bread, having a peculiar but rather agreeable flavour.

According to Einhof, 100 parts of the entire seeds consist of 65·6 pure meal, 24·2 husky matter, and 10·2 moisture; and the meal so procured is composed of 3·27 albumen, 9·48 moist gluten, 11·09 mucilage, 61·09 starch, 3·27 saccharine matter, 6·38 husk, and 5·42 undetermined acid and loss. From this it would appear that rye contains more gluten than any other grain, except wheat, and therefore should be next to it as a bread-corn, were its other properties equally valuable. 'The husk,' says Webster in his 'Cyclopædia of Domestic Economy,' 'possesses an aromatic and slightly acidulous flavour, which renders it agreeable to the palate. The bran should not, therefore, be entirely separated from the flour; for if the grain be ground fine, and divested entirely of the husk, the bread will be deprived of much of its pleasant taste. Rye-bread is consequently made of coarse flour, which, together with its dark colour, has probably given rise to much of the dislike to it in this country. The quantity of gluten which it contains accounts for the facility with which it may be fermented into spongy bread, which is not the case with oats and some other grains. But bread made of it very soon becomes sour, indeed it undergoes an acetous fermentation in the process of baking, and is thought to have a gentle action on the bowels. In some farmers' families household bread is made of a mixture of one-third rye and two-thirds wheaten flour, which makes a sweeter bread than that solely of wheat, and is preferred to any other by those who are in the habit of using it. The bread is very firm and solid, and retains its juiciness and moisture long, being also very nutritious.' Though little used with us, rye-bread, under the title of black-bread, is largely consumed by the peasantry of Sweden, Germany, Russia, and other northern countries.

Rice—the *Oryza sativa* of botanists—is a plant of Asiatic origin, but is now extensively cultivated not only in China, India, and other Eastern countries, but in the West Indies and the southern states of America, as well as in the rich alluvial lands of Lombardy and in the province of Valencia in Spain. 'It is the grand material of food,' says Marsden, 'on which a hundred millions of the inhabitants of the earth subsist; and although chiefly confined by nature to the regions included between and bordering on the tropics, its cultivation is probably more extensive than that of wheat, which the Europeans are wont to consider as the universal staff of life.' Requiring a warm climate, it cannot be grown in Britain; but we import it largely—the Carolina and Patna rice being the most esteemed in the market. It is brought chiefly in the shelled or cleaned state; but of late, attempts have been made to import the *paddy*—that is, rice in the husk—with a view to obtaining the grains in a fresher condition.

Rice consists chiefly of farina or starch, 100 lbs. from Carolina yielding, according to Braconnot, not less than 85 starch, 5 fibrous matter, 4 glutinous matter, and 5 water, the remainder being sugar, gum, and phosphate of lime. It is therefore evidently much less nutritious than any of the preceding cereals, though it is light and wholesome, and altogether a very valuable food when taken along with milk or some corrective condiment. It is prepared as an article of food in various ways, either whole or ground. It may be used like barley in broth, boiled and eaten with milk, boiled and dried as a substitute for potatoes, as an accompaniment to curried dishes, or baked in puddings, which is perhaps the best mode of using it. What are called *rice-cakes* consist of about one-third of their weight of ground rice, the rest being flour, eggs, and sugar. *Rice-water*, employed like barley-water as a demulcent, is obtained by boiling well-washed rice in water. Though, on the whole, light and digestible, rice possesses a constipating quality, which somewhat detracts from its value as an article of habitual use.

Maize or *Indian Corn* is the produce of the *Zea mays* of Linnæus—a cereal found native in America, but now largely cultivated not only in the new world, but in several of the warmer regions of the old. As an article of human subsistence, it is extensively used in the countries where it is grown; but has not, till the recent failures of the potato crop, met with much attention in Britain. In America, the tender young ears, in their milky state, are roasted and eaten with butter and salt as a delicacy, or boiled with meat. When green, they are also pickled as gherkins; and dried, they keep all the year. When the grains are ripe, the skin is taken off, and the farinaceous part is boiled whole, or ground into meal, and made into cakes, puddings, &c. It is this meal which is chiefly known in Britain, and of which a variety of puddings, cakes, and loaves have been recommended.

Being extremely productive, maize can in general be cheaply procured; hence the importance in years when the staple of our own country fails. According to chemists, 100 parts of the entire corn contain upwards of 80 starch, from 5 to 9 of a peculiar fatty principle, 2 saccharine matter, 2 gum, and small proportions of various salts of lime, &c. Such data do not certainly speak highly of its nutritive qualities, and yet we find those who live chiefly upon it robust, healthy, and fond of it as an article of diet. It is somewhat laxative, and requires to be taken with caution till the system becomes habituated to its use. To make good palatable *maize-bread*, Dr R. Thomson recommends the grains to be reduced to a fine meal, and then mixed with one-third its weight of best flour, and fermented. When thus prepared, the bread is dark-coloured, and cannot be made much lighter than coarse wheaten bread. The shade, however, is of a peculiar yellow, not to be mistaken for that of wheat, besides that the taste is altogether different.

Peas and *Beans*, which belong to the leguminous order of plants, are consumed partly in a green state, and partly when ripe and dried. It is the latter state with which we have at present to do; and it may be stated generally, that their meal or farina is now but little used as an article of human food. Peas, split or whole, are used in the preparation of peas-soup; their meal, either pure or mixed, is still employed in some districts in the making of cakes; and, very finely ground and bolted, it is used as a supper diet, under the name of *Glasgow brose-meal*. With regard to the amount of nitrogenous or nutritive matter which pulse and lentils contain, it is far beyond what is found in any of the cereals, being as 44 or 50 to 100 of wheat flour. The nutritive effect, however, does not agree with this theoretical conclusion, partly from their deficiency in other wholesome constituents, and partly from the difficulty with which they are digested, the flatulence and costiveness they occasion, as well as from the acridity they are said to communicate to the blood.

Sago—Tapioca—Arrowroot.—Of a considerable number of foreign starchy or amylaceous products, these are the most extensively used, and best known in Britain. The first is the produce of the sago palm (*Sagus rumphii*), a native of the East Indies and Indian Archipelago. 'The part which affords the sago is the pith; and to procure this, the body of the tree, when it is full grown, is sawn into pieces, and the raw sago cut out and put into a trough with water, in which it is well stirred, to separate the flour from the woody fibre. This is now suffered to rest, and the flour subsides to the bottom. The water is then poured off, and the meal laid upon wicker-frames to dry. To form it into the round grains in which it is imported, the sago, when moist, is passed through a cullender, and rubbed into little balls, like shot, and then thoroughly dried. The sago-tree requires to be seven years old before being fit for felling; and a full-grown specimen will yield about 600 lbs. of sago. The best sago is of a slightly pinkish hue, and readily dissolves to a jelly in hot water. Several other trees beside that above-mentioned yield sago, but neither so abundantly nor of so excellent a quality.' The sago of commerce is imported either as sago-meal, pearl-sago, or common brown sago, which states have reference more to its form than composition. In all, the main constituent is starch, which, being light and easily digestible, renders sago an eligible substance for the dyspeptic and invalid. *Sago-puddings* (made like tapioca) are by no means uncommon; but the common mode of use is *sago-milk*. This is prepared by soaking the sago in cold water for an hour, pouring off this water, and then either boiling slowly in milk, or in a little water to which milk is afterwards added. This mixture may be taken plain, or sweetened and seasoned to taste.

Tapioca is obtained from the tuberous root of the *Janipha manihot* by grating and washing. It is usually met with in small irregular lumps, a form it has acquired by being dried on hot plates. The heat breaks the starch globules, and renders them partially soluble in cold water. In boiling water tapioca becomes gelatiniform, transparent, and viscous. 'In its nutritive qualities,' says Pereira, 'it agrees with sago, than which it is much purer, being free from colouring matter. It also yields a more consistent jelly than some other kinds of starch. It is principally employed as an agreeable light nourishment for invalids, as well as for children.' 'No amylaceous substance,' says Christison, 'is so much relished by infants about the time of weaning; and in them it is less apt to become sour during digestion than any other farinaceous food, arrowroot not excepted.' Tapioca-milk is made in the same way as sago-milk; but tapioca being more soluble than sago, requires only half the time for its preparation.

The pure white amylaceous powder known as arrowroot, is obtained from the tubers of the West Indian plant *Maranta arundinacea*. It makes a tolerably strong jelly, stronger than that of wheat starch, and is free from colouring matter, and also from any unpleasant taste or odour. It is used either in the preparation of puddings, gruel, or milk, like sago and tapioca. 'The best arrowroot we have,' says Webster, 'is from Antigua, Jamaica, and Bermuda; but a great deal of what is sold in London is adulterated with potato-starch, which, though a substance not very different, has not precisely the same properties. Arrowroot, like every kind of starch, boils to a jelly, but it differs from potato-starch in this respect: the jelly formed from arrowroot will remain firm for three or four days without turning thin or sour, whereas the jelly from potato flour, in the course of ten or twelve hours, becomes thin as milk and acescent; hence it is not so well calculated for food, and particularly infants.' The proper value of all these starchy substances, however, is now much better known; and as starch can only supply heat-forming matter, the purer they are, the less fitted are they for the purposes of nutrition. As food for the young, they are by far too largely employed, as are all those so-called 'farinaceous compounds' of the quack and medicine-vender. 'The best American wheat flour, good Scotch oatmeal, and barley-meal,' says Dr R. Thomson, in his Experimental Researches, 'may all be employed at different times, by way of variety, and repeated according to their agreement with the child's organs of digestion. The digestion of all these forms of food containing starch is greatly promoted by long boiling either with water or milk, as this process is just so much saved to the intestinal organs. It is thus obvious that we have a great variety of food fitted for children, of which we know the composition, and that we should prefer it to any species of compounded stuff of the constitution of which we are ignorant.'

The Potato (*Solanum tuberosum*) is one of our most abundant amylaceous or starchy vegetables, and next to the cereals, is one of the most common articles of human food. Originally discovered in South America, it is now introduced into almost every quarter of the globe, where it seems to thrive, and to break into innumerable varieties, differing in shape, size, colour, flavour, and quality. Without noticing minutely the peculiarities of the numerous varieties, we may remark that those of middling size, and which become white, mealy, and void of any especial flavour when boiled, are in general the most esteemed, as they are the most wholesome and nutritious. As they are an easily-raised crop, producing twice as much food from the same extent of land as wheat, potatoes are very largely grown in the British islands, and notwithstanding the recent failures, are likely still to be so. The disease to which we allude having drawn much attention both to their natural history and economical importance, there is perhaps no object of culture or article of diet which has elicited so many and contradictory opinions. Some would apparently have the potato altogether eradicated from our soil; others, taking a more modified view, would 'never allow it under any circumstances to occupy, as the staple aliment of any class of our population, the place of the grain-bearing plants;' while a third party see in it 'a cheap and available source of subsistence to the poor, which has had, in addition, much effect in lessening the prevalence of scorbutic, calculous, and arthritic disorders.' Without pronouncing dogmatically on the subject, we shall merely present the leading dietetic properties of the potato, as set down by Liebig, Pereira, and Webster. The most correct opinion respecting the nutritive properties of potatoes will be obtained from the consideration of their constituent principles. They have been analysed by various chemists. The analysis of Einhof, which is generally considered the best, is in 100 parts—water 72·6, starch 15, fibrous matter 7, albumen 1·4, and mucilage 4. Here it is essential to observe the large proportion of water, and it is only the remainder that is to be considered as farinaceous. Like all the *Solanaceæ*, or Nightshade family, the potato contains a poisonous principle (solanine); but this is wholly destroyed by cooking. Citric and tartaric acids are also said to be present in various parts of the growing plant, and to these are likely to be ascribed the reputed antiscorbutic properties of the tuber. The fibrous matter in Einhof's analysis appears to be a peculiar modification of starch, which, as well as that substance, may be employed for food; but it is to be noticed that there is no gluten, except the albumen may be considered as nearly the same thing. Various kinds of potatoes afford these constituents in proportions a little different; but the preceding may be considered as the average of the best mealy potatoes—the alimentary part being about 27 per cent., of which starch is the principal ingredient. No doubt can be entertained of their wholesome nature, when we consider the numerous hardy peasantry of Ireland, many of whom subsist entirely upon this useful vegetable. It must not, however, be imagined that potatoes contain the same nutritive powers as bread, weight for weight. It has been estimated, as the result of experiments made by Percy and Vauquelin, that one pound of good bread is equal to two and a-half or three pounds of potatoes, and that seventy-five pounds of bread and thirty of meat are equal to three hundred pounds of potatoes.

In Britain, potatoes are generally brought to table boiled plain; but in France they are cooked in a great variety of ways, and furnish very agreeable dishes. *Potato soup* (see PREPARATION OF FOOD) is a very palatable and thrifty mode of cooking; and *mashing* them with various ingredients, though it produces a more savoury dish, does not certainly contribute to their digestibility. 'It is of little signification, as affecting the digestibility,' writes Dr Robertson, 'whether the potato be roasted or baked, or boiled, provided the quality and the cookery be unimpeachable. They are probably more nutritive—that is, contain more azotised matter, if boiled with their skins on, than if peeled before boiling; but it is equally probable that they are more easily digested if peeled before they are boiled. The new or immature potato is much less easily digested than the fully-ripened tuber, and should certainly be forbidden to the majority of dyspeptics. Early and forced potatoes must be less easily digested than those which have been grown with the advantages of free exposure to the air and the sunshine.' As already stated, potatoes are used in the manufacture of loaf-bread; and *potato starch*, which is nothing more than dry starch powder, is used not only in fine bread and pastry, but as a substitute and adulterant of arrowroot. *Bright's nutritious farina* is said to be a carefully-prepared potato starch, slightly scented; and we believe several of the 'farinaceous foods' of the shops are of similar origin. The most that can be said of them is, that they are sufficiently light, and not unwholesome, but by no means nutritious.

The *Cabbage tribe* (*Brassica*), which includes the common white and red cabbages, the savoy, greens, cauliflower, broccoli, &c. is pretty extensively cultivated in Britain (See KITCHEN GARDEN) for the purposes of human food. The parts used are the leaves which *heart* or gather together; and in the case of the cauliflower and broccoli, it is the young and compact flowering heads. As nutritive products, they rank high theoretically—dried cabbage being set down by Boussingault as 83 to 100 of wheat flour; but as they contain upwards of 90 per cent. water, a larger quantity requires to be consumed for the purposes of nutrition than would be either wholesome or agreeable. For healthy constitutions they supply a valuable mixture with animal food; but for the dyspeptic, they are apt to prove indigestible, and productive of flatulency. They are usually recommended to be well boiled; and like all the Cruciferous order, to which they belong, possess valuable antiscorbutic qualities.

The Turnip (*Brassica rapa*), which belongs to the same family, is perhaps still more largely consumed. The varieties best adapted for human food are the Swedish, yellow, and Dutch—all of which contain a considerable quantity of sugar and mucilage, but little or no gluten. 'A hundred parts of turnip bulb yielded Boussingault 92·5 water, and 7·5 solid matter; and this, when dried, only 1·7 of nitrogen—being but a third of the amount found in dried cabbage. Sir H. Davy estimates the nutritious matter of turnips at about 4 per cent.; but though thus slightly nutritive, they form an excellent culinary vegetable, and are either eaten alone, mashed, or cooked in soups or stews. Pereira regards them as of easy digestion, and has never seen them produce flatulence when well boiled. Turnip tops, or the young leaves gathered in spring, are occasionally used in England as greens, but are very apt to disorder the bowels.

The Carrot and *Parsnip* are two well-known umbelliferous roots, possessing highly-nutritive properties, if chemical composition is to be taken as the test of alimentary value. They contain vegetable fibrine, albumen, sugar, and a volatile oil; 1000 parts yielding 95 sugar and 3 starch, or about six times the amount of sugar found in potatoes. They are valuable culinary vegetables in soups and stews, and ought to be much more largely used. The fibrous matter they contain renders them somewhat difficult of digestion if not well boiled—a matter admitting of very easy remedy.

Beet-root, though largely made use of on the continent, is chiefly employed in England as a garnish for salads and other dishes, and as pickle. According to the experiments of M. Achard, 14 lbs. of beet yield 1 lb. of sugar; hence the manufacture of sugar from this root, and hence also its value in a culinary point of view. During the recent potato failures, various preparations of beet were recommended as a food for the poor; and among others, *beet-bread* from an admixture of finely-rasped beet and wheaten flour, fermented and baked in the usual form. 'We have had the experiment tried,' says Dr Lindley, 'by rasping down a red beet-root, and mixing with it an equal quantity of flour; and we find that the dough rises well, and forms a loaf very similar to good brown bread in taste and appearance. We regard this,' he continues, 'as an important discovery, because no crop is so readily cultivated, or will yield so large a return as beet, and likewise because of its great value in point of nutrition. In its relation to potatoes it stands as 1020 to 433, if its nutritive quality is considered; and as 6630 to 3480 in regard to utilisable produce of all kinds.' We may add, that either the red beet, the white sugar beet, or the carrot, may be used with success in this manner.

Of the vast variety of garden vegetables used as salads, pickles, garnishes, and so forth, none of them are consumed in such abundance as to entitle them to especial notice. Many of them are no doubt useful, others are useless, and not a few positively hurtful, though fashion and caprice may give them a place on our tables. Some notice of the more prominent—as lettuce, radish, spinach, celery, asparagus, artichoke, parsley, cress, onion, and the like—will be found under KITCHEN GARDEN, COOKERY, and MEDICINE.

Sugar.—As already mentioned, sugar exists both in vegetable and animal substances, but more abundantly in the former. In many of the products already noticed, the saccharine principle forms no unimportant item, though not in such proportion as to be considered characteristic. We now come to consider it as a distinct principle, and as an article of vast dietetic importance. Sugar, as a vegetable product, is found in considerable quantity in such dried fruits as the currant, raisin, fig, date, tamarind, and so forth; and these are now pretty largely consumed in Britain. Thus figs yield about 60 per cent. of sugar, tamarinds 12, prunes 16, and dates 35; and there can be no doubt that these, as well as many of our ripe fleshy fruits, owe their chief alimentary value to its presence. It is, however, as a separate and prepared article that we have now to do with it—as a substance obtained by art from the sugar-cane, the maple, the beet, the palm, and other plants yielding it in abundance. Though procured from the maple in America, from the beet on the continent, and from the palm in the East Indies, it is solely from the sugar-cane of the tropics that Britain obtains her supply, amounting annually to upwards of 5,000,000 hundredweights. When the canes, of which there are several varieties, have attained a certain height and age (about twelve or thirteen months), the cuticle having become smooth, dry, and brittle, they are cut, stripped of their leaves, and crushed between rollers to express the juice, which is mixed with lime, to saponify, and render more liquid and separable the uncrystallisable portion, known as molasses or treacle. The juice is now heated to the temperature of 140°, and separated from the scum, and again heated several times, and at length allowed to drain, for the separation of the *molasses* and the crystallisation of the sugar. The *raw* or *brown sugar* thus formed is again purified, by being dissolved in lime water mixed with bullock's blood: the one serving still more to separate the molasses, the other, by the coagulation of the albumen, effecting the clarification and mechanical separation of any foreign insoluble matters. Reduced to a certain syrupy consistence, the sugar is poured into moulds, and agitated for a certain time, to prevent the formation of large crystals, and secure a compact mass of closely-adherent, small, and glistening grains. This constitutes *loaf-sugar*, the quality of which depends greatly on the lowness of the temperature at which the boiling has been effected. When sugar thus refined has been again dissolved, and left to crystallise slowly at a somewhat elevated temperature, in boxes crossed with threads, to form centres of crystallisation, *sugar-candy* is formed; or if sugar so dissolved is made to cool more quickly, a transparent solid is obtained, known as *barley-sugar*. Sugar in one or other of these states constitutes the basis of almost all *confectionary*, as acidulated drops (sugar and tartaric acid), toffee, hardbake, comfits, lozenges, and the like. It forms also an excellent antiseptic, and for this purpose is used as a *syrup* for preserving fruits, roots, &c., as well as for the curing of meat and fishes.

In whatever form sugar or the saccharine principle may be made to appear in commerce or in diet, its ultimate composition, when pure, is carbon, oxygen, and hydrogen; or more simply, carbon and water. It contains no azotised principle, and thus its function in the animal economy is to supply heat, and not nutrition. Thus 100 parts of pure sugar-candy yield 42·85 carbon, and 57·15 water; refined sugar 41·5 carbon, 58·5 water; and raw sugar 40·75 carbon, and 59·15 water. According to the quantity of water which any sugar contains, so it is denominated *high* or *low;* that from the cane being a higher or stronger variety than that from the grape, and sugar-candy a higher form than that of raw sugar. Theoretically, therefore, sugar is merely an element of respiration—a result at variance with the common notion that it is nutritious. 'During the sugar season of the West India islands,' says Dr Wright, 'every negro on the plantations, and every animal, even the dogs, grow fat.' But the accumulation of fat is a diseased rather than a healthy condition; and though sugar, as furnishing the respiratory carbon and the fatty tissue, may be termed nutritious, it is certainly insufficient to sustain existence without the addition of some nitrogenous article of diet. 'The fondness of children for saccharine substances'—we quote Pereira—'may be regarded as a natural instinct; since nature, by placing it in milk (woman's milk contains upwards of 6 per cent. sugar), evidently intended it to form part of their nourishment during the first period of their existence. Instead, therefore, of repressing this appetite for sugar, it ought rather to be gratified in moderation. The popular notion of its having a tendency to injure the teeth is totally unfounded; Dr Wright informs us that no people on the earth have finer teeth than the negroes of Jamaica. Sugar is readily digested by the healthy stomach; though in some dyspeptic individuals it is apt to give rise to flatulency and preternatural acidity of the stomach. In some diseases—as diabetes, for example—it should be altogether excluded from the diet.' Contrary to this opinion as to the digestibility of sugar, Dr Robertson pronounces pure sugar to be 'by no means easily digested,' and that it only becomes so when sufficiently mixed and diluted with other juices. Molasses, on the other hand, from containing more component water, is more easily digested, at the same time that it is usually laxative in its effects. It is still, nevertheless, saccharine matter, and is still apt to irritate the digestive organs, and by so much to interfere with and derange the processes of ultimate assimilation.

Honey, though, strictly speaking, obtained through the medium of the animal kingdom, may with little impropriety be considered in this place. It is but a weaker form of sugar, and although elaborated by the bee, is still found ready-made, if we may so speak, in the flowering apparatus of many plants. It consists chiefly of cane and grape sugar, or, in other words, of crystallisable and uncrystallisable sugar, and according as the former predominates, so is its quality superior. Besides these two sugars, honey also contains a free acid matter not yet well understood, mucilage, sometimes a little wax, together with colouring and aromatic matter. These adjuncts differ, according to the kind of flowers on which the bees feed; and occasionally honey has been known to possess narcotic and poisonous properties. Its dietetic properties are thus spoken of: —Like treacle, honey often acts as a laxative, and to a greater degree. But, like all other concentrated forms of saccharine matter, the digestibility of honey is only a comparative question; and although honey may be much less apt to derange the functions of assimilation than cane-sugar or treacle, it is nevertheless by no means easily digested when the stomach is either weakened or otherwise less equal to its duties; and should always be used cautiously by the dyspeptic, if used at all by them. With some constitutions it by no means agrees, and has to be carefully avoided.

The fleshy fruits, as the apple, pear, plum, peach, and the like, though generally consumed during their seasons, cannot be regarded as a staple of food. Excluding water, which enters largely into their composition, they consist of sugar and mucilage, with peculiar acids. Any alimentary value they therefore possess, may be estimated from what has been already stated of sugar: some, as the pear and apple, are employed in the manufacture of BEVERAGES; and as to their acid properties, these will be fully considered under the principles of MEDICINE.

ANIMAL FOOD.

Animal, like vegetable substances, are resolvable into ultimate and proximate principles. The *ultimate elements* of 100 parts ox blood, for example, are—51·95 carbon, 7·17 hydrogen, 21·39 oxygen, 15·07 nitrogen, and 4·42 insoluble mineral matter. Again, 100 parts beef yield 52·59 carbon, 7·89 hydrogen, 19· oxygen, 15·22 nitrogen, and 3·30 insoluble ingredients. Comparing this with what has been said of vegetables, the vast preponderance of nitrogenous or nutritive matter will be readily perceived—thus giving to animal food a theoretical more than a practical superiority, inasmuch as nature seems to have intended our food to be used in a form rather coarse—requiring full mastication, insalivation, and a longer retention in the stomach. The *proximate principles* of animal food are—fibrin, or the fleshy fibre of meat when boiled to rags; gelatine, or animal jelly; albumen, as white of eggs; oil and fat; osmazome, which gives to meat its peculiar flavour; kreatine, a peculiar crystallisable juice; casein, such as the curd of milk or cheese, which is nearly allied to albumen; and, we may add, sugar, as in the case of milk. Of these principles are all animal bodies composed; always bearing in mind the large percentage of water which they contain. These principles vary considerably in ultimate composition—thus 100 parts of fibrin yield 53·36 carbon, 7·02 hydrogen, 19·68 oxygen, and 19·93 nitrogen; while albumen yields 50·00 carbon, 7·78 hydrogen, 26·67 oxygen, and only 15·55 nitrogen. Of course their relative values in point of nutrition depend upon the ultimate constitution; and this must be obtained with accuracy before any comparison can be instituted between fibrin and gelatine, gelatine and albumen, or albumen and casein.

In treating of animal food, some writers attempt to classify it according as it may be derived from the flesh, blood, viscera, bones, cartilages, ligaments, cellular tissue, milk, &c. As our limits, however, prevent any such minute consideration, we shall merely remark, that all these portions of the animal body are less or more prized and made use of; and that they differ in nutritiousness not only according to the kind or species of the animal, but according to the age, sex, food, and mode of life of the individual. Thus the flesh of young animals is more tender than that of old; that of the entire male adult coarser and tougher than that of the female; while the flesh of castrated animals is more delicate, tender, and better flavoured than that of animals left entire. Again, feeding and exercise are not without their influence; and just as the fibres of flesh are loose, tender, and minute, so are they the more easy of digestion. With these preliminary remarks, we shall proceed to notice in detail the leading articles of animal food made use of in Britain:—

Beef, or the flesh of the full-grown ox, is largely consumed in Britain, perhaps more largely than a due regard to health and economy would allow. The quality of this article depends upon a variety of circumstances, such as the breed, sex, and age of the animal, and likewise the kind of food with which it has been supplied. 'Bull beef,' says a leading authority on cuisine, 'has a strong disagreeable flavour, and is dry, tough, and difficult of solution. The flesh of the ox is more soluble; the fat is better mixed, the meat more sapid, and highly nourishing and digestible if the animal is not too old. The flesh of the cow is sufficiently fit for nourishment, but is inferior to ox beef; *heifer* beef, or that of the young cow, is much esteemed, but that of an old fatted cow is bad. The beef of the larger varieties of the ox is inferior to that of the smaller breeds; the former is in perfection from five to seven years old; the latter may be taken a year or two sooner. Grass-fed beef, or that produced from good farm produce, is always better-flavoured and more digestible than that reared from oil-cake, brewers' wash, and the like.' Beef is consumed both in a fresh and salted state; it is also pickled, smoked, and otherwise prepared. Salted, it is more difficult of digestion, while the salt, moreover, destroys a considerable portion of its albumen. Preserving it fresh in hermetically-sealed vessels, from which the air has been expelled, is now extensively adopted, with the best results. For various modes of pickling and preserving, as well as for an estimate of the comparative merits of boiling, broiling, and roasting, the reader is referred to the following article on the PREPARATION OF FOOD.

Veal, or the flesh of the calf, is tender and nourishing, but not so easy of digestion as the prime parts of beef and mutton. Veal, particularly if it be young, contains much gelatine, as is the case with all young animals, and therefore yields a great deal of soluble extract when boiled long in water. This fact has led to the idea of its being more nourishing than meat which is less soluble; but this does not follow, for the gastric juice acts differently from water, and can digest what that fluid cannot. Veal contains less nitrogenised matter than beef, as well as a smaller proportion of proteinaceous compounds.

Besides beef and veal, strictly so called, the intestines (tripe), heart, lungs, bones, marrow, cartilage, &c. of the ox are variously made use of; none of them, however, possessing the same amount of nutritious matter as the true flesh, nor being so digestible and wholesome. 'Animal flesh being identical with our own flesh and blood, say chemists, it requires neither addition nor subtraction to render it nourishing;' but in order that it may reach the different organs, it is necessary that it should be reduced to a liquid form (blood). It is for this reason that true flesh is preferable to liver, for example, which contains a peculiar oily matter; to kidney, in which urea has been detected; to heart, which is densely muscular and indivisible; or to tripe, which, though light and easily digested, consists chiefly of fibrine and albumen.

Mutton, or the flesh of the full-grown sheep, is also extensively consumed in Britain, and that almost wholly in a fresh state. Compared with beef, it is lighter, and more easily digested, owing very probably to the greater fineness of the fibres. 'The quality of mutton,' says the authority already quoted, 'varies much in the different breeds. In the large long-haired sheep (see No. 38) it is coarse-grained, but disposed to be fat. In the smaller and short-wooled breed the flesh is closest grained and highest flavoured; but the quality is probably most affected by the food on which the flocks are fed. Those which range over the mountainous districts of Wales and Scotland, or the chalk downs of England, and feed upon the wild herbage, possess a flavour very superior to those kept on rich pastures and marsh land. Marsh-fed mutton often becomes extremely fat, but the meat has a rank taste. Turnips, hay, chaff, bean, corn, and other vegetables, as likewise oil-cake and grains, are employed for fattening sheep; but such mutton is never so good as that produced where the animals range at freedom. *Tup* mutton, or the flesh of the ram, has a strong disagreeable flavour, and is usually tough; ewe mutton, if under two years old, is good, but after that, it becomes hard and tough; wedder mutton is the most esteemed. Mutton is in perfection at five years old, being then sapid, full-flavoured, and firm, without being tough; and the fat has become hard. Mutton under three years old is deficient in flavour, and is of a pale colour. *Lamb*, as the flesh of the young sheep is termed, is more tender and less exciting than mutton, but is not readily digested; nor is it improved in this respect by the mint sauce, sliced lemon, and other absurdities with which it is usually accompanied. It receives the name of lamb from the time it comes into season, in April or May, till the ensuing Christmas.

Pork, or the flesh of the pig, is invariably set down by writers on dietetics as difficult of digestion, but less so when pickled and cured than when fresh. 'The fat is so intimately mixed with the lean, and the tissue between the fibres contains so much of it,' say they, 'that it is utterly impossible to separate the one from the other. A man must therefore have unimpaired powers of digestion to render it nourishing, and a stomach that is not easily irritated to render it wholesome.' Notwithstanding, it is largely consumed, and forms a useful and economical diet for those leading an active and laborious life, chiefly, however, in a cured state—the preparation of the salted article for home consumption or exportation forming a large and flourishing business. Those who pursue the occupation cut the carcass in pieces, and pack it in kits formed to hold from one to two hundred pounds' weight. A brine is then made by dissolving salt in water, until the mixture is so thick that an egg will swim in it. This is boiled, and poured upon the pork after it has cooled. Russian pork, always much esteemed, is steeped in a brine containing 2 lbs. of loaf sugar and 3 ounces of saltpetre, to 6 lbs. of salt, the whole being boiled in six gallons of water. After brine is added to pork in kits, the end of the receptacle is fixed in, and the article is usually sufficiently cured in a few days.

Hams are the cured hind-legs of the pig, and are considered the finest parts of the animal. They are generally in great request, and form an article of extensive consumption in Britain. The following are general directions for curing them:—In the first place, the legs require to be cut in a neat rounded form, and it is usual to prepare a number at a time. Being properly prepared, pack them with rock-salt in a suitable tub or cask, being careful not to lay the flat sides of the large pieces upon each other, and filling the intervals with hocks, jowls, &c. To every 200 lbs. of meat, then take 20 lbs. of rock-salt, or Onondago coarse salt, 1 lb. of saltpetre, and 14 lbs. of brown sugar, or half a gallon of good molasses, and as much water (pure spring water is the best) as will cover the meat; put the whole in a clean vessel; boil and scum; then set it aside to cool, and pour it on the meat till the whole is covered some three or four inches. Hams weighing from 12 to 15 lbs. must lie in the pickle about five weeks; from 15 to 25 lbs., six weeks; from 25 to 45 lbs., seven weeks. On taking them out, soak them in cold water two or three hours, to remove the surface salt, then wipe and dry them. It is a good plan, in cutting up, to take off feet and hocks with a saw instead of an axe, as it leaves a smooth surface, and no fractures for the lodgment of the fly. Some make only six pieces of a trimmed hog for salting, but it is more convenient, when intended for domestic use, to have the side pork, as it is called, cut in small pieces. The goodness of hams and shoulders, and their preservation, depend greatly on their smoking, as well as salting. The requisites of a smoke-house are, that it should be perfectly dry; not warmed by the fire that makes the smoke; so far from the fire, that any vapour thrown off in the smoke may be condensed before reaching the meat; so close as to exclude all flies, mice, &c. and yet capable of ventilation.

Bacon is the whole side of a pig cured. The method of preparation is as follows:—After being killed, the carcass should not be scalded to remove the bristles, as in the case of pork, but singed off by being covered lightly with straw, to which fire is applied. When the burning straw has cleared one side, the other side may be cleared in the like manner. By this means all the hair is to be singed clean off, but without scorching the flesh, and then the skin is to be well scraped as a finish. This singeing process gives a fine firmness to the bacon, which scalded bacon never possesses. In Hampshire, as Mr Cobbett informs us in his 'Cottage Economy,' the plan of singeing is universally followed; and pig-keepers could not have a better example. The next steps in the process are related as follows by this writer:—'The inwards are next taken out, and if the wife be not a slattern, here, in the mere offal, in the mere garbage, there is food, and delicate food too, for a large family for a week, and hog's puddings for the children. The butcher the next day cuts the hog up, and then the house is filled with meat; souse, griskins, blade-bones, thigh-bones, spare-ribs, chines, belly-pieces, cheeks, all coming into use one after the other, and the last of the latter not before the end of about four or five weeks. All the other parts taken away, the two sides that remain, and that are called *flitches*, are to be cured for bacon. They are first rubbed with salt on their insides, or flesh sides, then placed one on the other, the flesh sides uppermost, in a salting trough, which has a gutter round its edges to drain away the brine; for, to have sweet and fine bacon, the flitches must not lie sopping in brine, which gives it that sort of taste which barrel-pork and sea-junk have, and than which nothing is more villanous. Every one knows how different is the taste of fresh dry salt from that of salt in a dissolved state; the one is savoury, the other nauseous; therefore change the salt often; once in four or five days. As to the time required for making the flitches sufficiently salt, it depends on circumstances—the thickness of the flitch, the state of the weather, the place wherein the salting is going on. It takes a longer time for a thick than for a thin flitch; it takes longer in dry than in damp weather; it takes longer in a dry than in a damp place. But for the flitches of a hog of twelve score, in weather not very dry or very damp, about six weeks may do; and as yours is to be fat, which receives little injury from over-salting, give time enough, for you are to have bacon till Christmas comes again. The place for salting should, like a dairy, always be cool, but always admit a free circulation of air; confined air, though cool, will taint meat sooner than the mid-day sun, accompanied with a breeze. The flitches of bacon are now to be smoked, for smoking is a great deal better than merely drying, as is the fashion in the dairy counties in the west of England. Great attention should be paid to this matter: the flitch ought not to be dried up to the hardness of a board, and yet it ought to be perfectly dry. Before you hang it up, lay it on the floor, scatter the flesh side pretty thick over with bran, rub it on the flesh, and put it well down upon it. This keeps the smoke from getting into the little openings, and makes a sort of crust to be dried on, and, in short, keeps the flesh cleaner than it would otherwise be.'

Bacon has been much vaunted by some as a remedy for indigestion, while by others a totally different opinion is entertained. 'In the large majority of cases,' says Dr Robertson, 'it cannot be so; but, on the contrary, must tax still further the powers of the stomach, or irritate still further its tissues, which under such circumstances may be already in a state of morbid sensitiveness. Bacon is obtained from the most difficultly-digested of the meats, the fleshy fibres of which are toughened by the salt and by the drying. That fat is rendered more digestible by being impregnated with salt, is an admitted fact; and this must of course qualify these strictures on the use of bacon. But the lean of bacon is rendered more difficult of digestion by the same process that has increased the digestibility of the fat; and the fat is not by any means so altered in character, as no longer to irritate the debilitated stomach. I have no hesitation in saying, that in the greater number of cases of dyspepsia bacon does harm.'

Brawn.—Boars are also fattened for the purpose of procuring an article of food under this name. Male pigs of all ages are put into feeding with this view, but those experienced in such matters prefer them of the age of two years. They are kept separately, in pens which will not permit of their turning round, perfect inactivity being held to conduce to their fattening. Their food is beans, with water, into which a small quantity of sulphur has been put. The collar of the animal is the part prepared for brawn, by the process of pickling and drying. A large collar will weigh about thirty pounds, and is valued at about £3 in the market.

Lard is that part of the fat of the pig which melts easily, and forms a fine, soft, white grease. It is extensively used not only in household economy, but by the pastry-cook, apothecary, and perfumer. It should be, according to Martin Doyle, of *two* qualities: the finest and whitest (that taken from the sides) should be chopped into small pieces in a pan, over a slow fire, and kept constantly stirred, lest it should stick to the sides of the boiler; then strained, and put into bladders turned inside out, and thoroughly purified by having all the fat cut out, and being well blown and dried in the open air. That of the first quality, when well made, is far better than any salt butter for cookery, and, from the delicacy of its colour, is used by confectioners for the finest kinds of cake and pastry. The inferior lard is obtained from the intestines, and is treated as the finer lard in every particular. The *blood* of the pig, we may also observe, furnishes a distinct article of food—being used in the preparation of the black-puddings of the shops.

Venison—Hare—Rabbit.—The flesh of the deer, hare, rabbit, and other game found in the British islands, can never be considered as an article of general consumption. The comparative scarcity of these animals, and the fact that they are in season or fit for food only during the colder months of the year, when they become objects of fashionable capture, render them more as luxuries for the middle and higher classes, than a staple of food for the bulk of the population. The ultimate analysis of their flesh is much the same as that of the domestic animals, differing, however, in proximate character, and also in containing certain flavouring principles of a bitter or acid nature. From their constant motion and exercise, wild animals acquire a drier and harder flesh than that of the tame; and those parts which have the least motion, as the back of a hare, for example, are most juicy and palatable. From the same cause, the fluids of these animals are more heating, and much more apt to putrefy than the fluids of the domestic kinds.

The term *venison*, though applicable to the flesh of all animals which are caught by way of hunting, is generally restricted to that of the deer kind, as the buck, the doe, the hart, and the hind. When well fed, killed at the right season, and properly dressed, venison forms a palatable as well as a wholesome and readily digested food. 'Chymification,' says our highest authority on this subject, 'is most easily effected on a soft solid, which is easily divisible into shreds or small particles. Such is particularly the character of venison, which is ascertained to be one of the most digestative substances.' To the injury of health, however, it is generally eaten when half putrefied, notwithstanding its natural tendency to putrescence. Cooked in this state, it forms highly objectionable food for those predisposed to scurvy or putrid diseases, and should never be partaken of unless with the addition of vinegar, acid of lemons, or some other corrective. The flesh of *hares* was in high repute among the ancients both in dietary and in medicine. 'Inter quadrupedes gloria prima lepus,' says the Latin epigram; 'but the poet,' quaintly remarks a surgeon of the last generation, 'knew little of diet; for the flesh of the hare is hard, and is neither good nor wholesome nourishment.' The youngest and fattest are the best; and those bred on plains and mountains are preferable to those which live in moist places—the former feeding on aromatic herbs, which gives to their flesh a peculiar flavour. *Rabbits* are in more common use than hares; and in certain districts of the country no man who has tenpence or a shilling to spare need be in want of a pair to furnish himself and family with a nice Sunday dinner. Rabbits are either found wild in warrens, or are reared in sheds and hutches as directed in No. 40. The former furnish the most dainty and agreeable food—having a greater opportunity of feeding on sweet aromatic herbs, such as thyme, juniper, and the like, which imparts to their flesh a rich and more pleasant flavour. Though a rabbit is in many respects similar to a hare, yet the flesh of the former is more tender as well as more juicy than that of the latter, and after boiling, becomes pale, and may be termed *white meat*. On the whole, it affords a good and nourishing diet, if taken at a middling age and size: when too young, it is not esteemed wholesome; and when old, it becomes dry, hard, and difficult of digestion. Rabbits are in prime season from the middle of October till the end of January.

Poultry—Game-Birds.—So far as experience goes, the flesh of all birds is edible, though that of some tribes is less palatable and wholesome than that of others. As an article of food, it is pretty largely consumed in this country—the domestic fowl, turkey, goose, duck, pigeon, partridge, grouse, and pheasant, being the species which afford the chief supply. According to Brande, 100 parts of chicken flesh yield 73 water, 20 albumen or fibrine, and 7 gelatine—that is, a total of 27 per cent. nutritive matter. Schlossberger's estimate is somewhat less; but of course chemical analysis will differ according to the condition, age, and other particulars of the specimen examined. 'The flesh of birds,' says Dr Duncan, 'differs very much in its sensible properties, not only in different kinds, but even in the different muscles of the same bird. The pectoral muscles which move the wings are drier and more tender than those which move the legs. The tendons of the legs are also very strong, and at a certain age become bony; but the flesh of the legs, when sufficiently tender, either from the bird being young, or from long keeping, or sufficient cookery, is more juicy and savoury than that of the wings. Of a few birds, especially the woodcock and snipe, the legs are at all times preferred to the breast. In the black-cock, the outer layer of the pectoral muscle is of a dark-brown colour, while the inner is white. A similar difference is observed in many other birds, and perhaps it is general in a slight degree. The muscular organs of birds differ from those of quadrupeds in their flesh never being marbled, or having fat mixed with the muscular fibres.' This is so far advantageous, as the fat of most birds, the aquatic in particular, is extremely difficult of digestion and assimilation.

It is usual for writers on dietetics to classify the flesh of feathered animals according to its colour, or according to the leading habits of the birds as regards their food and mode of life. Adopting some such distinction, Dr Pereira makes the following generalisations:—'The meat of the common fowl, turkey, and the like, is *white-coloured*, contains but little osmazome, when good, is generally liked, and when young, is exceedingly tender. Dr Beaumont states that it is more difficult of digestion than beef: he says that the texture of the chicken being closer than that of beef, the gastric juice does not insinuate itself into the interstices of the muscular fibre so readily as into beef, but operates entirely upon the outer surface, which it dissolves as a piece of gum-arabic is dissolved in the mouth, until the last particle is dissolved. Chicken flesh, however, is nutritious, and when young, is perhaps the least stimulating of animal foods. It is often retained on the stomach of invalids when other meats would be immediately rejected. Chicken broth is well adapted for irritable stomachs. The flesh of the wild gallinaceous birds, as the grouse, blackcock, &c., is *darker coloured*, firmer, richer in osmazome, somewhat less digestible, and more stimulating than that of the chicken. When sufficiently kept, it acquires a peculiar odour, called *fumet*, and an aromatic bitter taste, most sensible in the back. In this condition it is said to be *ripe* or *high*, and is much esteemed by epicures as a luxury. The flesh of aquatic fowl, as the goose and the duck, is mostly firm, penetrated with fat (which often acquires a rancid and fishy taste), and is more difficult of digestion. It forms, therefore, a less appropriate aliment for invalids.' On the whole, it may be remarked that the younger and smaller the bird, the more delicate and tender the flesh; but the female is generally more tender and delicate than the male; that domestication renders birds more fleshy and tender; and that the more cleanly and carefully the animals are reared, the more wholesome and palatable their flesh becomes. It may be also added, as the result both of experience and experiment, that poultry is more easily digested when broiled; is somewhat less digestible when roasted; and is least easily digested when boiled. The less it is mixed and qualified by sauces, stuffings, and other abominations, the better.

The eggs of birds—the hen, duck, goose, and turkey—are largely consumed in Britain, partly as a direct article of diet, and partly in puddings, pastry, and fancy breads. It is scarcely necessary to observe that the egg of the common fowl is that most extensively used, both on account of its superior flavour and digestibility. Both the white and yolk consist chiefly of albumen, the former almost entirely so. Thus 100 parts of white of egg yield about 80 water, 16 albumen, and 4 incoagulable mucilaginous matter; the yolk about 54 parts water, 18 albumen, and 28 a peculiar yellow oil. The white, upon an average, is about twice the weight of the yolk; and deducting from the weight of the whole egg one-tenth for the weight of the shell, and the half of the remaining nine-tenths for water, and less than a fourth of the further remainder for the oily portion of the yolk, about a third of the entire egg appears to consist of azotised or nutritious matter.

With respect to the eligibility of eggs as an article of diet, much depends upon the mode of preparation. 'If lightly boiled,' says Dr Robertson, 'the digestion of the yolk of egg is hardly ever felt. Not so the white: when boiled, this almost always irritates the disordered stomach, and by the dyspeptic and invalid it should not be eaten. The same observations apply to some extent to eggs when made to form part of a pudding: the yolk is still the part which is most easily digested—the white that which is the more likely to disagree; but the latter is not so likely to prove injurious as when eaten alone, and unmixed with other things. The probable reason of this is the same as that assigned for the increased digestibility of milk when mixed with flour or oatmeal; the albumen being prevented from coagulating into large masses, is offered to the action of the gastric secretions in smaller portions, which are therefore more readily acted upon by it. It is an important fact, that either the white or the yolk of egg, if eaten raw, and therefore uncoagulated, is much more easily digested than when it has been previously boiled. The albumen is of course, in this case, coagulated by the acid secretion of the stomach, as the first step to its digestion; but this coagulation is different from the coagulation by heat, and does not offer the same degree of resistance to the solvent powers of the stomach. A raw egg is not, then, liable to the objections, on account of its degree of digestibility, that a boiled egg may deserve; and on the contrary, it would seem that there are few articles of diet which are so quickly or so easily digested as uncoagulated albumen. Lightly-poached egg is probably more digestible than egg boiled in the shell; and this may be owing to the more rapid coagulation of the albumen, and the shorter time it is necessary to expose the albumen to the heat, in order to render it sufficiently cooked for palatibility. It is hardly necessary to say, that fried eggs, involving the addition of fat, part of which is necessarily browned, and by so much burned or converted into empyreumatic oil, and likewise involving the exposure of the albumen to a much higher temperature than that of boiling water, must be much less easily digested than boiled eggs. The digestibility of egg is much influenced by its having been recently laid. Containing so much azotised matter, and the usual proportion of sulphur and phosphorus, egg soon undergoes the changes of decomposition; and probably to a considerable extent before these are to be detected by the sense of smell.'

Turtle.—Of the reptiles, which rank next in the descending scale of animated life, none can be regarded as a staple of food in this country. We leave the edible frog to our continental neighbours, and the turtle to the inhabitants of those regions of which it is a native. As a luxury, however, turtle is consumed by the wealthy and great, and is yearly becoming more common, as the facilities of steam navigation bring it in much better condition, and much more abundantly. When cooked, the flesh of the green or edible turtle somewhat resembles that of chicken or veal; is pale, watery, soft, rich in gelatine, poor in fibrine, and contains little or no osmazome. It is said to be of easy digestion, and nutritive; and by decoction yields highly-restorative soups. The eggs of several of the turtle family are eaten as a palatable article of food.

Fish—Crustacea and Shell-fish.—This division embraces a large amount of the food of our countrymen, and is steadily, though slowly, on the increase. In the articles ANGLING and SEA-FISHERIES, the natural history and modes of capture of the fishes chiefly consumed in Britain are sufficiently detailed; we shall here restrict ourselves to their dietetic condition and importance. Unlike the flesh of birds, that of fish is not always to be eaten with impunity. Many, indeed, are highly poisonous; and even the best are not always in season. They are said to be in season after full recovery from the operation of spawning, up to the time when the roe and milt are ripe, and about to be shed—and the nearer this point the better. Almost every portion of the common edible fishes is available as food; but the muscular, fleshy, or flaky part is that which forms the staple. It differs little in composition in the various kinds, being composed mainly of water, albumen, and gelatine. Thus 100 parts of cod-flesh yield 79 water, 14 albumen or fibrine, and 7 gelatine; and that of the sole 79 water, 15 albumen, and 6 gelatine. In many fishes this flesh is mixed or covered with fat or oil, as in the salmon, herring, pilchard, &c.; but after the spawning season this fat is greatly diminished: in others, as the cod, skate, &c. the fat seems concentrated in the liver, leaving the flesh devoid of it. Fish-flesh contains, theoretically, a fair amount of nutritive matter; but this is greatly depreciated in many instances by its indigestibility. Taken in the aggregate, Dr Robertson arranges their relative indigestibility thus:—1. white-fleshed fish; 2. flat-fish; 3. shell-fish; 4. fresh-water fish; 5. red-fleshed fish; and lastly, the more oleaginous fish. From the quantity of water which the flesh of fish contains, it is less satisfying to the appetite than butcher-meat or poultry, at the same time that it is less substantial and nourishing. Besides the albumen, gelatine, mucus, and oil usually found in the substance of fishes, there are phosphates, chlorides and iodides of lime, magnesia, soda, &c. which may give to it peculiar dietetic and medicinal properties.

For dietetical purposes, fishes have frequently to undergo some sort of preparation, varying according to the situation, the necessities, or the tastes of the consumers. 'When circumstances permit,' says Dr Fleming, 'they are in general used in a *fresh* state; and in large cities, where the supply must be brought from a distance, various expedients are resorted to, to prevent the progress of putrefaction. By far the best contrivance for this purpose is the well-boat, in which fish may be brought to the place of sale even in a live state. Placing the fish in boxes, and packing with ice, is another method, and has been extensively employed, particularly in the supply of the metropolis with salmon. In many maritime districts where fish can be got in abundance, a species of refinement in taste, or at least a departure from the simplicity of nature, prevails, to gratify which the fish are kept for some days until they begin to putrefy. When used in this state, they are far from disagreeable, unless to the organs of smell. Where fish are to be procured only at certain seasons of the year, various methods have been devised to preserve them during the periods of scarcity. The simplest of these processes is to *dry* them in the sun. They are then used either raw or boiled, and not unfrequently, in some of the poorer districts of the north of Europe, they are ground into powder, to be afterwards formed into bread. But by far the most successful method of preserving fish, and the one in daily use, is by means of salt. For this purpose they are packed with salt in barrels, as soon after being taken as possible. In this manner are herrings, pilchards, cod, and salmon, as well as many other kinds of esculent fish, preserved. The fish, in many instances, after having been salted in vessels constructed for the purpose, are exposed to the air on a gravelly beach, or in a house, and dried. Cod, ling, and tusk so prepared are termed in Scotland *salt-fish*. Salmon in this state is called *kipper*; and haddocks are usually denominated by the name of the place where they have been cured. After being steeped in salt, herrings are in many places hung up in houses made for the purpose, and dried with the smoke of wood. In this state they are sent to market under the name of *red-herrings*. Although salt is generally employed in the preservation of fish, whether intended to be kept moist or to be dried, vinegar in certain cases is added. It can only, however, be employed in the preservation of those fish to which this acid is served as a sauce.' By the above processes of salting, drying, and smoking, the digestibility of fish is greatly impaired; though, in some cases, they may thereby be rendered more palatable and nutritious.

But though salting may thus impair the digestibility of fish, by hardening the fibres of the flesh, yet fresh fish are recommended by physicians to be eaten with a considerable quantity of salt. When salt is eaten with fresh fish, according to Dr Robertson, 'the fibres are not hardened by the salt; and the only effect of the salt is to stimulate the stomach so far as to promote or produce its speedy digestion. The more greasy the fish, the more salt should be eaten with it, and vinegar is usually a palatable and advisable addition. It answers the same end as salt, in correcting the effect of the fat, &c.; but this remark, it must be observed, applies only to such stomachs as can bear a moderate degree of acid without inconvenience. Broiling and boiling, especially the latter, are undoubtedly the most wholesome and easily-digested ways of cooking fish. Fried fish, from being cooked in butter or fat, is much less digestible. If the fish be not of greasy character, broiling is the most digestible mode of cooking it; if greasy, the fat is rendered more or less empyreumatic, and by so much less wholesome, by broiling—and boiling is then the way of cooking it. With the exception of salt—and in the case of oily fish, of sugar—all addition to fish, in the form of sauce or condiment, of necessity renders its digestion more difficult. The melted butter with which fish is almost invariably eaten, must render it less digestible; and the dyspeptic who will eat fish, should not add to it butter in any form.

The same observation, as to difficulty of digestion, is applicable to all the different kinds of shell-fish and crustacea. Mussels, cockles, &c. are less easily digested than oysters, and it is quite a mistaken notion that these are comparatively harmless in this respect. Prawns, shrimps, &c. like the lobster and crab, have hard, dense fibres, that are not readily dissolved by the gastric secretions. The character of the fibres, indeed, will afford a trustworthy guide (other circumstances being equal) to the digestibility of the different kinds of fish. Thus the denser fibres of the skate render this fish less digestible than the turbot; and the same circumstance makes the halibut less digestible than the salmon.' As to the nutritive properties of crustacea and shell-fish, they are in general greatly overrated. In the oyster, for example, 100 parts of the flesh yield about 88 water, and only 12 of solid or nutritive matter; while 100 parts of butcher-meat yield on an average from 25 to 28.

Milk—Butter—Cheese.—These are indirect animal products, all largely consumed in every country, whether savage or civilised. Milk, which is obtained only from the class Mammalia, and intended by nature for the nourishment of their young, is the basis of the whole—furnishing, according to certain changes, which it readily undergoes, cream, butter, curd, cheese, whey, and so forth. Intended by nature as the sole food of the young mammal, it necessarily contains all the elements of respiration and nutrition. Blood, flesh, bones, and every other tissue, are formed from its elements: it is, in fact, a perfect food; that is, perfect in its kind, up to a certain stage of animal development. Its proximate constituents are casein, butter, sugar of milk, various salts, and water; and these differ not only in various animals, as the following analyses will show, but also according to the food, the age, and the period after parturition. Thus 100 parts of

	Casein.	Butter.	Sugar.	Salts.	Water.
Cow's Milk yield	4·48	3·13	4·77	0·60	87·02
Ass's do. . .	1·82	0·11	6·08	0·34	91·65
Woman's do. .	1·52	3·55	6·50	0·45	87·98
Goat's do. . .	4·02	3·32	5·28	0·58	86·80
Ewe's do. .	4·50	4·20	5·00	0·68	85·62

Such analyses, however, are to be regarded only as approximations, for the food, age, &c. must ever be taken into account. A cow fed on carrots, for example, yields a milk differing from that which she produces when fed on beet-root:—

	Casein.	Butter.	Sugar of Milk.	Salts.	Water.
Carrots, .	4·20	3·08	5·30	0·75	86·67
Beet, . .	3·75	2·75	5·98	0·65	86·87

Notwithstanding these differences, there is always in the milk of a healthy mother sufficient nutriment for the young; the cream and butter yielding fat, which, along with the sugar, subserves the purposes of respiration or heat; the casein the elements of nutrition and growth; and the salts (chiefly phosphates of lime, magnesia, soda, and iron) matter for the construction of the solid skeleton. Milk as an article of diet for adults, is obtained in Britain almost solely from the cow; goat and ewe-milk being only occasionally used in the preparation of cheese; and that of the ass solely as a remedy in cases of consumption.

Referring the reader to the article DAIRY for the management and preparation of milk, cream, butter, cheese, and the like, we shall here merely advert to the respective dietetic peculiarities of these preparations. Cows' milk, when obtained from healthy, well-fed, and properly-kept animals, is a very useful and valuable article of food, as well for adults as for children. Its principal drawback, according to Pereira, is the difficult digestibility of its fatty constituent, or butter—an objection, however, which can be got rid of by using it in the *skimmed* state. Under the name of *milk diet*, it is extensively employed in conjunction with bread, oatmeal, rice, sago, potatoes, and other farinaceous substances, and forms in every case a readily assimilated and nutritive aliment. *Cream* consists of butter, curd, and serum or whey, and though less digestible than milk, properly so called, is not so liable to this objection as butter. *Fresh butter* is more easily digested than salt; and whether salted or fresh, preference is always to be given to that most recently prepared. *Whey* is chiefly composed of water and lactic acid, with a slight proportion of casein, butter, and sugar. It is therefore very slightly nutrient, but forms an excellent diluent in inflammatory complaints, and also gently promotes the secretions. *Buttermilk*, as containing the casein, the sugar, and the salts of milk, must possess nutritive properties. It is deserving of wider adoption, both as an article of diet, and as a cooling and agreeable beverage. *Curd* is less easily digested than cream; but more so than butter. It consists mainly of casein, and this from fresh milk yields 54·82 carbon, 7·15 hydrogen, 15·63 nitrogen, and 22·39 oxygen and sulphur. *Cheese*, or casein dried, and having probably undergone some chemical change during the process of 'ripening,' is generally very difficult of digestion. It almost always contains a considerable proportion of the fatty part of the milk, and in some cases is made almost entirely from cream. The impunity with which many persons can eat toasted cheese may be partly attributed to the mustard, &c. eaten along with it, although the cooking has much to do with the greater digestibility. Cheese made from cows' milk is more easily digested than that from goats' milk; and the richer or more oleaginous the cheese, the more easily is it digested. Ripe cheese is preferable to that which is green or immature, and also to that which is partially decayed. In whatever stage, cheese should be eaten with caution, as apt to produce not only indigestion, but crudity and consequent irritation in the intestines. It will thus be observed that none of the artificial or secondary preparations from milk possess its own bland and generally unobjectionable character; and this arises from the fact of their being concentrated forms of certain principles, while in milk these principles are mingled and diluted in right and natural proportion.

Animal fat, like the oil of vegetables, consists essentially of carbon, hydrogen, and oxygen; and therefore, when taken as food, can supply only respiratory or heat-forming matter. Containing about 80 per cent. of carbon, *heat* is its proper function, and thus is explained the fact why the inhabitants of cold climates can consume with impunity so much of this aliment. All fatty matters are digested with difficulty, and are apt to irritate and derange the stomach and its functions. The fat of different animals, however, differs in point of digestibility; and what is more curious still, differs also according to the part of the animal from which it is taken. The digestibility of fat is much affected by modes of cooking; it is also greatly modified by the action of vegetable acids, and of common culinary salt.

MINERAL FOOD.

It has been already mentioned that man derives little of his food directly from the mineral world. No doubt all plants and animals contain a certain amount of saline and earthy ingredients, which are indispensable to healthy aliment; but these are indirect products, and are always taken into account when estimating the relative dietetic value of vegetable and animal compounds. In fact, the only substances obtained directly from the inorganic kingdom, and consumed in large quantities, are water and salt—two substances as necessary to existence as the air we breathe. The former, as has been seen, enters largely into the composition of every species of food; it acts as a solvent and diluent in all cases, and permeates everywhere the tissues to whose subsistence and growth it administers. The latter, though usually taken as a palatable condiment, is really essential to the maintenance of health and vitality, and accordingly appears as a constituent of the blood and the tissues elaborated therefrom.

Water, as consumed by man either as a beverage or as a constituent of his food, is generally in a fresh state; that is, contaminated as little as possible by foreign ingredients. The nature and constitution of water has been already detailed under the heads CHEMISTRY and SUPPLY OF WATER: all that is necessary to be here observed is, that the supply for dietetic uses should be freed from all mechanical impurities, and from all chemical impregnations, which may render it unpalatable, unsuitable for culinary purposes, or detrimental to the system of the consumer. Absolutely pure water is not found in nature, nor does it indeed seem to be required by the animal economy. It is only pure when distilled, and in this state it is neither pleasant to the taste nor nourishing. The purest waters always contain some amount, however small, of lime, clay, iron, or other mineral; and what is more curious still, analysis always detects some trace or per centage of organic matter. It is only when these foreign substances exist to any amount that water becomes objectionable. Good water is generally known by its softness, its limpid and somewhat sparkling appearance, its agreeable flavour, and its non-liability to become putrid. Its softness it acquires from the absence of saline or mineral ingredients, its sparkling aspect and agreeable flavour from the carbonic acid which it absorbs from the atmosphere, and its resistance to putrescence from the comparative absence of animal or vegetable matter. By filtration, which is now generally practised, all mechanical impurities can be got rid of; but for the removal of chemical impregnations, boiling, or the admixture of chemical reagents, is required.

The ordinary sources of fresh water are rains, springs, rivers, lakes, and wells; and according as it is obtained from one or other of these sources, so is it characterised by peculiar properties. *Rain water*, if collected in mountain districts, far from human dwellings, is perhaps the purest of all; but if collected in the neighbourhood of towns, it is found to be largely impregnated with soot, and other extraneous substances; and the rapidity with which it putrefies, demonstrates the presence likewise of organic matter. Being soft, it is valued by the housewife for washing; but is unfit for internal or culinary purposes without undergoing rigid filtration. Unimpregnated with mineral substances, its action on lead is more rapid than that of other waters, and it should never therefore be kept in lead cisterns. All *spring water* is less or more impregnated with the substances through which it has percolated to the surface; but with the exception of those commonly termed 'saline' or 'mineral'—and which are noticed under MEDICINE—most springs yield water of sufficient purity for domestic purposes. Those issuing from the primitive and igneous rocks, or from extensive beds of sand and gravel, are generally the purest; those from the carboniferous and other secondary strata always hold in solution compounds of iron, lime, sulphur, salt, and magnesia. *River water*, which is a combination of rain and spring water, is often well fitted for human purposes. Its impurities are more of a mechanical than of a chemical kind, and may be removed by careful filtration. Much, however, depends upon the soil and district through which the river flows; meadows, morasses, and forests yielding organic matter, and factories and towns bequeathing heterogeneous impurities, not to be got rid of by any ordinary process. Water drawn from fresh *lakes* is less turbid than that from rivers; but is always (unless from deep mountain tarns) more largely impregnated with vegetable and animal matter. *Well or pump water* is that obtained by boring or by sinking shafts into the rocky strata. It must of necessity, like spring water, partake more or less of the mineral ingredients through which it percolates; and not unfrequently is injured by the pumps, pipes, and other apparatus by which it is raised. Such are the ordinary sources from which man derives his dietetic waters; and it were greatly to be desired that more efficient modes of purification, as well as abundance of supply, were more generally adopted in reference to our towns and cities, which, with few exceptions, have neither quantity nor quality to boast of.

Respecting the alimentary functions of water, Dr Pereira, after remarking that it is the natural drink of all adults, observes—'It serves several important purposes in the animal economy: *firstly*, it repairs the loss of the aqueous part of the blood, caused by evaporation and the action of the secreting and exhaling organs; *secondly*, it is a solvent of various alimentary substances, and therefore assists the stomach in the act of digestion, though if taken in very large quantities, it may have an opposite effect, by diluting the gastric juice; *thirdly*, it is probably a nutritive agent—assisting in the formation of the solid parts of the body. It has not, indeed, been actually demonstrated that water is decomposed in the animal system; or, in other words, that it yields up its elements to assist in the formation of organised tissues; yet such an occurrence is by no means improbable. It appears from Liebig's observations, that the hydrogen of vegetable tissues is derived from water; and it is not probable that the higher orders of the organised kingdom should be deficient in a power possessed by the lower orders. Dr Prout appears to admit the existence of this power, but thinks that it is rarely exercised by animals. The water which constitutes an essential part of the blood and of the living tissues, assists in several ways in carrying on the vital processes. "In the blood," says Prout, "the solid organised particles are transported from one place to another; are arranged in the place desired; and are again finally removed and expelled from the body, chiefly by the agency of the water present." It is from water that the tissues derive their properties of extensibility and flexibility. *Lastly*, this fluid contributes to most of the transformations which occur within the body. As a solvent it serves not only to aid digestion, but also to effect other changes, as, for example, the conversion of uric acid into urea, and sugar or starch into sugar of milk and diabetic sugar. So also the hydrochloric acid of the gastric juice, and the soda of the blood and bile, are derived from common salt (chloride of sodium) by the aid of water.'

Salt.—Referring the reader to our article on MINING AND MINERALS, p. 363, for an account of the modes of procuring and preparing this indispensable article, we shall here strictly confine our remarks to its dietetic or alimentary importance. 'By virtue of its chlorine,' says a popular authority, 'salt largely promotes the functions of the stomach and bowels in assimilating the food; by virtue of its soda, it greatly subserves the uses of the bile in the economy; and in its every action—whether by means of its separated constituents, or in its combined state, serving probably to maintain the blood in its singularly compound and yet homogeneous condition—is shown to be great on all the functions and conditions of the body. There can be no question, however, that even salt may be too much or too little used in the food: that in the one case, the tissues and the expending organs are too much stimulated; in the other case, the system is unduly, and not without serious risk, deprived of that agent, by which so large a share is performed in the nutrition of the body; and which in itself, by its ultimate elimination from the body in the several excretions, probably serves to keep up the action of the excreting organs, and promotes the disintegration and throwing off of the effete matters, no longer fitted for the purposes of the economy, and which could not be retained without injury. The less readily assimilated the articles may be, and the less of saline matter contained in them, the more essential is salt as a part of the food; hence the oily articles of food, and the purer forms of the starchy principle, when largely used as means of nutrition, require usually more salt to be eaten with them than the more ordinary and less pure forms of vegetable or even animal diet. And yet animal diet of any kind, probably from its putrescent tendency, if not mixed with vegetable food in sufficient proportion, is found to require a large mixture of salt with it, for the maintenance of health and strength.' The amount of salt consumed by a full-grown person has been estimated at 16 lbs. a year, or about 5 ounces a week; but of course this estimate will vary exceedingly, according to the tastes and habits of individuals.

All the varieties of salt, whether small-grained, like the *basket or table salt*, or in large crystals, like the *bay* and *fishery salts*, consist essentially of chloride of sodium, which is composed of 60 per cent. chlorine and 40 sodium. The salt of commerce, however, is never found absolutely pure, being less or more contaminated with salts of lime and magnesia, as well as insoluble matter. Thus an average of foreign bay salts yielded to analysis 3½ per cent. of such impurities; British salt from sea-water upwards of 4 per cent.; and that from English rock-salt somewhat more than 1½ per cent. The purer salt is, of course the more wholesome will it be as an article of diet, and the more effectual for the purposes of pickling and curing provisions.

BEVERAGES.

Writers on dietetics are in the habit of classifying drinks or beverages according to their sensible, chemical, or medicinal properties. Thus we have—1. Mucilaginous, farinaceous, or saccharine drinks; 2. Emulsive or milky drinks; 3. Animal broths, or drinks containing gelatine and osmazome; 4. Aromatic or astringent drinks; 5. Acidulous drinks; and, 6. Alcoholic and other intoxicating drinks. Water, however, is the only true natural beverage: it forms the basis of the whole of the above—the other constituents being but infusions, decoctions, and solutions of solid elementary substances already described. Being reduced to a liquid form, the alimentary action or effect of these substances is much facilitated, and thus, in point of easy assimilation, beverages are immensely superior to solid food. In certain cases, therefore, it is advisable that diet should be taken in this form; not only on account of its ready assimilation, but from the accuracy with which it can be reduced to the necessary strength. In all cases, however, of healthy existence, food in a solid form is indispensable, and beverages are to be regarded simply as diluents, demulcents, and correctives. Setting out with this view, and following the above distinctions, we shall now briefly allude to the more abundant and familiar beverages—adopting as authorities Liebig, Pereira, and Robertson:—

1. The mucilaginous, farinaceous, and saccharine drinks are perhaps the simplest, next to water. They are merely solutions, infusions, or decoctions of substances already described, and are known by such terms as *gum-water*, *toast-water*, *sugar-water*, *barley-water*, *mucilage of rice*, and *gruel* from oats, sago, arrowroot, or tapioca. They are all very slightly nutritive; and are used chiefly in the sick-chamber as demulcents and diluents. Toast and barley-waters are placed by the faculty at the head of this division.

2. Emulsive or milky drinks are such as hold in suspension any oily or fatty substance in a finely-divided state. *Animal milk* (already described) is at the head of this section; others, as *milk* and *syrup of almonds*, fall more properly to be noticed under MEDICINAL PREPARATIONS.

3. Broths and soups, or drinks containing gelatine and osmazome, are usually prepared from beef, mutton, veal, and chicken. A number of receipts are given for their preparation in the following article (COOKERY); the rationale of their aliment has been already described. Boiled meat of good quality yields kreatine and osmazome, coagulated albumen, gelatinous cellular tissue, fatty matter, saccharine matter, some salts and water; and to prepare a soup so that none of these may be dissipated and lost, is the chief point requiring attention. When pot vegetables, as turnips, carrots, onions, barley, &c. are used, of course these communicate new principles to the liquid—as mucilage, sugar, azotised products, volatile oil, and salts. Extract of the pure or lean meat is always preferable for invalids and convalescents—*beef tea* and *chicken broth* being the most highly recommended.

4. Of the aromatic and astringent drinks, tea, coffee, and chocolate are pre-eminently the most familiar. 'We shall never, certainly, be able to discover,' writes Baron Liebig, 'how men were led to the use of the hot infusion of the leaves of a certain shrub (tea), or of a decoction of certain roasted berries (coffee). Some cause there must be, which would explain how the practice has become a necessary of life to whole nations. But it is surely still more remarkable that the beneficial effects of both plants on the health must be ascribed to one and the same substance, the presence of which in two vegetables belonging to different natural families, and the produce of different quarters of the globe, could hardly have presented itself to the boldest imagination. Yet recent researches have shown, in such a manner as to exclude all doubt, that *caffeine*, the peculiar principle of coffee, and *theine* that of tea, are in all respects identical.' The fact is certainly striking enough, and all the more so that cocoa or chocolate also yields a principle (*theobromine*) identical, or all but identical with theine and caffeine. These principles furnish elements precisely the same as those of the bile; hence their effect on the processes of secretion, on nutrition, and vitality.

Tea is usually distinguished as *black* or *green*; the former including such marketable varieties as Bohea, Congou, Souchong, Caper, and Pekoe; the latter Twankay, Hyson, Imperial, and Gunpowder. Of the black teas, Pekoe is one of the best; of the green, Gunpowder. When subjected to analysis, they all yield less or more volatile oil, chlorophyle or colouring matter, wax, resin, gum, tannin, theine, albumen, lignin, and extractive matter. The dietetic and medicinal properties of tea are thus detailed, throwing out of view the qualities usually imparted by the addition of sugar, milk or cream:—It acts on the system as a stimulus or a sedative, according to the strength of the infusion that is taken. When taken in smaller quantity, its effect is, in general, simply and in a small degree sedative, even in the first instance; when used in larger quantity, its primary action is decidedly that of a stimulus. Its well-known effect of inducing wakefulness illustrates this. To many people, when taken late in the evening—and in some when taken strong at almost any time—it produces a very sensible degree of stimulation, and a state of sleepless excitability. Besides inducing wakefulness, tea seems to sharpen the mental faculties, and perhaps, in an especial degree, the imagination. Green tea has, generally speaking, more stimulating, black tea more sedative properties. The stimulating effects are, however, always and necessarily followed by sedative effects, which may amount in extreme cases to depression, or even to a degree of narcotism; and in most cases it acts as a narcotic on the organs of excretion, producing more or less visceral torpidity and sluggishness. To the man who has a sufficiency of nourishing and wholesome food, the use of tea in moderate quantities, and at proper times, cannot be said to be ever followed by unpleasant or unsatisfactory consequences. If taken in excessive quantities, tea becomes decidedly debilitating to the nervous system, affecting it much in the same way as any other stimulant and narcotic. But though tea, when used in moderation, is serviceable to the individual who takes a sufficient quantity of nutritious food, unquestionably serving some important purpose, in completing and perfecting the last stages of digestion; and although, under such circumstances, the use of tea is not injurious, this is by no means the case when the aliment that is taken is deficient in quantity, or of too poor a quality. Under such circumstances, tea acts on the nervous system to a degree that is often productive of disorder, and which probably sometimes leads to disease. The effect of tea on the second stage of digestion, and probably on the secretion of the bile, points out and explains its value when taken about three or four hours after the principal meal of the day, and illustrates the well-known anxiety of the dyspeptic for tea-time, and the comparative comfort he enjoys after this beverage, which is aptly said 'to cheer, but not inebriate.' Taken at the same time as a heavy meal of food, or such a meal as contains a large proportion of the day's alimentary supply, tea may prove to be too much of a diluent, or too directly narcotic; and in some cases may rather retard the primary digestion than otherwise. This, however, depends very much on the quantity and the strength of the infusion made use of. Green tea, although said to be used almost exclusively in some countries, is found to be much too narcotic and stimulating for exclusive use in this country, and is necessarily forbidden to most invalids, from its evidently enervating effects.

The *Coffee* of commerce is the seed of a berry-bearing tree or shrub, found originally in Arabia, but now extensively cultivated in all tropical countries. It is usually distinguished by the place of its growth—as Mocha, Jamaica, Mountain-Jamaica, Demerara, Ceylon. Raw coffee can be kept for any length of time without deterioration—indeed the older the better; but on being roasted, it developes a fragrant and aromatic principle, which is extremely volatile. Roasted coffee should therefore be ground and used as speedily as possible. Coffee yields to analysis caffeic acid, tannic acid, caffeine, wax, resin, gum, albumen, lignin, extractive matter, and salts of lime, magnesia, and iron. Its dietetic properties and peculiarities are thus detailed by the preceding authority:—Used in infusion or decoction, coffee is more nutritious than tea, but is more difficult of digestion. Whether owing to the tannin, which the roasted coffee is said to contain, or to the aromatic oil, or the mucilage, or the bitter extract, or to the combination of these different constituents, coffee deranges considerably the stomachs of some people, and is usually somewhat difficult of digestion to invalids, and to those who are more seriously dyspeptic. It is probable that this is not referable to the aromatic principle, as the best coffee, which contains more aroma, is less likely to disagree than the commoner sorts. The infusion is usually less apt to disagree than the decoction, unless the latter have been most carefully clarified. The consequence of coffee proving to be of difficult digestion is rather to produce considerable acidity than to give rise to any other marked dyspeptic symptom. Supposing that coffee does not disagree, which in the healthy and strong is seldom does, it is a peculiar and decided stimulus, quickening the circulation, promoting the secretions and excretions, very perceptibly warming the system and elevating the spirits. Supposing that the powers of the digestive organs are adequate to its complete assimilation, coffee, from being much more nutritious, and more decidedly restorative to the system, forms a better addition to other articles of food that are taken at breakfast than tea. If its ready digestibility be suspected, the question of its being mixed with sugar, and the known difficulty with which sugar is digested, should be considered, before coffee is pronounced to be unsuited to the individual. The addition of milk to coffee adds much to its nutritiousness, diminishes in some degree its directly stimulating effects, and seldom makes its digestion more difficult. As to the addition of *chicory* (the roots of the wild succory, or endive, dried and ground), now so commonly practised, medical authorities are rather in favour of a moderate admixture than otherwise. The chicory root is perfectly wholesome, contains no alkaloid or oil, and only a small amount of resinous and narcotic matter. When added in small quantities, it rather improves the flavour of coffee, apparently combines with, or neutralises its oil, and altogether renders it less difficult of digestion.

Cocoa is derived from the seeds or nuts of the chocolate-tree (*Theobroma cacao*), a native of tropical regions. The seeds grow in pods, and are prepared for use by being roasted, deprived of their husks, and ground. Cocoa is either used in the form of the ground seeds, simply made into a decoction; or these are ground into a paste mixed with cloves, cinnamon, vanilla, &c. forming *chocolate*. In either form, cocoa is described as oleaginous, and somewhat acrid, and is in general by no means so easily digested as tea or coffee. Still, there are many people, both dyspeptic and sedentary, with whom it invariably agrees; and this much can be said in its favour, that it is devoid of the disagreeable qualities of disturbing the nervous functions. The ground seeds are preferable to the paste or cakes, of whose composition, or, we should rather say, adulteration, we are ignorant.

5. The acidulous beverages in common use are *lemonade, ginger-beer, soda-water, effervescing saline draughts, Seidlitz powders*, and the like. Their action being medicinal and corrective, rather than alimentary, their consideration properly belongs to a subsequent number. When prepared from the acid juices of fruits—as lemon, raspberry, apple, &c.—they form cooling refreshing antiscorbutic drinks, and are well adapted for hot seasons, and for febrile and inflammatory cases. When compounded of some alkali and acid, like the common effervescing draughts, they are also slightly aperient.

6. Beverages which are the products of fermentation are usually classed as *spirits*—brandy, gin, whisky, and rum; *wines*—port, sherry, claret, champagne, &c.; *liqueurs*—embracing all the sweet or home-made wines; and *malt liquors*—ale, porter, and beer.

Referring the reader to APPLIED CHEMISTRY, p. 363, for the theory and principles of fermentation, we shall here merely allude to the alimentary or dietetic effects of these well-known, and, in many cases, too largely-consumed beverages. *Alcohol*, or the leading principle in spirits, consists of carbon, hydrogen, and oxygen; it contains no nitrogen, sulphur, phosphorus, or other ingredient capable of administering to growth or nutrition. Its function is that of a heat-former; it is merely an element of respiration serving to support the temperature of the body. But in subserving this purpose, it stimulates, excites, and, if taken in any quantity, intoxicates; and the question for those in search of animal heat simply resolves itself into this—Can we not gain our end by means more simple, natural, and less dangerous? It has been well remarked, that 'though alcohol evolves heat in burning, it is an obnoxious fuel. Its volatility, and the facility with which it permeates membranes and tissues, enable it to be rapidly absorbed, and when it gets into the blood, it exerts a most injurious operation, before it is burnt in the lungs, on the brain and the liver. Though, by its combustion, heat is evolved, yet, under ordinary circumstances, there are other better, safer, and less injurious combustibles to be burned in the vital lamp.' It is only, indeed, as a restorative and corrective that its use is at all admissible; and there can be no doubt that, in cases of extreme exertion and privation of food, the cautious and moderate dietetic use of spirits has on many occasions proved invaluable. *Brandy*, derived from the distillation of wine, is perhaps the least objectionable form in which alcohol is administered. Its constituents are alcohol, water, volatile oil, a minute quantity of acetic acid, œnanthic ether, and colouring matter. It is distinguished from other ardent spirits by its cordial and stomachic properties. *Rum*, distilled from molasses and sugar skimmings, is very similar to brandy in its effects, but more heating, and more disposed to cause sweatings. *Gin*, obtained from corn spirit, and flavoured with juniper, sweet flag, &c. is, owing to the oil of juniper it contains, more powerfully diuretic than either brandy or rum. *Whisky*, also a corn spirit, agrees in most of its properties with gin, but is somewhat lighter, and more stomachic.

Wine is the general term applied to liquors prepared by the vinous fermentation of the juice of the grape. 'The peculiar qualities of the different kinds of wine depend on several circumstances; such as the variety and place of growth of the vine from which the wine is prepared; the time of year when the vintage is collected; the preparation of the grapes previously to their being trodden and pressed, and the various manipulations and processes adopted in their fermentation.' Though thus varying, and known by a thousand names, the general constituents of all wines are—water, alcohol, volatile oil, sugar, gum, tannin, tartrate, and bitartrate of potash, acetic acid, extractive and colouring matters, and carbonic acid in the effervescing varieties. The amount of alcohol in wines is exceedingly varied; in claret, for example, it seldom exceeds 7 or 8 per cent. by weight; while in ports and sherries it ranges from 12 to 18 per cent. As to the dietetic properties of wine, Dr Paris asserts 'that there exists no evidence to prove that the *temperate* use of good wine, when taken at *seasonable* hours, has ever proved injurious to *healthy* adults.' Dr Pereira is by no means disposed to question this assertion, qualified as it is; but maintains, on the other hand, that 'for healthy individuals wine is an unnecessary article of diet. It may prove,' he continues, 'a valuable restorative when the powers of the body and mind have been enfeebled by fatigue; but, on the other hand, it cannot be denied that the most perfect health is compatible with total abstinence from wine; and that the habitual employment of it, especially by the indolent and sedentary, is calculated in many instances to prove injurious. Disorders of the digestive organs, and of the brain, gout, gravel, and dropsy, are the maladies most likely to be induced or aggravated by the use of wine. Intoxication, in its varied and lamentable forms, is the effect of the excessive use of it.'

Malt liquor is the generic term for all fermented infusions of malt flavoured with the bitter principle of hops. Normally, they ought to contain less or more of alcohol, starch, sugar, dextrine or starch gum, extractive and bitter matters, fatty, aromatic, and glutinous matters, lactic acid, carbonic acid, salts, and water. They are, however, often largely adulterated; molasses and other wash being used for malt, quassia substituted for hops, flavours imparted by capsicum, ginger, and coriander; and intoxicating qualities conferred by cocculus Indicus, nux vomica, and opium. Keeping out of view these adulterations, the genuine liquors are fitted by their constitution to quench thirst and act as diluents, to yield heat and nutrition, and to operate as tonics and stimulants. The only drawback to their use in large quantities is the intoxicating effect of their alcohol—common beer containing about 1 per cent. by measure of this spirit, porter from 4 to 6, and strong ale from 6 to 8.

PREPARATION OF FOOD—COOKERY.

COOKERY, or the preparation of food, is an art upon which so much of our daily comfort and health depends, that it is of the highest importance that it be well performed. Every housewife may not be able to procure the finest kinds of food, but every one has it in her power to make the most of that which she does procure. By a certain degree of skill and attention, very humble fare may be dressed in such a manner that it will almost rival the most expensive dishes, both in savouriness and nutritiousness. A good housewife suffers nothing to be lost or spoiled. Mere scraps, which a careless individual would perhaps throw away, are put to a proper use; and, by means of certain auxiliary *seasoning*, brought to table in a new and attractive guise. Even if little or nothing be absolutely saved by these economical arrangements, the dressing of food in a tasteful manner is a point of some importance. When a dish has a slovenly appearance, is smoked, underdone, or prepared with rancid or unclean seasoning, both the eye and the appetite are offended, which is a serious evil in itself, independently of the injury which may possibly be done to the stomach of the eater. In every respect, therefore, it is consistent with good judgment to prepare food for the table in the most tasteful and agreeable manner.

One of the chief points to be attended to in cookery is *cleanliness*—scrupulous cleanliness in every department of the business of the kitchen. The hands of the cook, in particular, should be always clean; that is, washed every time after doing any kind of work which has soiled them, or before proceeding to handle meat for dressing. She should also be careful in having her hair always neatly trimmed up, so that no loose hairs may drop into the dishes. The next point of regulation is to keep all the saucepans and other utensils perfectly clean in their inner parts, and also in the insides of the lids; carefully washing with hot water, and scouring and rinsing when necessary. If the cooking utensils are not kept thoroughly clean, they will be very apt to taint the food prepared in them, and will certainly detract from the agreeable taste of the dishes. It is the duty of every housewife, either in her own person or by her deputy, the housekeeper, to see that these and all other rules affecting the cleanliness of the kitchen are attended to by servants, for she is understood to be responsible both for the wholesomeness and the tidy appearance of the dishes presented at table.

Another essential point in cookery is *attention*. Many persons think they have done all that is necessary, when they have fairly commenced or set agoing any particular process in cooking. They seem to imagine that they may safely leave a joint to be roasted, or leave a pot of soup or broth to be boiled, and that they have only to go back to the fire at a certain time, and they will find the things ready for dishing. Now this kind of inattention is certain to spoil the best meat ever put to a fire. Some processes require less attention than others, but none can be properly performed if left long to itself. A good cook is frequent in her visits to the fire, and seizes the right moment in giving her assistance.

Perfection in the culinary art is only attainable by lengthened experience, and a careful study of the qualities of meats, and the application of sauces and seasonings. It is chiefly in knowing how to make and apply these adjuncts that a cook shows her skill.

KITCHEN ARRANGEMENTS.

A young and thriftily-disposed housewife will, if possible, proceed to market herself, in order to lay in butcher-meat and other fresh provisions for her family. By this plan she will possess two advantages—that of selecting the best pieces, and of getting them at the lowest price. The frequency of her visits to the market will of course depend on the number of her family, and their taste as to the staleness or freshness of the meat to be purchased. If circumstances permit, it is advisable to purchase a whole week's provisions at a time, at least the chief things which will be required for the ensuing eight days. We would recommend a housewife to act upon a system in varying the kinds of meat which she buys, not only as they may be suitable to the seasons, but as calculated (see No. 45) to promote the health of a family. Let the housewife, therefore, exercise a little ingenuity and judgment in her marketing expeditions, contriving to present at table a succession of different descriptions of animal and vegetable food: as, for example, sometimes meat roasted, and sometimes boiled or stewed; sometimes fresh meat, at other times salted; sometimes butcher-meat, and other times fish; and so on, according to taste and other circumstances. It does not necessarily follow that, in thus varying the bill of fare, greater expense is incurred than if the same kind of articles were continually purchased.

The best meat is that which is moderately fat. If it be lean, or almost free of fat, it is an indication that the animal has been ill fed, and that the meat will prove tough and tasteless. Avoid lean beef—it forms wretched fare, and will be dear at any price. The fat of good beef is slightly yellowish; the fat of good mutton is pure white. The flesh of both beef and mutton should be of a clear red colour. The mutton of well-fed black-faced or of Southdown sheep is the most tender or sweet, and may be known by the shortness of the shank. Mutton is in perfection at between four and five years (wether-mutton), but is seldom to be had older than three years. Cow and bull beef are considerably inferior to ox beef; and even this depends much upon the kind of animal and mode of feeding—grass-fed being sweeter than stall-fed, and that fed on farm produce being finer than that reared upon oil-cake, brewers' wash, and the like.

In choosing lamb, select that which has a delicate appearance, and is perfectly fresh. Young veal has a dark and flabby look, and is tasteless when dressed. Veal is best when the animal is between four and six months old. The flesh is then white and delicate, and is firm in the fibre. Pork should be white and delicate like veal, and thin in the skin. Lamb, veal, pork, and all other young or white meat should be fresh, and not bought long before being used.

Fowls, ducks, and other feathered animals should be purchased young, and should all be firm and fleshy to the touch. If the thin bone which projects over the belly feel hard on being handled, the animal is old; if it feel softish like gristle, the animal is young. This is the safest rule for choosing in the poultry market. The age of game is of little consequence, as it is hung for a considerable length of time before dressing.

All kinds of fish should be purchased as fresh as possible. Freshness in cod, haddock, and generally all fish, is indicated by stiffness in all parts of the body, and a clear glittering appearance in the scales. Freshness is likewise known by the smell. If there be the least staleness, the fish has an offensive odour. As tricks are sometimes performed with the eyes and gills, freshness of appearance in these is not to be trusted.

It is very difficult to ascertain when eggs are perfectly fresh. There are different rules on the subject, but they are all liable to failure. One mode of judging is to hold the egg between the eye and the light of a candle, shadowing the eye with the hand; if the appearance is universally luminous, without any cloudiness, the egg is fresh; if cloudy, or not uniformly luminous, it is probable that the egg is unfit for use.

Butter may be easily selected by the taste and the smell; but in buying both eggs and butter, it is best to deal with a person on whom you can rely, as it is troublesome to be continually seeking out and examining these articles to determine their freshness.

Good ham and bacon have a fresh savoury smell; the fat is white, and free from any yellowness. If it be yellow, reject it, as it will soon become rank.

Flour for culinary purposes should be new and fresh. Old flour is liable to spoil and become full of animal life, in which condition it is unfit for pastry and other dishes. The best kind of salt for the kitchen is that which is purchased in lumps and cut down. All condiments and spices should be sought for fresh, full-flavoured, and as little exposed to the air as possible.

Cutting up Meat.—Butcher-meat is not cut up in the same manner in all parts of the country. There are two chief plans of cutting followed—the English and the Scotch plan, and consequently the pieces of meat in a carcass differ in number, size, and name, in England and Scotland. This circumstance creates a certain degree of difficulty in giving directions for cooking; and to obviate this as much as possible, we subjoin the following drawings and explanations:—

Figure 1 represents a bullock marked for cutting up on the English plan. No. 1 is the loin or sirloin, 2 the

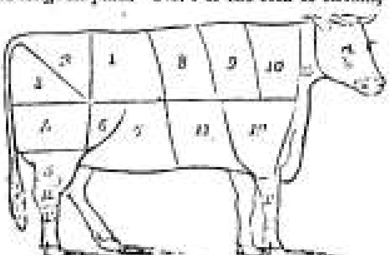


Fig. 1.

rump, 3 the itch or edge bone, 4 buttock, 5 hock, 6 thick flank, 7 thin flank, 8 fore rib, 9 middle rib, 10 chuck rib, 11 brisket, 12 leg of mutton piece, 13 clod, sticking, and neck pieces, 14 shin, and 15 the leg. From 1 to 7 is the hind quarter, and from 8 to 15 is the fore-quarter. Nos. 1 and 2 on both sides united constitute what is called a *baron of beef.*—Figure 2 represents a bullock marked for cutting up on the Scotch plan.

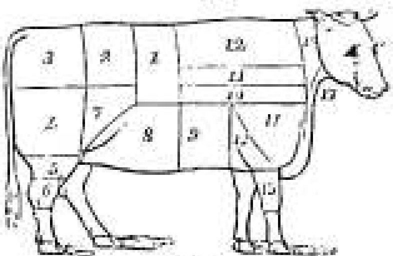

Fig. 2.

No. 1 is the sirloin or back sye, 2 the hook bone, 3 buttock, 4 large round (3 and 4 together make the rump), 5 small round, 6 hough, 7 thick flank, 8 thin flank, 9 nineholes, 10 and 11 large and small runner, 12 spare rib or fore sye, 13 brisket, 14 shoulder lyer, 15 nap or shin, 16 neck, and 17 the sticking piece. From 1 to 8 is the hind quarter, and from 9 to 17 the fore.

According to the English plan, the meat is cut up more advantageously for roasting and broiling than by the Scotch plan. For instance, the rump and itch bone, Nos. 2 and 3, figure 1, are cut in such a manner that the meat affords a much better steak than when cut as in figure 2. The Scotch plan, on the other hand, gives more pieces for boiling; and thus each way seems suitable to the taste of the people who have respectively adopted them.

Figure 3 represents the English plan of cutting up mutton. No. 1, extending across and marked as a circle, is the shoulder, 2 is the scrag end of the neck, 3 breast, 4 loin, 5 leg, 6 best end of neck. The slanting line betwixt 4 and 5 is the division of the fore and hind quarter. The dotted line across the shoulder shows where the neck is separated from the breast after the shoulder is off. Two loins united form a *saddle*

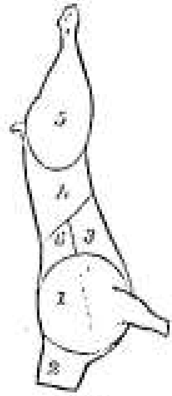

Fig. 3.

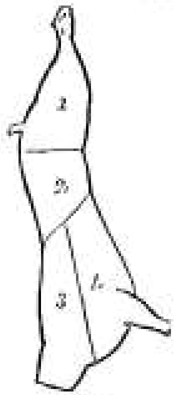

Fig. 4.

of mutton. Fig. 4 represents a side of mutton marked for cutting on the Scotch plan. No. 1 is the gigot, 2 the loin, and both together form the hind quarter; 3 is the back ribs, and 4 the breast, both forming the fore quarter. Lamb is cut up in the same manner, when not sold in quarters.

Veal is usually cut up both in England and Scotland in a manner somewhat uniting the plans for cutting beef and mutton. A fillet, which is believed to be the most elegant joint, is cut from the upper part of the hind-leg, being partly of the buttock and flank. The piece at the extremity of the loin is called the *chump.*

The larder is a place where fresh meat is kept till it is in a fit place for being cooked, and where cold meat or any other kind of food may be set aside. The larder should be cool and dry, with the outer air playing freely through it. It should also be impervious to vermin or insects, particularly flies. Two or three shelves (of slate or stone where the larder is a built apartment), and a few strong iron hooks for hanging the meat, are the only furniture.

Beef and mutton are always improved by hanging some time after being killed before they are cooked. The length of time which they may be kept depends on the state of the weather. The best weather for the purpose is when the atmosphere is cool, clear, and dry; in such circumstances beef and mutton may hang from four to eight days; mutton, if well managed, may hang for a fortnight. A moist thick atmosphere is the worst for keeping meat; and when it occurs, great care must be taken with the contents of the larder. The meat should be wiped daily with a cloth, to free it as much as possible from the moisture that gathers upon all meat when kept for many days. In all cases fresh meat should hang from a hook, and not be laid on a plate.

In most instances, fresh meat is cooked too soon after being killed, a circumstance perhaps arising from the general deficiency of proper larders, and the dread of the meat being spoiled. The consequence is, that instead of being tender and palatable, the meat is tough and disagreeable, and not so nutritious or so easily digested as it ought to be. But while beef and mutton may with great propriety be kept some days to become tender, veal, lamb, and pork (being young or white meat) will not endure keeping more than a day, or two days at the utmost. Game may be kept for two or three weeks, that which is feathered being kept with the feathers on, and hares being embowelled or paunched. A fowl will keep a week, and a turkey a fortnight. A goose will not keep above eight or ten days. Great care should be taken in picking feathered animals which have been kept, for their skin will in such a case be easily torn.

When newly-cooked meat is brought from table, and has to be set aside for after use, put it on a clean dry dish; if any liquor or gravy be left about it, the meat is apt to become sour. The drier and more cool that cold meat is kept the better. Cold meat is always best when it has not been cut while warm, as in that case the juices have not escaped.

Green vegetables of all kinds should be used as soon after gathering as possible. They begin to ferment, and to lose both their flavour and their wholesomeness, very shortly after being taken from the ground. When they have necessarily to be kept for a day or two, place them in a perfectly dry and cool situation, but not exposed to currents of wind. Keep also each kind of vegetable separate from another, to prevent contamination of flavour. They should never be washed or placed in water till immediately before being used.

The Kitchen Range or Grate is the most important part of culinary apparatus; and in general too little care is bestowed by young persons, when setting up housekeeping, in making a proper choice of this article. A common error consists in buying ranges which are too large, and which consume a great deal more fuel than is necessary, either for cooking or giving forth heat. One of the chief points in housekeeping, is to cook victuals with the smallest possible quantity of coal. To effect this desirable object, let the range be of a small size, consisting of a fireplace in the centre, large enough for only one vessel, with an oven upon the one side and a boiler on the other; the boiler also going round the back of the fireplace; the top of the whole to be flat. The fire in the grate will thus heat the water in the boiler without any trouble, and will in a great measure render the use of a kitchen kettle unnecessary. The fire will also assist greatly in heating the oven, which at least will at all times heat dinner plates; and if required for baking, a very small quantity of live coal put into the furnace beneath will be sufficient. A range of this description, which will cost about £4, 10s., will at once roast meat in front, boil water, bake a dish in the oven, though not so well as by a separate or large oven, and keep boiling or simmering at least three vessels on the fire and top of the boiler and oven. Care should be taken to have the range set in such a manner that the smoke from the oven may pass upwards behind to the chimney. By being altogether of iron, this kind of range requires very little building, and is not apt to get out of order.

The main advantage of such a range is the constant and large supply of hot water which it affords. Every one experienced in family arrangements knows that a *house should never be without hot water*, as it may be wanted at a single moment's notice for various purposes besides those of cooking; among others, for hot fomentations, bathing of infants, and so forth. A life may be saved by the ready supply of this article alone.

Boiling and Stewing Vessels are now to be had of every size and description; and the choice of these will depend on the taste and judgment of the purchaser. The best kind (called goblets in Scotland, and saucepans in England) are those made of iron, well tinned inside, and these may be had of all sizes. It is convenient to have one or two of the very smallest dimensions, made of block tin; and also to have several to be kept for delicate stews or preparations, for which purposes those lined with delft are preferable. It is likewise advantageous to have a few shallow saucepans to be used for stews, or where little liquor is required. Also one large fish kettle, with a flat drainer to place below the fish in boiling, and for lifting to the dish when done. All the vessels should have tightly-fitting tin or iron covers; and one or two should be fitted with perforated apparatus for steaming.

Roasting and other Utensils.—Roasting is always best performed with a twirling hook and bottle-jack. A spit spoils a small piece of meat, and is an instrument which, with the jack that moves it, should never gain an entrance into the kitchen of a family in the lower or middle ranks of life. The bottle-jack, which is in every respect preferable, should be attached to the top of a tin screen of the usual semicircular form. This screen reflects the heat upon the meat, and aids the roasting. Sometimes the screen has the effect of drawing out the smoke from the chimney; when this is the case, have the upper part of the screen taken away, and suspend the jack from a projecting arm or rack on the chimney-piece. This arm, which may be folded back when not used, is made of brass, and may be had for about eighteenpence from any London or other ironmonger. A tin box with an open side, called a Despatch, and resembling a bachelor's oven, is a most useful utensil for baking small puddings or potatoes. Two other indispensable utensils are a gridiron and frying-pan.

ROASTING.

Meat is roasted by being exposed to the direct influence of fire. This is done by placing the meat before a fire, and keeping it constantly in motion, to prevent scorching on any particular part. According to Liebig, beef or mutton cannot be said to be sufficiently roasted until it has acquired throughout the whole mass a temperature of from 150 to 158 degrees; but poultry may be well-cooked when the inner parts have attained a temperature of from 130 to 140 degrees. This depends on the greater amount of blood which beef and mutton contain—the colouring matter of blood not being coagulable under 150 degrees or thereby. Roasting is generally considered to be the least thrifty mode of dressing meat; but much of the loss may be avoided by care and cleanliness in saving the dripping for other processes of cookery.

Dripping.—Roast beef yields a dripping, which is a valuable article in the economy of the kitchen. It should be removed from the pan beneath the meat before it becomes overheated, or scorched by the fire, leaving sufficient for basting. Dripping is prepared for future use in the following manner:—As taken hot from the dripping-pan, pour it into boiling water, when all particles of cinder or other improper matter will fall to the bottom, and leave the pure fat on the surface. Collect these cakes of fat, and by heating them in a jar, placed in a saucepan of boiling water, the whole will become a solid mass, and may be thus put aside for use. This process not only purifies dripping, but gives it a clear white colour. A little salt must be added, to assist in preserving it. The dripping from mutton, being tallowy, is little used in cookery, as is also that from most other kinds of meat and poultry. The dripping from lamb may be preserved for use in frying fish, or in making pie-crust.

To roast Beef.—The best piece of beef for roasting is the sirloin. If the suet be not required, it may be ordered to be cut off before purchasing the joint; a small piece of suet is all that is requisite for the purpose of basting. Do not wash the meat, unless when it is musty, as already directed. Wipe it quite dry, and hang it on the hook of the jack, in the way most advantageous for being operated upon uniformly by the fire. Handle it as little as possible. At first, place it at such a distance from the fire that it may be warmed thoroughly before being scorched on the outside. The fire must be quite clear and brisk. It is customary to allow a quarter of an hour for every pound of the meat. While roasting, baste it very frequently with its own dripping. In dishing, pour a little boiling water and salt over it for a gravy. A well-roasted joint ought to have a nice rich brown tinge, and this is to be obtained only by careful basting, attention to the fire, and removing at the proper time, when experience tells that the joint is 'done.' Garnish with scraped horse-radish.

To roast Mutton.—The best parts of mutton for roasting are the leg, the shoulder, and the loin. The pieces may be kept longer than would be desirable for mutton for boiling. It should have a clear and brisk fire. A leg will take two hours to roast; but this, as well as the time for roasting the other parts, must be regulated by the fire and the weight of the meat, and can be learned only by attention. The joint of mutton should be basted the same as beef, with its own dripping. A gravy for roast mutton, as in the case of beef, may be made by pouring a little hot water and salt over it; if wanted of a richer quality, a gravy sauce may be made from beef, as directed under the head SAUCES. Most persons prefer mutton 'well done.' In roasting the loin, take away the fat surrounding the kidney, otherwise the dish, on being brought to table, will, when cut up, be floured with oil. The back-ribs and loin of mutton ought to be well jointed or cut before being put to the fire.

To roast Venison.—Venison is roasted in the same manner as mutton, but requires longer time at the fire. It is such a dry meat, and the fat is so easily melted, that it should be covered with buttered paper, and well basted. Serve with a good gravy and currant jelly.

To roast Veal.—The best parts of veal for roasting are the fillet, the breast, the loin, and the shoulder. The fillet and the breast should be stuffed, particularly the fillet; the stuffing to be composed of crumbs of bread, chopped suet and parsley, a little lemon peel, and pepper and salt, wet with an egg and a little milk. The piece should have a slow fire at first, and will require longer time to dress than beef or mutton. Let it be well basted with butter when there is not sufficient dripping from the joint. The gravy for roast veal is either the usual hot water and salt, or thin melted butter, poured over the meat.

To roast Fillet of Veal.—The fillet of veal, which is the thick fleshy part of the hind-leg, requires care in the preparation for roasting. The knuckle or bone must be cut out neatly, without disfiguring the joint; then stuff the flap, as above; roll it up firmly, and bind it with tape or string. Allow the stuffing in this, as in all other cases, room to expand in dressing. Cover the ends with buttered paper, and baste the piece frequently with butter. Take off the paper a short time before the meat is done. Gravy as above. This dish may be garnished with sliced lemon.

To roast Lamb.—Lamb also requires to be well roasted. It is usually dressed in quarters; all parts, particularly the spinal bone, should be well jointed or cut by the butcher or cook; and the ribs of the fore quarter broken across the centre, in order to accommodate the carver. In roasting, baste, as already described, with its own dripping. The gravy for lamb may be the same as for beef or mutton—namely, hot water and salt poured over it: it is also customary to serve it up with mint sauce in a small tureen.

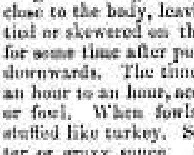
To roast Pork.—Pork requires a longer time in roasting than any of the preceding meats. When stuffing is to be used, it must be composed of chopped sage and onion, pepper and salt. The pieces should be neatly and well scored in regular stripes on the outer skin, to enable the carver to cut slices easily. Before putting to the fire, rub the skin with salad oil, to prevent its blistering, and baste very frequently. The basting may be done by rubbing it with a piece of butter in a muslin bag, where there is not enough of dripping. The gravy for pork may be the same as for other joints, hot water and salt poured over it on the dish. It is considered an improvement to have apple sauce served in a small tureen, as it assists in overcoming the richness or lusciousness of the meat, and imparts an agreeable acidulous flavour.

To roast Bullock's Heart.—Wash the heart well, freeing it completely from blood. Then fill all the openings at the top or broad end with a stuffing composed of crumbs of bread, chopped suet, parsley, pepper and salt, moistened with an egg and a little milk. Suspend with the pointed end downwards. An hour and a-half or two hours, according to the degree of heat, will cook the dish. It should, however, be well done. Send to table with beef gravy.

To roast Pigeons.—Pick and draw them well, and truss, keeping on the feet. Make a stuffing of the liver chopped, crumbs of bread, minced parsley, pepper, salt, and a little butter; put this inside. Make a slit in one of the legs, and slip the other leg through it. Skewer and roast them for half an hour, basting them well with butter. Serve with brown gravy in a small tureen. Some serve roast pigeons and game with toast bread beneath them, and bread sauce.

To roast Fowls.—Pick, draw, and singe them. A fowl should be so cleanly or well drawn as to require no washing. Take care not to break the gall-bag in drawing; if the gall be spilled, it will communicate a bitter taste to every part it touches. Press down the breast-bone. Break the legs by the middle of the first joint, drawing out the sinews, and cutting off the parts at the break. It being proper that roast fowls should have a neat appearance at table, it is customary to *truss* them—that is, to fix their legs and wings in a particular position. This is done by fixing down the knees of the animal close to the tail by a skewer or piece of string, leaving the stumps of the legs projecting. The pinion ends of the wings are then turned round on the back, the liver being placed as an ornament in one wing and the gizzard in the other. Cut the head off close to the body, leaving a sufficiency of the skin to be tied or skewered on the back. Baste well with butter for some time after putting to the fire. Suspend neck downwards. The time of roasting will vary from half an hour to an hour, according to the size of the chicken or fowl. When fowls are large, they are frequently stuffed like turkey. Serve roast fowls with melted butter or gravy sauce. Before sending to table, remove all skewers and strings which may have been used in trussing. This, which should be done in all cases of serving dishes to table, is too frequently neglected, and shows slovenliness in cookery. Fowls and all other feathered animals are served with the breast upwards.

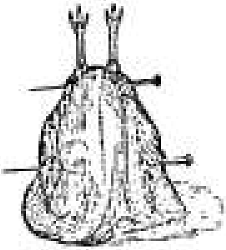
To roast Turkey.—Pick, draw, and singe the turkey well. Press down the breast-bone, and follow all the directions given for trussing fowls. The breast should be stuffed with crumbs of bread, minced beef suet or marrow, minced parsley, a little nutmeg, pepper and salt; wet it with milk and egg; a little sausage meat may also be added. On finishing, sew up the orifice or neck. Before putting to the fire, cover the breast with a sheet of writing-paper well buttered, to preserve it from scorching, and which may be removed a short time before taking from the fire, to allow the breast to be browned. Baste well with butter. A turkey will take from an hour and a-half to two hours. Serve with gravy sauce and bread sauce.



To roast Partridges and other Game.—Pick, draw, singe, and clean these birds the same as fowls. Leave the head on. Make a slit in the neck, and draw out the craw. Twist the neck round the wing, and bring the head round to the side of the breast. The legs and wings may be trussed in much the same manner as fowls. The feet are left on, and crossed over one into the other, as seen in the annexed figure. Baste well with butter before a clear fire. When about half done, dust a little flour over them to be browned. A partridge will take from twenty minutes to half an hour, and a pheasant three-quarters of an hour. Serve on toasted bread, with gravy and bread sauce; the toasted bread may be dipped in the gravy. Grouse and black-cock should be dressed and served in the same manner; the head being trussed under the wing. Snipes and woodcocks are not drawn.

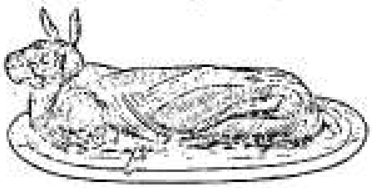
To roast Goose.—Pick, draw, and singe the goose well. Cut off its head and neck. Take off the legs and wings at the first joint. The portions of the legs and wings that are left are skewered to the sides. Stuff with chopped sage and onion, and crumbs of bread, with pepper and salt. The skin of the neck must be tied securely, to prevent the gravy from running out. Paper the breast for a short time. A goose does not require so much basting as fowl or turkey, for it is naturally greasy. It will require from two hours to two hours and a-half in roasting. It ought to be thoroughly done. Serve with gravy sauce and apple sauce. The liver, gizzard, head, neck, feet, and the pinions of the goose, form what is termed the *giblets*, and compose a good stew or pie.

To roast Ducks.—Pick, draw, and singe them well. Take off the head. Dip the feet in boiling water to take off the outer yellow skin. Truss them neatly, turning the feet flat upon the back. Stuff as in the case of goose, and serve with the same sauces. A duck requires about an hour in roasting.



To roast Pheasants.—Pick, singe, and draw them, the same as fowls. Truss them by twisting the head round one of the wings, and turning both wings on the back. The legs are fixed on each side, much in the same manner as in a roast fowl, the feet being left on, as here represented. Serve with beef gravy and bread sauce.

To roast Hare.—A hare will keep with the skin on it, and paunched, for about three weeks in cold weather. It is then fit for roasting. First cut off the feet, and commence drawing off the skin at the hind-legs, proceeding along the body to the head. Be careful not to tear the ears in skinning them. Soak and wash well in several waters, and then wipe quite dry. Stuff with crumbs of bread, chopped parsley, a bit of beef or veal suet chopped finely, a little grated



lemon-peel and nutmeg, a piece of liver boiled and finely chopped or grated, and pepper and salt; the whole moistened with an egg, a little milk, and a spoonful of ketchup. The skin of the belly afterwards to be sewed. Commence trussing, by placing the hind and fore-legs flat against the sides. To make the hind-legs lie flat, the under sinews must be cut. Fix the head between the two shoulders, on the back, by running a skewer through it into the body. In roasting, suspend head downwards. It may be basted first with milk, afterwards with butter, flouring it lightly. It will require from an hour and a-half to two hours. The hare is dished back upwards, as represented above, and served with a dish of rich beef gravy, and a dish of currant jelly.

BAKING.

Meat is prepared for baking in the same manner as for roasting. It should be placed in a deep dish for receiving the fat which flows from it; not laid, however, on the sole of the dish, but raised on a stand, to prevent the grease soaking into it. Small iron stands are made and sold for this purpose. Few dishes are so good when baked as when roasted, the meat being so liable to be shrivelled for lack of basting; and being liable, moreover, if done in a baker's oven, to partake of the flavour of the multifarious articles which are there prepared. Perhaps the only dishes which are better baked than roasted are bullock's heart and leg of pork, because in roasting they are liable to be scorched on the outside before they are thoroughly cooked in the inner parts. In baking a heart, place it in a stand in a dish with the point downwards; a piece of writing-paper, buttered, may be placed over it to keep the stuffing from drying. The sauce used is beef gravy.

BROILING.

Broiling is the rapid cooking of any kind of animal food by the influence of fire. The apparatus required in broiling is very simple, and consists only of a gridiron; which should have small bars, and be kept thoroughly clean, not only on the tops, but on the sides of the bars. An improved form of gridiron consists of channeled bars leading to a trough or receptacle for the exuded juices. Before placing the meat on the iron, let it be heated for a few minutes; and if the bars, when warm, be rubbed with a piece of brown paper, the meat will be prevented from sticking to them. The operation of broiling requires a clear strong fire, with no smoke. In almost all cases, the meat ought to be frequently turned, which may be best done by a pair of small tongs; a fork should on no account be used in turning, for it breaks the skin of the meat, and allows the gravy to run out. Broiling possesses the peculiarity of being applicable only to meat which is to be eaten immediately on being dressed. This is an advantage when expeditious cooking is required, but a disadvantage when there is any uncertainty as to the time at which the meat is to be eaten. It is by no means an economical method, as a great proportion of the nutritious juices is discharged from the flesh beyond the means of recovery.

To broil Beef-Steak.—A beef-steak is the most suitable of all kinds of meat for broiling, and is a dish universally relished. There are several parts of beef used for steaks, but in every case it should not be too newly killed. The best steak is that cut from the rump (called in Scotland the *heuk-bone*), because it is the most juicy and well flavoured. Steaks should be cut in slices of from three-quarters of an inch to an inch in thickness, and into pieces of a convenient size for turning. Some persons dust the steaks with pepper before putting them to the fire, by which means the flavour of the pepper is infused through the mass. When placed on the gridiron, turn them very frequently; it is said indeed that the steaks should never be at rest, but this is carrying matters to an extremity. It is impossible to state any exact length of time to be employed in cooking a steak, for much depends on the tenderness and thickness of the meat, and the strength of the fire. The taste of the individual who is to eat the steak must also regulate the length of time; because, while some prefer steaks in a half-raw state, others wish them to be well done; that is, to have the colouring matter of the blood fully coagulated. When cooked to the extent which is required, place the steak on a hot dish, and after rubbing the steak with a little good fresh butter, sprinkle it with a little fine salt. Beef-steaks should be carried to table immediately on being dressed, and eaten forthwith, in order to be in perfection. Every moment they stand they lose a portion of their flavour and juice. When sauce is required, either mushroom or oyster sauce may be used.

To broil Mutton Chops.—Mutton chops should be cut from the middle of the hind loin, and about the same thickness as steaks. They are broiled in the same manner as steaks, and require equal attention. No butter is to be used on dishing, as the chop is sufficiently fat of itself. Sprinkle a little salt on it, and carry to the table immediately. Mushroom sauce may be used as an adjunct.

To broil Fowls and Pigeons.—Clean and prepare them as for roasting; then split them down the back, laying them quite flat. Dust with pepper. They should be broiled more slowly than steaks or chops, being thicker, and requiring to be more thoroughly dressed. Rub occasionally with a little butter, to prevent the skin from cracking. In no case should the skin be taken off before broiling. On dishing, sprinkle with salt. Various sauces are used—parsley and butter, melted butter, beef gravy, or mushroom sauce.

FRYING.

Frying is as expeditious a mode of cooking as broiling, requires less activity and care, and is more thrifty. The thriftiness of frying is a point of material consequence, and may be thus explained. It affords a ready means of dressing in a savoury manner many odd pieces of uncooked or cold meat, thereby saving that which might otherwise have been thrown away as useless. A skilful housewife, with the aid of a frying-pan and some unexpensive vegetables, such as onions and potatoes, along with a slight seasoning, will make a small portion of meat dine a large family. A frying-pan should be of malleable, not of cast iron. It should also be thick in the bottom, and of an oval form. It should always be kept clean, by being washed with boiling water, but not scoured. In all cases of using, a small piece of dripping, butter, or lard, must be put into it and melted, to prevent the meat from adhering. In frying all meats, excepting those which are sufficiently fat in themselves, it is necessary to use some kind of grease or fat. The best fat for this purpose is lard, which is more economical, and less likely to get burnt than butter. When lard is not employed, the best substitute for it is dripping.

To fry Beef-Steaks.—Cut the steaks as for broiling, and, on being put into the pan, shift and turn them frequently. Let them be done brown all over, and placed in a hot dish when finished. Gravy may be made by pouring a little hot water into the pan after the steaks are out, and the fat poured away, with a little pepper, salt, ketchup, and flour. The gravy so formed is to be poured into the dish with the steaks. Serve to table immediately. If onions be required along with the dish, cut them in thin slices, and fry them till they are soft. They should be fried after the steaks, and merely with part of the fat in which the beef has been fried.

To fry Mutton Chops.—They require to be cut in the same manner as for broiling, and may be dressed according to the preceding directions for steaks. None of the grease which flows from the chops is to be used along with them, and the whole must be poured away before preparing the gravy.

To fry Veal Cutlets.—Veal cutlets form a delicate dish, and should be fried with butter. The best cutlets are from the fillet, because they are free from bone; the fore or hind loin—that is, the back-ribs or loin—may be used, but the bone must be cut away, which causes a waste. Cut them half an inch in thickness. They require to be dressed slowly and thoroughly, and should be of a light-brown tinge when finished.—Another and more tasteful way of dressing cutlets, is first to dip them in a beat egg and then strew them with crumbs of bread, and parsley chopped very fine, along with pepper and salt, after which put them in the pan. They will require more lard or dripping this way than when fried plain. Gravy may be made for cutlets the same as for fried steaks, but add a little juice of a lemon, and skim the gravy before pouring it over the cutlets.

To fry Lamb Chops.—Lamb chops may be either simply fried in the same manner as mutton chops, or dressed with egg and crumbs of bread (but with no parsley), as in the case of cutlets. Gravy made in the pan, as for fried steaks.

To fry Pork Chops.—Pork chops should be cut rather thin, and be thoroughly dressed. They may be either simply fried in the same manner as chops, or fried after being dipped in egg, and sprinkled with crumbs of bread, and sage and onion finely chopped. No gravy is expected with pork chops. If any sauce be used, it must be apple sauce.

To fry Beef or Pork Sausages.—All sausages are fried alike, and require to be dressed very slowly. Before being put into the pan, they should be pricked in several places with a fine fork, to prevent their bursting by the expansion of the air within. It is common in England to bring fried sausages to table neatly laid out on a flat dish of mashed potatoes. The sausages and potatoes are helped, together. They may also be laid in links on toasted bread, and garnished with poached eggs round the dish. Fried sausages are sometimes used for garnishing roast turkey.

To fry Tripe.—The tripe must be washed well, and boiled till tender. Take the thickest parts, and dry them well with a cloth. Make a thick batter of egg, flour, and milk, seasoned with salt, and for those who wish it, a little minced onion. Dip the tripe into the batter so formed, after which fry in lard or good fresh dripping, of which there must be a sufficiency in the pan almost to cover the tripe. Let it be done to a light-brown. Garnish with fried parsley.

To fry Bacon, or Ham and Eggs.—The bacon should be cut very thinly in slices not more than a quarter of an inch in thickness. The best bacon is that which is alternately streaked with fat and lean. No butter or dripping is required in the pan in frying bacon, which does not need much dressing, and is soon prepared. When done, take the slices from the pan, and place them in a hot dish before the fire. Have the number of eggs required previously broken, each in a separate cup, and place them gently in the pan, so as to preserve them in a round flat shape. Let them remain in the pan till the white is set, and take them out carefully with a slice, and place them on the bacon. The tasteful appearance of this dish is spoiled if the eggs be either broken or ragged, which is very apt to be the case if they are not previously put into cups.

To fry Collops.—The difference betwixt this dish and fried steaks is, that the collops or pieces of meat are partially stewed, as well as fried. It is consequently a more economical process, as retaining a larger proportion of the nutritious juices of the flesh. In preparing, cut the meat thinner than for broiling, and put the slices in a pan along with a large piece of butter and sliced onions. Cover it close, and when the meat is sufficiently dressed, add a little hot water and ketchup to the liquor already in the pan.

BOILING.

Boiling is the preparation of meat in water, and it is necessary that the vessel employed be large enough to allow the meat perfect freedom; if it be cramped, and have only a little water, it will be stewed, not boiled. In all cases of boiling, there must be a sufficiency of water to cover the meat. In boiling meat there is less waste than in roasting; and in some cases soup may be made of the liquor. It is the general direction for boiling, 'that all meat, poultry excepted, should be put into *cold* water, and not boiled too fast; and as the water decreases from evaporation, it ought to be replenished with *hot* or *boiling* water, so as to keep the meat always covered.' Now, according to Liebig, our greatest and most scientific authority, cold water can dissolve the most important ingredients of flesh, so that if meat is put into cold water, and slowly boiled up, the water will have carried off all the albumen and several other substances, and the remaining beef will be a kind of husk, insufficient to nourish the system, unless the water it has been boiled in is taken at the same time in the form of soup. To boil beef without losing the nutritious and savoury elements, he accordingly gives the following directions:—The water is, in the first place, to be put into a brisk boiling state; into this boiling water the meat should be plunged, and allowed to lie for a few minutes; it is then taken out, and cold water is to be poured into the boiler till the heat be reduced far below boiling, or to about 160 degrees; the meat is then put in again, and kept in the water at this temperature for two or three hours. Everything is in this way effected that can render the flesh pleasant and wholesome as food. The contact with the boiling water at the outset coagulates the albumen of the flesh all round the surface of the meat, and closes up its pores with a solid wall, that none of the internal juices can pass through, and the meat is preserved in all its integrity while undergoing the action of the heat.*

* Mr Leach of Vernon House (a retreat for mental invalids), Briton Ferry, near Neath, South Wales, has adopted Liebig's directions for preparing meat, soups, &c. for the inmates (150 in number) of his establishment, and finds that he thereby effects a saving of fifty per cent., while the quality of the food is greatly improved.

When meat of any kind is done, and has to be lifted from the pot, take care not to put a fork into any part where there are juices; if this be not attended to, a portion of the juices will escape, and the marks of the fork will produce an unsightly appearance in the meat. All parts of mutton and lamb may be roasted, but it is only the leg, neck, and head that are boiled.

To boil a salted Round of Beef.—If large, cut out the bone, roll it up firmly, and bind it with a tape; then put it into the pot, and keep the lid close. Boil it slowly and equally, allowing, as above-mentioned, a quarter of an hour for each pound of the beef. The appropriate garnishing for this and other pieces of boiled salt beef, is carrot and small greens; some add turnips. Put a little of the liquor in which it has been boiled in the dish.

To boil a Leg of Mutton.—A leg of mutton should be kept four or five days before boiling. Before putting it into the pot, bend round the shank, cutting the tendon at the joint if necessary, so as to shorten the leg. Two hours of slow equal boiling will be sufficient for a good-sized leg of mutton. Some persons, to make the leg look white and tasteful, wrap it tightly in a cloth in boiling; but this spoils the liquor for broth. It is not safe to boil vegetables with a leg of mutton, as they are apt to flavour the meat. Dish the leg with a little of the liquor, placing the lower side uppermost, conveniently for carving. A good leg of mutton will soon yield sufficient gravy. Sauce, finely-chopped capers in melted butter. Turnips mashed or whole form the appropriate vegetable to be eaten with this dish.

To boil a Leg of Lamb.—A leg of lamb, when well boiled, is a delicate and excellent dish. It requires about an hour and a-half. When whiteness is desirable, it is wrapt in cloth, the same as mutton. When dished, garnish with the loin cut into chops, and fried, to lay round it. The sauce used is plain melted butter, or parsley and butter.

To boil Veal.—Veal is seldom boiled, being too insipid by that mode of dressing. The only part boiled is the knuckle, which requires much boiling, in order to soften the sinews. It is eaten with boiled ham or bacon. The sauce used is parsley and butter. The liquor from veal is the best of any for making soup.

To boil a Turkey.—Boiled turkey is one of the most delicate and excellent dishes which can be brought to table, and should be dressed with as much care as possible. Clean the turkey from all feathers, and singe the hair with burning paper, being careful not to blacken the skin. Clean it well inside by drawing and wiping. Cut off the legs at the first joints, and draw out the sinews; then pull down the skin, and push the legs inside. Cut off the head close to the body, leaving the skin long, and draw out the craw. Make a stuffing of chopped suet, crumbs of bread, chopped parsley, pepper, salt, and a little nutmeg, which wet with an egg and milk. Put this stuffing into the breast, leaving room for the stuffing to swell; after which draw the skin of the breast over the opening, and sew it neatly across the back; by which means, when the turkey is brought to table with its breast uppermost, no sewing will be seen. Place the liver in one wing, and the gizzard in the other, turning the wing on the back, and fixing the wings to the sides with a skewer. The turkey being now ready for the pot, put it into a cloth and boil it for a length of time according to the size and age. A small young turkey will not require more than an hour and a-half; an old and larger one perhaps two and a-half or three hours. Let the water be warm in putting in, and of sufficient quantity to keep the turkey always covered. When done, and placed in a hot dish, pour a little sauce over the breast, and put the remainder in a sauce tureen. The sauce used is various—as parsley and butter, celery, or oyster sauce. One of the most delicate and agreeable sauces is that which is made of melted butter, boiled maccaroni, and milk.

To boil a Fowl.—A fowl is to be prepared for boiling in the same manner as a turkey, except that no stuffing is used. It may be boiled with or without a cloth. Small fowls will require from half an hour to three-quarters of an hour; large fowls will require from an hour to an hour and a-half. Sauce, parsley, and butter.

To boil Rabbits whole.—Wash them well in warm water. They may be either stuffed or not stuffed, according to taste. When stuffing is required, make it of crumbs of bread, suet, parsley, and onions—all chopped—and pepper and salt; moisten with milk and egg. Sew this neatly into the belly. Truss in the same manner as roast hare, and boil slowly for an hour. The sauce to be made of boiled onions, milk, melted butter, and flour, with pepper and salt, which pour over the rabbits when dished. This is called *rabbits smothered in onions*. When two rabbits are dished together, always lay the head of one in a contrary direction to that of the other.

To boil a Ham.—If the ham has been cured long, it may require soaking in cold water to soften it, from twelve to twenty-four hours before dressing. Put it in a large boiling vessel, with plenty of cold water, and let it simmer slowly from two to four hours, according to the size. Skim it frequently, to remove the grease which is constantly rising to the top. When done, skin it, and strew bread raspings over the upper side; then place it before the fire to dry and brown. Garnish with greens or cabbage.

To boil Leg of Pork.—Pork requires to be particularly well boiled. Place it in the pot with the skin side uppermost, with a plate below it, for pork is very apt to stick to the bottom of the pot. Peas pudding is generally served separately with this dish.

To boil a Tongue.—If hard, soak the tongue in water all night before using. Boil it from two hours and a-half to three hours. Skin it before dishing. Garnish with greens or cabbage.

To boil Tripe.—When tripe is purchased from the butcher in a raw state, it requires to be boiled a very long time, to be thoroughly soft and tender. The length of time will depend on the age of the animal from which it has been taken. Sometimes, for young tripe six or seven hours will be sufficient, while old tripe will perhaps take ten or twelve. In all cases, boil, or rather simmer it very slowly, for quick boiling hardens it. It should be cut into moderately-sized pieces for helping at table. When to be served plain, carry to table in a hash dish, in some of the water with which it has been boiled, with boiled onions in it. A tasteful way of serving is to take it from its liquor after boiling, and stew it for about ten minutes in a saucepan with milk, which thicken with a little arrowroot, or flour and butter, and season with pepper and salt. This makes a delicious and cheap dish.

To boil Cow-heel.—Cow-heel should be boiled for five or six hours, or till the bones will slip out. Serve with a sauce of chopped parsley and butter.

To boil Eggs.—The boiling of eggs is a very simple operation, but is frequently ill performed. The following is the best mode:—Put the egg into a pan of hot water just off the boil. When you put in the egg, lift the pan from the fire and hold it in your hand for an instant or two. This will allow the air to escape from the shell, and so the egg will not be cracked in boiling. Set the pan on the fire again, and boil for three minutes or more, if the egg be quite fresh, or two minutes and a-half, if the egg has been kept any time.

STEWS, HASHES, AND MADE DISHES.

Stewing is the preparing of meat by slow simmering or boiling, and by which all the liquor is to be used along with the meat at table. This is a much more savoury and nutritious mode of cookery than boiling, because the substance of the meat is partly in the liquor, and is seasoned to have a high relish or flavour. Generally, much more can be made of meat by stewing than by roasting, boiling, or frying, because nothing is lost in the process of dressing. It also possesses the decided advantage of being a way by which meat may be dressed for a person whose time of dining is uncertain. A stewed steak, for instance, will keep warm and in good condition for an hour, but a broiled or fried steak cannot keep a minute after dressing.

To stew a piece of Beef, or make Beef Bouilli.—Take a piece of beef—the brisket or rump, or any other piece that will become tender. Put a little butter in the bottom of the stew-pan, and then putting in the meat, partially fry or brown it all over. Then take it out, and lay two or three skewers in the bottom of the pan; after which replace the meat, which will be prevented from sticking to the pan by means of the skewers. Next, put in as much water as will half cover the meat. Stew it slowly, with the pan closely covered, till done, with a few onions, if required. Two hours are considered enough for a piece of six or eight pounds. When ready, take out the meat, and thicken the gravy with a little butter and flour. Cut down into handsome shapes a boiled carrot and turnip, and add them to the liquor; season with pepper, salt, and ketchup. Boil all together for a few minutes, and serve in a hash dish.

To stew a Shoulder of Mutton.—Take a shoulder of mutton, and cut out the blade bone without injuring the form of the meat. Make a stuffing of crumbs of bread, chopped suet, and parsley, a little green or dried sweet herbs, chopped onion, and pepper and salt, moistened with egg and milk. Lay this stuffing in the place from which the bone was cut out; then roll it up, and skewer or bind it firmly with tape. Rub the bottom of a stew-pan with suet or butter, and brown the mutton. When sufficiently brown, lay two skewers in the bottom of the pan; add a little stock or boiling water, and let it stew for an hour and a-half; the gravy drawn from itself will be sufficiently rich for sauce, seasoned with pepper and salt. Skim it before serving.

To stew Steaks and Chops.—Cut the beef in slices rather thinner than for broiling or frying. Put them in a stew-pan, with water sufficient to make gravy. Add grated carrot, turnip cut in small squares, and pepper and salt. Stew for an hour, or till tender. Skim if necessary. When done, thicken the gravy with a little arrowroot or flour, and flavour with ketchup. Some persons add a little maccaroni or vermicelli, which requires from ten to twenty minutes' boiling along with the stew. Mutton chops are stewed in the same manner, but require to be trimmed of the superfluous fat, and more carefully skimmed. This is called *haricot of mutton* when the chops have been previously browned. The same directions will serve for stewing slices or pieces of any other kind of meat.

To stew Veal.—The best parts of veal for stewing are the fillet, the breast, and the shoulder. The shoulder must be stuffed when the knuckle is cut out, which must be done neatly, without disfiguring the meat; the stuffing should consist of bread-crumbs, minced suet, chopped parsley, grated lemon-peel, white pepper and salt, moistened with egg and milk; fill the shoulder, and sew it up. Rub the bottom of a large stew-pan with butter, lay in the veal, and brown it on both sides. When sufficiently brown, put in a pint of cold water, and stew it slowly for two hours, or, if large, two hours and a-half. Before it is to be dished, draw off the gravy, and if not thick enough, brown a little butter, and dust in a little flour; put it amongst the gravy, and season with Cayenne, salt, and the squeeze of a lemon (a glass of sherry will be an improvement); skim the sauce, and pour it over the meat.

To stew Kidneys.—Cut the kidneys into slices; wash them, and dry them with a clean cloth; dust them with flour, and fry them with butter until they are brown. Pour some hot water or beef gravy into the pan, a few minced onions, pepper and salt, according to taste; let them stew slowly for an hour, and add a spoonful or two of mushroom ketchup before dishing.

To stew Pigeons.—Pick and wash the pigeons well, trussing them as fowls for boiling. Put a piece of butter and some pepper inside; dust them with flour, and brown them in a covered stew-pan with a good piece of butter; put in a little flour; add some gravy or hot water. Season them highly, and let them stew slowly for twenty minutes or half an hour. Before dishing, add half a glass of port wine, if the flavour be approved.

To stew Rabbits.—Wash the rabbits well; cut them in pieces, and put them in to scald for a few minutes. Melt a piece of butter, in which fry or brown the rabbits for a short time. When slightly browned, dust in some flour; then add as much gravy or hot water as will make sufficient sauce. Put in onions, ketchup, pepper and salt, according to taste. Stew for an hour slowly. When required, flavour the gravy with a small quantity of curry powder.

To make Irish Stew.—Take a piece of loin or back-ribs of mutton, and cut it into chops. Put it in a stew-pan with pared raw potatoes, sliced onions, pepper, salt, and a little water. Put this on to stew slowly for an hour, covered very close; and shake it occasionally, to prevent it from sticking to the bottom.

To make English Stew.—English stew is the name given to the following excellent preparation of cold meat:—Cut the meat in slices; pepper, salt, and flour them, and lay them in a dish. Take a few pickles of any kind, or a small quantity of pickled cabbage, and sprinkle them over the meat. Then take a teacup half full of water; add to it a small quantity of the vinegar belonging to the pickles, a small quantity of ketchup, if approved of, and any gravy that may be set by for use. Stir all together, and pour it over the meat. Set the meat before the fire with a tin behind it, or put it in a despatch, or in the oven of the kitchen range, as may be most convenient, for about half an hour before dinner-time. This is a cheap and simple way of dressing cold meat.

To hash Cold Beef or Mutton.—Cold roast beef, or cold roast or boiled mutton, may be dressed as a hash in the following manner:—Cut the meat from the bones into small pieces, and lay them aside; then put the bones in a stew-pan, with a little water and sliced onion. After stewing for a short time, take out the bones and put in the meat. When the meat is perfectly hot, thicken with a little flour and butter, and season with pepper and salt, and a little ketchup. Dish the hash, and stick small triangular pieces of dry toasted bread round the inner edge of the dish.

To dress Cold Boiled Beef, or make Bubble and Squeak.—Cut the beef in slices of about the third of an inch in thickness. Fry the slices till lightly browned and heated through. Then take them from the pan, and place them on a warm plate before the fire, to keep hot. Fry some cabbage which has been previously boiled and chopped; stir this about a short time in the pan, and season with pepper and salt. Spread the cabbage in a dish, and place the slices of meat upon it; or heap the cabbage in the dish, and place the meat around it.

To mince Cold Veal.—Cut the veal from the bones, and mince it in small square bits, and lay them aside. Then put the bones in a stew-pan with a little warm water, to make a gravy. After stewing for a short time, take out the bones and put in the bits of veal, with a small piece of lemon-peel, chopped very fine. When perfectly heated, thicken with a little flour and butter, and season with pepper and salt, and a little lemon-juice. Dish with small pieces of toasted bread, as in hashed mutton.

To dress a Lamb's Head and Pluck.—Lambs' heads are procured skinned. Take the head with the neck attached; split up the forehead, and take out the brains, which lay aside. Wash the head carefully, cleaning out the slime from the nose by rubbing it with salt, and take out the eyes. The head being thus cleaned, put it on to boil, along with the heart, and the lungs or lights. Let the whole boil for an hour and a-quarter; then take them out, and dry the head and neck with a cloth. Rub it over with an egg well beaten; strew crumbs of bread, pepper and salt, over it; also stick small pieces of butter over it, and lay it in a dish before a clear fire, to be browned lightly. Mince the lungs and heart, and part of the liver, with some onion, parsley, pepper, salt, a little flour, grated nutmeg, and a tablespoonful of ketchup; mix all together, and add some of the liquor in which the head was boiled to form a gravy; let it simmer by the side of the fire for half an hour. Take the brains and beat them well with two eggs, two tablespoonfuls of flour, and a sprig of fine chopped parsley, also a little pepper and salt, and two or three tablespoonfuls of milk—the whole forming a batter. Have a frying-pan with a little lard or dripping, and fry the batter in small round cakes, which turn and brown lightly on both sides. Cut the remainder of the liver in slices, and dust it with flour, and fry it. Now lay the head upon a dish; place the hash round it, and lay a slice of liver and a brain cake alternately on the hash all round. This forms a handsome and a savoury dish, but requires great attention on the part of the cook, to have all the various parts hot and equally ready at the time of dishing.

To make Potted-Head.—This is a dish to be eaten cold as a jelly. Take the half of a bullock's head and clean it; soak it in warm water, with a cow-heel, for two or three hours. Then boil it with the heel till tender. When done, cut them in small pieces, and lay them aside; after which strain the liquor in which they have been boiled, and let it stand till it is cold, so that the fat may be easily skimmed. Put the whole into a sauce-pan, and boil for half an hour, and season with pepper and salt according to taste. Pour it into basins, or tin or earthenware shapes, which stand in a cool place. When quite cold, it forms a jelly, and is ready for being turned out on a dish for use. If it do not come out easily, dip the basin or shape in hot water, and the heat will immediately loosen it. Garnish with sprigs of fresh parsley.

SOUPS AND BROTHS.

Soups are the substance of meat infused in water by boiling, and are of many different kinds, but may be divided into two classes—namely, *brown* and *white*. The basis of brown soups is always beef, while the basis of white soups is generally veal. Broths are preparations of soup, but more simple in their nature, and usually containing some kind of vegetables or matter for thickening—as rice, barley, &c. Soups of every description should be made of sound fresh meat and soft water. It is a general rule to allow a quart of water for every pound of meat; also to boil quickly at first, to make the scum rise, which is assisted by adding a little salt; and after skimming, to simmer gently.

To make Brown or Gravy Soup.—Take a shin or piece of the rump of beef, and break it in several places. Cut the beef from the bones; take out part of the marrow, and lay it on the bottom of the pot. If there be no marrow, use butter. Then lay in the meat and bones to brown. Turn the whole, when browned, on one side, and take care that it does not burn. When it is thoroughly browned, add a pint of cold water to draw the juice from the meat, also a little salt; and in a quarter of an hour after, fill in the quantity of cold water which may be requisite. Now add the vegetables, as, for instance, two carrots, a turnip, and three or four onions, all sliced; also a stalk of celery, some sweet herbs, with some whole black and Jamaica pepper. Let the soup boil slowly for from four to five hours, after which take it off, and let it stand a little to settle. Then skim off the fat, and put it through a hair sieve to clear it. The soup, if cleared, may now be either served or set aside for after use. It should have a clear bright look, with a brownish tinge. Frequently, it is made the day before using, in order that it may be effectually skimmed of fat. In such a case it is heated again before serving. On some occasions it is served with a separate dish of toasted bread cut in small squares. The meat which has made the soup is supposed to be divested of nearly all its nourishing qualities; but where thriftiness is consulted, it may form an agreeable stew, with vegetables, a little ketchup, and pepper and salt.

Brown soup, made as above directed, forms what is called *stock*—that is, a foundation for every other soup of the brown kind, also a gravy for stews where richness is required. It likewise forms any kind of vegetable soup, by merely adding to it, when just finished boiling and clearing, the particular vegetable which may be required. Thus are formed *carrot soup*, the carrots being cut into small stripes or straws; *leek soup*, by adding leeks cut into short pieces, and boiling an hour; *vermicelli soup*, by adding boiled vermicelli; and so on with other vegetables.

Liebig's Brown Soup.—The following plan is that proposed by Baron Liebig for obtaining a soup which shall contain the whole, or nearly the whole, of the nutritious elements of the flesh employed:—'When one pound of lean beef, free of fat, and separated from the bones, in the finely-chopped state in which it is used for beef-sausages or mince-meat, is uniformly mixed with its own weight of cold water, slowly heated to boiling, and the liquid, after boiling briskly for a minute or two, is strained through a cloth or sieve from the coagulated albumen and the fibrine, now become hard and horny, we obtain an equal weight of the most aromatic soup, of such strength as can be obtained even by boiling for hours from a piece of flesh. When mixed with salt, and the other usual additions by which soup is usually seasoned, and tinged somewhat darker by means of roasted onions or burnt sugar, it forms the very best soup that can be prepared from one pound of flesh.' An extract of meat thus prepared is found to be an invaluable provision for an army in active service. Administered along with a little wine to wounded soldiers, it immediately restores their strength, exhausted by loss of blood, and enables them to sustain the fatigue of removal to the nearest hospital. Of course what is so useful in this extreme case must be useful in thousands of minor occasions of bodily prostration. The loss of strength means the loss of the substances that support vitality, such as these very ingredients of fleshy juice. The fleshy fibre itself is wasted more slowly than the substances that float in the liquid that invests it; so that, in fact, a supply of these matters has a more instantaneous action than any other refreshment. We can thus explain the effect of soups upon convalescent patients.

Beef Tea.—This is but another name for the pure extract of beef, as above recommended by Liebig. The common plan is merely to cut the meat into thin slices; but of course mincing is to be preferred, as a much more effective method of obtaining the essential juices. After boiling, skim, and season with salt.

Kidney Soup.—Make a stock or gravy soup as above directed. Cut two beef kidneys in slices; wash them well, and stew them in water or soup for an hour. Take out the kidneys and strain the soup. Then return the kidneys to the soup so strained, and add as much stock or gravy soup as is required. Let the whole boil for a few minutes, and serve in a tureen.

Ox-tail Soup.—Make a quantity of brown soup, as previously directed. Take two or three tails, and separate them at the joints into pieces. Put the whole in the soup, and boil till the meat is tender, but not till it comes from the bones. Add a little ketchup, and serve with the pieces of tail in the soup.

Hare Soup.—Take a fresh hare, and, when skinned, wipe it well with a cloth. Cut it open, and take out the entrails, taking great care not to lose any of the blood. Then cut the body into separate pieces, and put them in a pot with two or three quarts of water, along with any blood that may have run out. Put into the pot also two or three pounds of beef cut into pieces, likewise a sliced carrot, turnip, and onion, a few sprigs of thyme, a few Jamaica peppercorns, and four tablespoonfuls of flour mixed with cold water. Keep stirring till it boil, and let it boil for an hour and a-half. When this is done, take the best pieces of the hare, which are the back and upper joints of the hind-legs. Lay these aside. Let the soup boil for other two hours. Then take out the remainder of the meat, and cut it off the bones, and pound it in a mortar, or otherwise mash it well. Put the meat thus pounded back into the soup, and strain the whole through a hair sieve. Put the soup so purified into the pot, along with the best pieces of the hare which were laid aside, also two tablespoonfuls of ketchup. Boil this for half an hour; then add pepper and salt, and serve with the pieces of hare in the tureen.

Jugged Hare.—After having skinned, drawn, and washed the hare, cut it into pieces, and put the pieces into a jar with an onion, a bunch of sweet herbs, and a little water. Cover the top of the jar so close that very little of the steam can escape from it; the cover may be tied down to the jar. Place it in a saucepan of water, the water not to cover the top of the jar. Keep the water constantly boiling. Boil between three and four hours. When done, skim off any fat, thicken the sauce with flour and butter, season with salt and pepper, and serve altogether in a hash dish.

Mock-Turtle Soup.—This is made with a calf's head. It is best to get the head ready scraped and cleaned from the butcher, but with the skin on. If it be got in an uncleaned state, wash it, and put it into a pot with cold water, and boil it for a short time till the hair is loosened. Then scrape off the hair, split the head, clean it thoroughly, and take out the brains. The head is now supposed to be clean, and ready for making the soup. Put it into a pot with considerably more water than will cover it. Skim it frequently as it warms, and let it boil gently for an hour. Take out the head, and when it has cooled, cut the meat off into handsome pieces of about an inch square. Scrape and cut the tongue in the same manner. Lay all these pieces aside. Then put into the water in which the head was boiled about three or four pounds of hock of beef and a knuckle of veal, with the bones broken. Add to this four or five onions, a carrot and turnip sliced, a small bunch of sweet herbs, and some black and Jamaica pepper, whole. Add also the brains, after you have boiled them separately in a cloth, and pounded them. With all these additions let the soup boil slowly for four or five hours, after which strain it, and when cool, take off the fat. Take a quarter of a pound of fresh butter, and melt it in a stew-pan; when melted, put in two handfuls of flour and let it brown, stirring it all the time; add a little of the soup, a sprig or two of sweet basil, and a few heads of parsley. Boil this for a quarter of an hour; strain it through a sieve; then put this, the pieces of meat, and the soup, all together, and boil it for an hour. Add two tablespoonfuls of ketchup, the juice of a lemon, Cayenne pepper, and salt to taste. It is usual to put in at the same time four glasses of sherry wine. When dished in a tureen, put in two dozen of egg-balls.

Egg-balls for mock-turtle soup are made as follows:—Boil four or five eggs till they are quite hard. Take out the yolks, and beat them in a mortar, with salt and Cayenne pepper. Make this into a paste with the white of one or two raw eggs. Roll the paste into balls the size of small marbles. Roll them in a little flour, and either fry them in butter or brown them before the fire, being careful to keep them whole and separate. They are now ready for being put into the soup.

Peas Soup.—This is an excellent soup, if well made, and is one of the cheapest dishes that can be put on the table, for it may be formed of cold meat or marrow-bone, or, what is cheaper still, merely water, or the liquor in which any piece of mutton, lamb, or veal has been boiled. We give the following recipes:—

Peas Soup with meat or bones.—Take a good marrow-bone, or the bones of cold roast beef; a slice or shank of ham may be added, if the flavour be liked. Break the bones, and put them in the pot with four quarts of cold water. According to the thickness and quantity required, take two or three pounds of the best split peas, and put them among the cold water and bones; add to this two carrots, two turnips, half-a-dozen small onions, a stalk of celery cut in pieces, a bunch of thyme, and some whole black and Jamaica pepper. Let all this boil for two hours, stirring frequently, as the soup is very apt to burn. When the peas are quite soft and broken down, take the soup off, and put it through a sieve, into another pot; rub it well through until the pulp be mixed with the soup. Add salt melted amongst a little water, and boil the soup again for a few minutes. When to be served, cut a slice of toasted bread into small square pieces, and put in the tureen with the soup.

Peas Soup without meat or bones.—Put two pounds or pints of peas in five quarts of water. Boil for four hours; then add three or four large onions, two heads of celery, a carrot and a turnip, all cut up; and season with salt to taste. Boil for two hours longer. If the soup become too thick, add a little water. The peas may be boiled the evening before being used, and the longer they boil, the smoother and more mellow the soup will be; but do not put in the vegetables until the day the soup is to be used. By this plan the soup does not require straining.

Mutton Broth.—This is a broth of a mild nature, being intended chiefly for invalids. Take a scrag or thick end of a loin of mutton, and put it into a pot with cold water; the proportion being a quart of water to a pound of meat, which will allow for loss in boiling. Turnip and onion may be added when not considered injurious. Let this boil slowly for three hours, and skim off all the fat before serving. The meat is supposed to be useless.

SCOTCH DISHES.

Sheep's Haggis.—There are different ways of making a haggis, as far as the exact composition of the materials is concerned. Some put minced tripe in it, others put no tripe. The following is the more common, and, we believe, the best manner of making it:—Procure the large stomach bag of a sheep, also one of the smaller bags called the king's hood, together with the pluck, which is the lights, the liver, and the heart. The bags must be well washed first in cold water, then plunged in boiling water, and scraped. Great care must be taken of the large bag; let it lie and soak in cold water, with a little salt, all night. Wash also the pluck. You will now boil the small bag along with the pluck; in boiling, leave the windpipe attached, and let the end of it hang over the edge of the pot, so that impurities may pass freely out. Boil for an hour and a-half, and take the whole from the pot. When cold, cut away the windpipe, and any bits of skin or gristle that seem improper. Grate the quarter of the liver (not using the remainder for the haggis), and mince the heart, lights, and small bag very small, along with half a pound of beef suet. Mix all this mince with two small tea-cupfuls of oatmeal, previously dried before the fire, black and Jamaica pepper, and salt; also add half a pint of the liquor in which the pluck was boiled, or beef gravy. Stir all together into a consistency. Then take the large bag, which has been thoroughly cleansed, and put the mince into it. Fill it only a little more than half full, in order to leave room for the meal and meat to expand. If crammed too full, it will burst in boiling. Sew up the bag with a needle and thread. The haggis is now complete. Put it in a pot with boiling water, and prick it occasionally with a large needle, as it swells, to allow the air to escape. If the bag appears thin, tie a cloth outside the skin. There should be a plate placed beneath it, to prevent its sticking to the bottom of the pot. Boil it for three hours. It is served on a dish without garnish, and requires no gravy, as it is sufficiently rich in itself.

Lamb's Haggis.—This is a much more delicate dish, and less frequently made than a sheep's haggis. Procure the large bag, pluck, and fry of a lamb. The fry is composed of the small bowels, sweetbreads, and kernels. Prepare the bag, as in a sheep's haggis. Clean thoroughly the small bowels and other parts; parboil them, and chop them finely along with a quarter of a pound of suet. Mix with dried oatmeal, salt, and pepper, and sew the mixture in the bag. Boil it, and attend to it in the same manner as a sheep's haggis.

Broth or 'Kail.'—Broth is made of beef or mutton, but mutton is preferable, and is generally employed. The best broth is made as follows:—Put into a pot three quarts of cold water, along with a cupful of pearl barley, and let it boil. As soon as it boils, put in two pounds of the best part of the neck or back ribs of mutton. Allow it to boil gently for an hour, skimming occasionally, and watching to prevent boiling over. Then add one carrot grated, two small turnips cut in squares, a few small onions shred; also two or three pieces of carrot and turnip uncut. Instead of part of these vegetables, according to taste put in the half of a small cabbage chopped in moderately-sized pieces, or if cabbage cannot be procured, a similar quantity of greens. Leeks are also used instead of onions. Boil the whole for an hour longer, adding, if necessary, a small quantity of hot water to compensate the loss in boiling. The broth is now supposed to be done. Season with salt only, and serve in a tureen. The meat, which is not expected to be over-boiled, is served in a separate dish, garnished with the uncut pieces of turnip and carrot. By this preparation both the broth and meat are used, so that a small quantity of meat produces food for a large number.

Hotch-Potch.—This is a dish only to be obtained in perfection in summer, when green peas are in season. Put on two quarts of water, and when it boils, put in three pounds of the back ribs of mutton or lamb, paring off the fat if there be too much. Put in with the meat two or three carrots cut into squares, and two grated, also three or four sweet young turnips in squares, a cauliflower and a lettuce cut down, a few young onions shred, a little parsley, and about a pint of sweet young peas. Boil this for an hour and a-half, then take out the meat and cut it in chops, laying it aside. Add another pint of young peas, seasoning with pepper and salt; and when these peas are done, put in the chops. A few minutes afterwards, serve up in a tureen.

Sheep's Head.—Procure as good a sheep's head as possible. The first thing done is to singe it with a hot iron, so as to free it completely from every particle of wool. This process is always performed in Scotland by a blacksmith, or some other person who makes a business of singeing heads. The horns should have been previously sawed off by the butcher. When singed and ready for the cook, soak the head for some time in warm water, and then scrape it till it is perfectly clean, and as nearly white as possible. The head must now be split, and the brains removed. Take out the eyes, and scrape and clean out the nose; after which wash the head again, and let it lie in warm water for a short time. It is usual to procure the trotters along with the head, and to subject them to a similar treatment as regards singeing, cleaning, and washing. The head and trotters being now ready for the pot, put them in with a sufficiency of water, and let them boil till the skin is soft and tender, which may be in three hours. When ready, serve with the trotters round the dish, and garnish with boiled carrot and turnip.

Minced Collops.—Take a pound of good juicy beef, and a proportionate quantity of suet. Mince the whole very fine, as if for sausages, taking away any bits of gristle or skin. Melt a piece of butter in a frying-pan, and then put in the collops. Stir them well, adding a little flour, a little hot water or gravy, and season with pepper and salt, and a little ketchup. Onion may be chopped, and put in along with the meat, if required. Ten minutes will dress a pound, which will form a dish for four or five persons. Serve in a hash dish.

Potato Soup.—Take any bones of cold roast meat, or a marrow-bone, or, failing these, a piece of dripping, which put into a pot with cold water, according to the quantity required. Let it boil a short time; then put in a quantity of potatoes well peeled or scraped, which have been previously soaked in boiling water, to extract any disagreeable flavour from them. Add also one or two onions cut in pieces, a little pepper and salt, and let all boil for half an hour.

SAUCES AND FLAVOURS.

Sauces are liquid preparations, to be used in giving a flavour or relish to dishes, and are of various kinds. A number are formed of melted butter, with an infusion of some other ingredients; others are in the form of gravies drawn from fresh juicy meat; and a third kind are composed partly of water, and some preserves, condiments, or spices. There is little merit in making a good sauce when a person has good and proper materials to make it with. The chief merit consists in furnishing a fine flavour from inadequate materials; as, for instance, giving a rich flavour of meat to a mass of potatoes, or some other plain dish, when no meat has been employed. This can only be done by knowing the qualities of various vegetable products, and how these, by means of cookery, may be made to resemble the juices of animal food. The vegetable products of which by far the most can be made by a skilful cook are onions, mushrooms, and carrots. Onions and mushrooms alone furnish the most effectual substitutes for animal juices, and may be dressed so exquisitely, as hardly to be distinguished from the gravy of beef.

Onion Flavour.—Onion flavour is made by stewing. Take several large onions, and remove the thin outer film from them. Put them in a saucepan with a little salt and flour, and a small piece of butter or dripping, to prevent their burning. Cover them quite close, and set by the fire to brown and stew gently. Two hours will dress them, and at the end of this time they will be quite soft, and with the addition of a little water, they will yield a rich gravy. This may be used to fry potatoes with, or to flavour any other dish.

Mushroom Sauce.—Pick out the stems, and skin the mushrooms and the stems. Cut them in small pieces, and wash them. Then put them in a saucepan, with rather more water than will cover them. Let them stew gently for about half an hour, or till they are soft. They will now have yielded a fine rich sauce. Stir in a little flour and butter kneaded together, and season with pepper and salt. This preparation may be eaten with potatoes, the same as meat; it also forms an excellent sauce to many dishes.

Melted Butter.—This must be made of fresh butter. Cut down the butter into small pieces, and put them into a small saucepan with cold water, in the proportion of an ounce of butter to a tablespoonful of water. Throw in flour from a dredger with the one hand, while with the other you turn the saucepan rapidly round, so as to cause the flour to mix without lumping. A small quantity of flour is sufficient. You now for the first time take the saucepan to the fire, and continue turning or shaking it till the butter is thoroughly melted. When it boils, it is ready; it should then have the consistency of rich cream. If it should oil in making, it may be partially recovered by putting a little cold water into it, and pouring it several times into and out of a basin. This sauce is the foundation of a number of other sauces, various additions being made to it for the sake of variety.

Onion Sauce.—Skin the onions, and boil them in plenty of water. When soft, take them from the water and chop them very fine. Melt butter as above, stir them in, and season with a little pepper and salt.

Egg Sauce.—Boil three or four eggs till they are quite hard. Peel and chop them, and then stir them into melted butter. Season with pepper and salt.

Caudle Sauce for Plumpudding.—Melt butter, as above directed, and stir into it a glass of sherry, half a glass of brandy or rum, a little sugar, grated lemon-peel, and nutmeg. Do not let it boil after the spirits have been added.

Lobster and Crab Sauce.—Melt the butter, as above directed. Pick out the meat of a boiled lobster or crab; chop it down very fine, and put it amongst the butter. Season with Cayenne pepper and salt. If the lobster be procured raw, with berries or spawn on the outside, these should be taken off previous to boiling, and being mashed in a little cold water, may be added to the sauce after the lobster is put in. By boiling a little, the whole will become a bright red. This forms an improvement on common lobster sauce.

Bread Sauce.—Grate down crumbs of bread. Put it in a saucepan on the fire, with as much sweet milk as will allow it to be thick. Add a piece of sliced onion, and stir it till the bread is soaked and the sauce is quite smooth. Season with pepper and salt.

Mint Sauce.—Take the leaves of fresh green mint. Wash them, and after drying them, chop them very fine. Mix them with vinegar, and add a little sugar.

Beef Gravy.—A pound and a-half of beef will make a pint of good gravy. Cut the beef in slices, or score it very deeply. Place it in a saucepan, with a bit of butter to prevent it from sticking, and a sliced onion. Brown the meat gently, being careful not to let it burn. Cover it closely, and let it stand beside the fire for about half an hour, to allow the gravy to run from the meat. Then put in about a pint of hot water, and let it boil slowly for an hour and a-half, with some whole pepper. Some persons put in to boil along with it a piece of bread toasted hard and brown, which thickens the gravy a little and adds to its richness. Season with salt, and strain it through a hair sieve.

To make a Stuffing.—Roast veal, fowls, turkey, and some other things require a stuffing. These stuffings have been alluded to in various recipes in the preceding pages, and may here be expressly defined. Take a quarter of a pound of the crumbs of stale white bread, a quarter of a pound of chopped beef suet or marrow, as much chopped parsley as will lie on a tablespoon, about half a spoonful of chopped sweet marjoram, and a little grated lemon-peel, pepper, and salt. Mix all these thoroughly together with one beat egg and a little sweet milk. This forms a species of dough in sufficient quantity for a small turkey or large fowl.

Force-meat Balls.—These are balls formed of stuffing, used as a garnish for roast veal or veal cutlets. Make a stuffing like the above; but instead of being wet with one egg and milk, wet the mixture with two eggs. Roll the dough into small balls about the size of nutmegs. Roll them in flour, and fry them with a little lard, butter, or dripping. When required to be more savoury, the composition may be enriched with a little chopped ham, tongue, or sausage meat.

FISH.

Fish are dressed in a variety of ways, according to the taste of individuals. They are boiled, broiled, baked, stewed, and fried; but the most common modes of preparation are boiling and frying—boiling when required to be done in a plain way, and frying when a high relish or flavour is to be given to them. In all modes of preparing fish, much care is required to prevent them from being broken or disfigured.

To boil Salmon.—Clean out, scale, and rinse the fish in water; then put it in a good roomy fish-kettle, with plenty of cold water, and a handful of salt. The usual time allowed for boiling salmon is twelve minutes to each pound; but this must in a great measure depend on the thickness of the fish. The way to ascertain when it is ready, is to raise one end from the water, and try if a knife will pass easily betwixt the fish and the bone. If it pass easily, it is dressed sufficiently. When done, lift it immediately from the water, and place the fish-drainer across the kettle, to allow the water to drip from the fish. Serve on a dish with a fish plate and white napkin under it, the napkin being next it. Garnish with green parsley. Sauce—plain melted butter, parsley sauce, or lobster sauce in a tureen.

To broil Salmon, or Salmon Steaks.—Cut slices from the thick part of the fish, and having cleaned and scaled them, dry them, and dust them with flour. Broil them on a gridiron over a clear fire. When ready, rub them over with butter, and serve hot, with any of the sauces used for boiled salmon. Slices of hung or *kippered* salmon are broiled in the same manner.

To fry Trouts or similar Fish.—Trouts of a moderate size are dressed whole, and frying is the best mode of preparation. Take the trouts and clean out and scale them. Dust them with flour, and put them in a frying-pan with hot dripping or lard. Turn them, so as to brown them on both sides. Lift them out and serve them on a dish; they will be improved by laying a napkin under them to absorb the grease. In the country parts of Scotland trouts are rubbed with oatmeal instead of flour, and some reckon that this improves the flavour.

To boil Turbot.—Select a thick fish of a white creamy colour. After cleaning, but not cutting any part, except in gutting it, lay it in salt and water, with the addition of a little vinegar, and let it soak a short time before boiling. Put it with the white side or belly upwards in a fish-kettle on the fire, with plenty of cold water, a handful of salt, and a cupful of vinegar. Let it heat slowly, and boil for half an hour after it has come to the boil. When done, serve with belly upwards, and garnish with any small fish fried, or with parsley and scraped horse-radish. Sauce—lobster, oyster, or plain butter.

To bake Turbot.—Cut a small turbot into slices, which clean and free from bones. Dip the slices in beat egg; and roll them in a mixture of crumbs of bread, minced parsley, pepper, and salt. Place them in a dish well buttered all round, and bake them in an oven not very hot, or in a bachelor's or Dutch oven before the fire. They must be basted frequently with butter. When done, lay the pieces in a dish, and pour round them lobster or oyster sauce, highly seasoned with Cayenne pepper, salt, and ketchup. Instead of being baked, slices of turbot may be fried after being prepared as above, and served with plain butter sauce.

To boil Cod.—Wash, clean, and boil as directed for turbot. Serve on a napkin, garnished with parsley and scraped horse-radish. Sauce—oyster sauce.

To dress a Cod's Head and Shoulders.—Take a cod's head and shoulders in one piece, which clean, and let lie among salt all night. When you are going to dress it, skin it, and bind it with tape to keep it firm. Put it in a fish-kettle, back upwards, with plenty of cold water, a handful of salt, and a little vinegar. Let it heat slowly, and boil for about half an hour. Then let it lie on the drainer across the top of the kettle, for the water to drip from it. After this, place it, back upwards, on the dish in which it is to be carried to table, cutting and drawing away the tapes very carefully. Brush it over with beat egg, strew crumbs of bread, pepper, and salt over it, and stick pieces of butter thickly over the top. Set it before a clear fire to brown. A rich oyster sauce, made with beef gravy instead of water, and highly seasoned with Cayenne pepper, salt, and ketchup, is poured in the dish around the fish.

To dress a Middle Cut of Cod.—Clean the piece of cod, and make a stuffing of bread crumbs, parsley, and onions chopped small, pepper and salt, a bit of butter, moistened with egg. Put this stuffing into the open part of the fish, and fix it in with skewers. Then rub the fish over with beat egg, and strew crumbs of bread, pepper, and salt over it. Stick also some bits of butter on it. Set it in a bachelor's or Dutch oven before the fire to bake. Serve with melted butter or oyster sauce.

To boil Haddocks.—This is the simplest of all operations. Select haddocks of a middle size. Clean them well, and wash them, and boil with a little salt in the water. Twenty minutes or half an hour's boiling will be sufficient. Serve with oyster sauce.

To dress Haddocks.—This is a most delicious dish when well prepared. Take pretty large haddocks, which clean and wash well. They will be firmer and better if they lie for a night in salt. When to be dressed, wash them and dry them. Cut off the head, tail, and fins; then skin them, being careful not to tear the flesh. Cut the flesh neatly from the bone, and divide each side into two pieces. Dust them with flour, dip them into beat egg, and strew bread crumbs over them. Fry them in a frying-pan, with a sufficiency of hot dripping or lard to cover them. Be careful that the dripping is not hot enough to scorch the fish. The way to ascertain the proper degree of heat of the fat is to dip a thin slice of bread into it, and when it makes the bread of a light brown tinge, put in the fish. If the fat be too hot, it will make the bread of a deep brown. Turn the pieces carefully, so as to brown both sides, and when done, lay them before the fire on a drainer for a few minutes. Serve in a dish, garnished with parsley. Sauce—oyster sauce, or plain melted butter. The fat in which haddocks are fried will answer the same purpose again, if put through a hair sieve, and poured in a jar, and kept in a cool place.

To fry Skate, Soles, Flounders, Whitings, and Eels, and any other white fish.—Skate and soles are skinned and dressed in the same manner as haddocks, but soles are fried whole, not cut in pieces. Flounders are fried in the same manner, whole, but do not require to be skinned. Eels must be skinned and cut in pieces.

To bake Haddocks.—Take two or three haddocks, gut and clean them, and lay them all night among salt. When to be used, skin them, and cut off the heads, tails, and fins. Make a stuffing of bread crumbs, chopped onions and parsley, and a little bit of butter. Sew this into the bellies of the fish. Rub them over with butter, strew bread crumbs over them and bake them in an oven or before the fire.

Fish and Sauce.—Take two or three haddocks, gut and clean them, and lay them all night among salt. When to be used, skin them, cut off the heads, tails, and fins. Boil these trimmings for three-quarters of an hour in a little water. Brown a little flour and butter in a stew-pan, and then strain the liquor and put it to the butter; add sliced onion, chopped parsley, salt, a little Cayenne pepper, and a spoonful of ketchup. When all this has been boiled for a few minutes, cut the fish in pieces, and let it boil gently till dressed.

To scallop Oysters.—Scald the oysters in their own liquor. Pick them out of the liquor, and lay them in a dish, or scallop shells, or tins, strewing crumbs of bread mixed with pepper and salt over each layer, and finishing with crumbs. Moisten the whole with a small quantity of the liquor in which the oysters were scalded, and stick pieces of butter thickly over the top. Place the dish before the fire to bake. From ten to twenty minutes will be required, according to the quantity.

DRESSING VEGETABLES.

All vegetables ought to be cooked fresh from being gathered, or as nearly so as possible. Excepting peas and spinach, each kind of vegetable should be boiled in a large quantity of water, to carry off any rankness of flavour. They should also be served as soon as dressed, and not permitted to lie a moment in the water after they are ready for dishing. All kinds of cabbage and greens are the better for being boiled with a little carbonate of soda in the water, which will preserve their green appearance. The carbonate of soda is a material resembling flour in appearance, and may be obtained from any druggist. Cauliflower and broccoli require great care in boiling, for the flower easily breaks, and their appearance is spoiled. The time for boiling vegetables depends so much on their age, freshness, and size, that no directions can be given on that point. The best way to ascertain when they are ready, is to pass a fork through the stem.

To boil Green Peas.—Peas should not be shelled till just before they are to be used. After shelling, put them into boiling water, just enough to cover them, with a little salt; and when they are not very young, put a little sugar in the water. They will require about twenty minutes to boil. When done, strain them through a cullinder, and put them into a vegetable dish with a few bits of butter; stir them gently till the butter is mixed with them.

To boil Carrots and Parsnips.—Carrots require to be scraped, and to boil till they are soft. The length of time for them boiling depends on their age and size. Small carrots are served whole, but large ones should be cut in four pieces lengthwise. Parsnips require to be scraped and prepared in the same manner.

To boil Turnips.—Old turnips require to be pared much deeper than young ones. When they are very small, peel off the skins, but do not pare them; and after boiling, serve them whole, with a little melted butter in the dish. Large turnips are cut in pieces before being put in the pot, and they are either served in three pieces, or mashed with a little butter, pepper, and salt.

To boil French Beans and Scarlet Runners.—Cut off the tops and tails, and strip the strings from the backs of the pods. Then cut the pods in pieces slantingly across, or split them from one end to the other, and then cut them across. Lay them in cold water for a few minutes; and after straining them, put them into boiling water with a little salt and carbonate of soda. Boil till they are soft; strain them with a cullinder, and serve them with melted butter in a separate dish. Scarlet runners are prepared in the same manner, but usually require to be split into three or four pieces.

Potatoes.—These useful vegetables, as every one knows, may be dressed in a variety of ways. When to be presented plain at table, they may be either boiled in water or steamed. Some potatoes are best when boiled, while steaming is more suitable for other kinds. There is therefore no exact rule upon the subject. In general, they are better when they are boiled, and when put into just enough of cold water to cover them. A little salt should be put into the water to impart a flavour, and they should boil very slowly. Fast boiling will break their skins before they are soft in the inside. In most instances they are spoiled by over-quick boiling. When sufficiently done, pour the water from them, and set them by the side of the fire with the lid off, to allow the steam to escape, or fold a napkin and place it over them to absorb the moisture. Before serving, peel them, and place them in a dish with a napkin over them. Plain potatoes should never be sent to table without a napkin, for it keeps them warm, and at the same time allows the moisture to escape. When potatoes are to be mashed, they are pared either before or immediately after boiling, and mashed so as to be free from lumps. Some milk and butter, and a little salt, are stirred in before serving.

To boil Rice for Curry.—It is customary to serve boiled rice along with dishes which have been seasoned or stewed with curry. When rice is required for this purpose, it should not be soft or pulpy as in boiling for puddings; each grain should retain its perfect individual form, though swelled to nearly its fullest size. After picking and washing the rice, put it into boiling water, and let it boil smartly for about twelve minutes. Just before taking it out, put in a tablespoonful of salt. Drain the rice in a cullinder; then shake it gently out upon a doubled cloth, and lay it before the fire for a few minutes, with a fold of cloth over it. By this process the water will be absorbed from it, and it will be ready for dishing. Pour it lightly into the dish.

Salads.—Salad is a general name for certain vegetables prepared so as to be served and eaten raw. Salads are composed chiefly of lettuce, endive, radishes, green mustard, land and water cresses, celery, and young onions. All or any of them should be washed, and placed ornamentally in a salad bowl; the lettuce is generally cut in pieces lengthwise, and stuck round the dish; the celery, also divided, is placed in the centre; and the small salads, such as cresses and radishes, are placed between. This is the mode of serving a salad plain.

A dressed Salad.—When a dressed salad is to be served, the whole is cut in small pieces, and mixed in the bowl with a dressing. The dressing is made in the following manner:—For a moderate quantity of salad, boil one egg quite hard; when cold, take out the yolk and bruise it with the back of a spoon on a plate; then pour on it about a teaspoonful of cold water and about a teaspoonful of salt. Rub all this together till the egg has become quite smooth like a thick paste. Add a teaspoonful of made mustard, and continue mixing. Next add and mix a tablespoonful of salad oil or cold melted butter. After this, add and mix a tablespoonful or more of vinegar. The dressing is now made, and may be either mixed with the salad, or put into a glass vessel called an *incorporator*, which is sent to table along with the salad. The top of the salad may be ornamented with small bits of the white of the egg and pieces of pickled beetroot.

PIES AND TARTS.

Pies are of two distinct kinds—meat pies and fruit pies or tarts. Both are composed partly of paste, and therefore a knowledge of making pastry is indispensable in the economical housewife and cook. For this operation, the hands should be washed very clean, and care taken to have the board for working upon smooth, clean, and dry. A marble slab is better than a board, but few can command this convenience, and a board is usually kept for the purpose. Should the board or table be anyway rough, lay a sheet of stout white paper upon it. Before commencing to roll or knead the paste, dredge a little flour upon it. In all cases of making paste, the butter, whether fresh or salt, should be perfectly free of taint, or any rankness of flavour. It is very necessary to give this direction, for many persons seem to imagine that butter of any kind, however bad, is good enough for paste. Dripping, when well prepared and kept, or lard, will answer as a substitute for butter, and make the paste equally agreeable to the taste. At one time, raised pies—that is, pies covered all over with paste—were common, but these are now rarely seen of a large size for families. Pies are now made in earthenware dishes, and merely covered with paste prepared as follows:—

Paste for covering Meat Pies.—A good common paste for covering dishes or meat pies, and which paste is intended to be eaten, is made as follows:—Three ounces of butter, and one pound of flour, will be sufficient for one dish. Rub the butter well amongst the flour, so as to incorporate them thoroughly. If the butter be fresh, add a little salt. Mix up the flour and butter with as much cold water as will make a thick paste. Knead it quickly on a board, and roll it out flat with a rolling pin. Turn the dish upside down upon the flattened paste, and cut or shape out the piece required for the cover. Roll out the parings, and cut them into strips. Wet the edges of the dish, and place these strips neatly round on the edges, as a foundation for the cover. Then, after putting in the meat, lay the cover on the dish, pressing down the edges closely to keep all tight. If any paste remain, cut or stamp it in ornaments, such as leaves, and place these as a decoration on the cover.

On taking pies from the oven, and while quite hot, the crust may be glazed with white of egg and water beat together, or sugar and water laid on with a brush.

Beef-Steak Pie.—Take some slices of tender beef mixed with fat; those from the rump are the best. Season them with pepper and salt, and roll each slice up in a small bundle, or lay them flat in the dish. Put in a little gravy or cold water, and a little flour for thickening. Cover as above directed, and bake in an oven for about an hour.

Veal Pie.—Take chops from the back ribs or loin, and take out the bones. Lay the chops flat in the dish, and strew over each layer a mixture of minced parsley, flour, pepper, and salt. Add a little gravy, which may be made from the bones. Cover as above directed, and bake for rather more than an hour, for veal requires to be well dressed.

Pigeon Pie.—Pick and clean the birds well. Cut off the heads, and truss them by turning the wings on the back, cutting off the feet, and drawing the skin of the belly over the legs. Put a bit of butter, and a little pepper and salt, inside each bird. Place a single layer of beef or veal in the bottom of the dish. Lay the birds on the meat, with breasts upwards, and with the gizzards and livers round them. Some add a few whole hard-boiled eggs. Add a little gravy or water. Cover as above directed, and bake for an hour.

Icing for Tarts.—After tarts are baked, they are sometimes iced on the top, to improve their appearance. The icing is done thus:—Take the white of an egg, and beat it till it is a froth. Spread some of this with a brush or feather on the top or cover of the tart, and then dredge white sifted sugar upon it. Return the tart to the oven for about ten minutes.

Apple Pie.—Pare and take out the cores of the apples, cutting each apple into four or eight pieces, according to their size. Lay them neatly in a baking dish, seasoning with brown sugar, and any spice, such as pounded cloves and cinnamon, or grated lemon-peel. A little quince marmalade gives a fine flavour to the pie. Add a little water, and cover with puff paste, as above directed. Bake for an hour.

Gooseberry Pie.—Pick the heads and stems from unripe or hard gooseberries, and rub them with a towel to clean them. Fill the dish with them, and add a considerable quantity of brown sugar, with a very little water. Cover as above directed, and bake for upwards of an hour. Some persons stew the gooseberries in sugar before putting them in the dish, in which case they require less baking.

Rhubarb Pie.—Take stalks of fresh-pulled rhubarb. Cut off all the leaf, and strip off the skins. Cut the stalks into pieces of an inch long. Fill the dish, adding plenty of sugar. Cover as above directed, and bake for half an hour. Some persons stew the rhubarb before baking; the advantage of this is, that more can be put into the dish, for it shrinks considerably in dressing.

Cranberry, Raspberry, and other Tarts.—Cranberries, raspberries, and other small fruits, may be made into pies in the same manner as gooseberries. All require to be picked and wiped, and to have sufficient sugar to sweeten them. The dish should also be well filled, and raised higher in the middle than the edges, for the fruits diminish considerably in bulk in baking.

Mince Pie.—Mince pie is a composition of meat, fruit, various spices and seasonings, and also spirits. The following is a properly-proportioned mixture:—Take and mince a pound of beef suet, and a pound of roast beef, or dressed fresh bullock's tongue; also a pound of apples pared and cored, minced separately from the suet and meat; a pound of currants washed and picked, a pound of stoned and chopped raisins, an ounce of ground cinnamon, half an ounce of ground ginger, an ounce of orange and an ounce of lemon peel, and a little salt; half a pound of raw sugar, one nutmeg grated, two glasses of brandy and two of sherry. Mix all these ingredients together, and lay the bottom of your dish or small tin pans with paste; fill these with the mince, and then cover them with puff paste. Put in the oven, and bake for half an hour. If the whole of the mixture be not used, what remains over will keep for a long time if placed in a close jar. Some persons do not put any meat in their mince pies.

Open Tarts.—These are tarts without covers, made in flat dishes. Cover the bottom of the dish with a common paste; then cut a strip of puff paste and lay round the edge of the dish. Fill in the centre with any jam or preserved fruit. Decorate the top of the jam with narrow bars of paste crossed all over, or stamped leaves. Bake for half an hour.

PUDDINGS AND DUMPLINGS.

Care should be taken in making puddings to have the suet and the eggs which are put into them perfectly fresh. If there be any doubt of the freshness of the eggs, break each individually in a teacup, for one bad egg will spoil all the eggs in the dish. The cloths used for puddings should be of tolerably fine linen. Let them be carefully washed after using, and laid aside in a dry state, ready for the next occasion. Before putting the pudding into the cloth, dip the cloth in boiling water, and after the water has run from it, spread it over a basin, and dredge it with flour. Every pudding should be boiled in plenty of water, so as to allow it room to move freely; and it must be kept constantly boiling. It is a general saying among cooks that a pudding *cannot be too well boiled*; and it is certain that there is much more danger of boiling it too short than too long a time. When you take the pudding from the pot, plunge it for a few seconds into a jar of cold water. This will chill the outside, and allow the cloth to be taken away without injuring the surface. The best way to dish a pudding is to place it with the cloth in a basin, then open the cloth, and lay the face of the dish upon the pudding; turn the whole upside down, lift off the basin, and remove the cloth.

Plumpudding.—A plumpudding may be made either rich or plain, according to the quantity of fruit and spices put into it. The following is the direction for making what would be considered in England a *good Christmas pudding*:—Take a pound of good raisins and stone them; a pound of currants, which wash, pick, and dry; a pound of rich beef suet minced, and a pound of stale bread crumbs, and half a pound of flour. Mix the bread, flour, and suet in a pan. Beat six eggs in a basin, and add to them about half a pint of sweet milk. Pour this egg and milk into the pan with the suet and flour, and beat it well with a flat wooden spoon for some time. Then stir in the currants and raisins, mixing well as you proceed; mix in also a quarter of a pound of candied orange and lemon-peel, cut in thin small pieces, an ounce of powdered cinnamon, half an ounce of powdered ginger, a nutmeg grated, and a little salt. Next add a glass of rum or brandy. The pudding is now made, and ready to be either baked or boiled, according to taste. If to be baked, butter your tin or basin, and put the pudding into it, and bake in an oven for an hour and a-half, or nearly two hours. If to be boiled, pour it into a cloth; tie the cloth, allowing a little room to swell if made of bread, and boil for six hours. Serve with caudle sauce.

Currant Pudding.—An excellent family pudding may be made of the following ingredients:—A pound of minced suet, a pound of bread crumbs or flour, three-quarters of a pound of currants, washed and picked, a little powdered cinnamon and grated nutmeg, and a very little salt. Beat two eggs, and add as much milk to them as will wet the whole. Mix all together, tie in a cloth, as previously directed, and boil for three hours. Serve with caudle or any simple sweet sauce.

Hard Dumpling.—This is the plainest of all puddings, and is sometimes served with boiled salt beef. It is also sometimes cut in slices and placed in the dripping pan below roasting meat for about half an hour before the meat is dished. Take a quarter of a pound of suet minced very fine; mix it with a pound of flour; add a little salt, and wet it with water to the consistency of dough. Divide it into small dumplings, and put them into boiling water, and boil for an hour and a-half, taking care that they do not stick to the bottom of the pot. No cloth is used.

Bread Pudding.—Boil as much milk as will be sufficient for the pudding you want. When it begins to boil or rise in the pan, pour it upon crumbled down stale bread in a basin. The quantity of bread should be as much as will thicken the milk to a stiff consistency. Cover it up for ten or fifteen minutes, to allow the bread to swell. Then beat or mash it up to make a fine pulp, stirring in a small piece of butter. Beat three or four eggs, a teaspoonful of ground cinnamon, a little grated lemon-peel, and sugar according to taste. Stir this among the pudding. A little brandy or rum may be added; also a few currants, if required. The pudding may be either boiled or baked. If to be boiled, put it in a well-buttered pudding shape or basin, with a buttered paper over it, and also a cloth over all: boil for an hour. If to be baked, put it into a buttered baking dish, and bake in an oven for half an hour.

Rice Pudding.—Take a pretty large cupful of rice, pick it, and wash it well in cold water. Boil it in water for about five minutes. Drain the water off, and put it on again with as much milk as you require. Let it boil till the rice is quite soft, stirring it frequently, to prevent it from burning. When done, put it into a basin, and stir in a piece of butter, or some suet minced very fine. When cold, add to it four eggs, beaten, with a little ground cinnamon, grated nutmeg and lemon, and sweeten with sugar. All is to be mixed well together. It may be either boiled or baked, as directed for bread pudding. The above composition may be enriched by using more eggs and less rice, also by adding currants, spirits, and candied orange peel.

Custard Pudding.—Take four eggs, and beat them well with two tablespoonfuls of flour and a little cold milk. Season this with sugar, ground cinnamon, grated lemon-peel, and pour on a pint of boiling milk, stirring all the time. It may be either baked or boiled. By using more eggs, the flour may be omitted.

Bread and Butter Pudding.—Cut several slices of bread rather thin; butter them on one side; put a layer of them in a pudding pan or dish, and a layer of currants above; then another layer of bread; and so on till the dish is full. Beat four eggs, with a little ground cinnamon and nutmeg, also some sugar. Add milk to this, till there is sufficient to fill up the dish. Then pour it over the bread, and allow it to stand for a time to soak. It will now be ready for either baking or boiling, as directed for bread puddings.

Tapioca Pudding—Sago Pudding.—Take a quart of milk, and put in it six tablespoonfuls of tapioca. Place it on the fire till it boil; then sweeten to taste, and let it simmer for a quarter of an hour. Stir it frequently, and be careful that it does not burn. Then pour it into a basin, and stir into it a little fresh butter and three eggs well beaten; you may now pour it into a buttered pudding dish, and bake for about an hour; or, after adding another egg, boil it in a basin or mould for an hour and a-half. Sago pudding may be made in the same manner.

Batter or Yorkshire Pudding.—Take a quart of sweet milk, and mix in it a large cupful of flour, making the mixture very smooth. Beat four eggs, and strain them into the batter. Add a little salt, and mix all well together. Butter your dish or tin, and pour the batter into it. Place the dish either before the fire under roasting meat, or under meat sent to the oven. The pudding, when done, easily shakes out of the dish into another dish to be carried to table. It should have a nicely browned appearance. When dressed before the fire, either turn the pudding, or place the dish a short time on the fire to brown the under side.

Peas Pudding.—Pick a quart of split peas—that is, remove all impurities, or discoloured peas, or shells. Tie them loosely in a cloth, leaving plenty of room for the peas to swell. Boil till they are soft, which may be in from two to three hours. Take the pudding from the water, and put it into a basin. Open the cloth, and bruise or mash the peas well. Mix in a piece of butter, with pepper and salt. Then tie it up tightly, and put it into the pot again, and boil for about half an hour. When ready, turn it out of the cloth into a vegetable dish. If properly managed, it will turn out whole.

Fruit Puddings.—Fruit puddings consist of fruit enclosed in a paste, and boiled. They may be made of apples pared and cut in pieces, green unripe gooseberries, currants, raspberries, cherries, and other fruits. They are all made in the same manner. The best paste for them is made of beef suet chopped very fine, and flour, in the proportion of four ounces of suet to a pound of flour. Mix it into a dough with water and a little salt; then knead it, and roll it out; place the fruit in it, gather up the edges, and tie it in a cloth, or place it in a basin, as directed for other puddings.

A Roll Pudding.—Make a paste of flour and dripping, or suet, as previously directed for plain paste. Roll it out flat, to about half an inch thick. Then spread gooseberry jam, or any other preserved fruit, over the paste, but not quite to the edges. After this, roll it up, and cause the outer edge to adhere. Next roll it in a cloth, and tie the ends tightly. Boil it for an hour or an hour and a-half, according to the size. When done, take the cloth off, cut the pudding in slices, and serve with any sweet sauce over it.

Meat Puddings.—Meat puddings are made in the same manner as fruit puddings, the only difference being, that pieces of beef, mutton, lamb, or veal, are placed inside of the paste instead of fruit. The meat should be seasoned with salt and pepper. One of the commonest of this kind of puddings is a beef-steak pudding. If it contain two pounds of meat, it will require about two hours and a-half to boil, and if larger, it will take a longer time.

Omelettes.—Omelettes are composed of eggs and anything that the fancy may direct to flavour and enrich them. For a common omelette, take six eggs, and beat them well with a fork in a basin; add a little salt. Next take a little finely-chopped parsley, finely-chopped eschalot or onion, and two ounces of butter cut into small pieces, and mix all this with the egg. Set a frying-pan on the fire with a piece of butter in it; as soon as the butter is melted, pour in the omelette, and continue to stir it till it assume the appearance of a firm cake. When dressed on one side, turn it carefully, and dress it on the other. It will be dressed sufficiently when it is lightly browned. Serve it on a dish. The flavour may be varied by leaving out the parsley and onion, and putting in finely-chopped tongue or ham, oysters, shrimps, grated cheese, or other ingredients.

Pancakes.—Pancakes are made of eggs, flour, and milk, in the proportion of a tablespoonful of flour to each egg. To make two small pancakes, take two eggs, and beat them well, and add to them a little milk. Then take two tablespoonfuls of flour, and work it into a batter with the egg and milk; add a little salt. Set a clean frying-pan on the fire, and put a piece of butter or lard into it. When the butter is quite hot, pour in the batter. Shake it frequently, to prevent it from sticking. When the under side is of a light brown, turn it. Serve the cakes folded, with sugar strewed between the folds. This is the way of dressing common pancake; when required to be lighter, use more egg and less flour; and grated nutmeg may be added.

Fritters.—Make a batter of eggs, flour, and milk, as for pancakes, but with a little more flour. Apple fritters are made by cutting large pared apples in slices, dipping the slices in the batter, and frying them separately. They are done when lightly browned on both sides. Another, and perhaps more common way, is to cut the apples in small pieces, and mix them with the batter, frying them, a spoonful in each fritter. Fritters may be made with currants in the same manner. Serve all fritters with sugar sprinkled over them.

LIGHT DISHES AND CONFECTIONS.

Under this head is included those various light and elegant dishes which are generally put upon the table in the last course, along with puddings and pies; also those preserves which are occasionally served at tea and supper parties. In making all articles of this description, very considerable care and cleanliness are required. The tin shapes or moulds for jellies should be kept particularly clean; if they are used with any particles of dirt inside, the jellies will in all likelihood not turn out neatly. It has been already mentioned that the turning out may be facilitated by dipping the mould for an instant or two in hot water. It is a common belief that fruits, such as gooseberries and currants, cannot, without spoiling, be dressed for preserving except in a brass, copper, or silver pan. This is an error. They may be dressed equally well in a tinned iron sauce-pan. Every kind of berries for preserving should be gathered in sunny weather, when the fruit is as free of moisture as possible.

Custards.—Boil a quart of sweet milk with stick cinnamon, the rind of a lemon, and a few laurel leaves or bitter almonds, and sugar. Beat the yolks of eight eggs along with the whites of four of them; add a little milk, and strain the egg into another dish. When the quart of milk boils, take it off the fire and strain it; then stir the egg into it. Return the whole to the sauce-pan, and set it on the fire again, stirring constantly. Let it come to the boiling point; then take it off the fire, pour it into a large jug, and continue stirring it till it is nearly cold. It should now have the consistency of thick cream, and is ready for being poured into custard glasses. When the glasses are filled, grate a little nutmeg over them.

Calf's-foot Jelly.—Take two calf's feet, well cleaned; break them in several pieces, and put them in a sauce-pan with three quarts of cold water. Boil it slowly, till it is reduced to about a quart and a-half. Strain it, and let it stand till cold. Take off the fat carefully when cold. Put the jelly into a sauce-pan, keeping back the sediment; put in along with it the juice and the yellow rind of three lemons, two stalks of cinnamon, half a bottle of sherry wine, the whites of eight eggs well beaten, with the shells broken, and white sugar according to taste. Mix this all together, and put it on to boil for twenty minutes. Take it off, and let it settle with a cloth over it for a few minutes. Then pour it through a clean jelly-bag made of thick flannel. It will take some time to run; therefore hang the bag near the fire, cover it, and let the liquid run slowly from it into a jar. If not perfectly clear, run it through the bag again; but if as clear as is required, it is now ready, and may be poured into the shapes. Plain calf's-foot jelly may be made with ale instead of wine, and vinegar instead of lemons.

Blamange.—Blamange, or Blanc-Mange—so called from its white appearance—is a jelly made of isinglass and milk. Take a quart of sweet milk, or cream, and put in it two ounces of the best isinglass. Put it in a sauce-pan, with the rind of a lemon, a blade of mace, and white sugar to taste. Let it boil a quarter of an hour. Take the skins off six bitter almonds and twenty-four sweet ones, and pound them to a paste with a little water. Mix this with the boiling milk, and strain it through a muslin sieve. Let it settle for a short time, and then pour it into the shape, keeping back the sediment. Turn out when cold, as already directed.

Arrowroot Blamange.—This is a jelly closely resembling the above, and is made with much less trouble. Take a quart of sweet milk, and put it all in a sauce-pan, excepting about half a pint. Sweeten it with white sugar. Mix about three tablespoonfuls of arrowroot with the half pint of milk, taking care to bray it all well down. When the milk on the fire boils, pour in the arrowroot, stirring quickly, to prevent lumping or burning. It will become thick immediately. Let it boil for two or three minutes. Wet the shape with cold milk, and pour the arrowroot into it. Let it stand till cold, and turn out as already directed. Some flavour the milk in the pan with essence of lemon.

Moss Blamange.—There is a moss of a peculiar kind found on the sea-shores of Iceland, Ireland, and other places, which is of a glutinous quality, like isinglass, and which, when boiled in milk, forms a fine white jelly. It is called Iceland or Irish moss, and is sold by druggists, and when bought, resembles dried sea-weed of a yellowish colour. Take one ounce, and pick from it all gritty or sandy particles. Soak it in cold water for about twelve hours. Take it from the water, place it in a cullinder, and drain it. Being drained, place it in a sauce-pan on the fire with a pint and a-half of sweet milk. Let it boil for half an hour, and keep stirring it all the time, to prevent it from burning. During the boiling, sweeten it with sugar, and flavour with cinnamon, or any other spice you please. At the end of the half hour's boiling the moss will be almost entirely dissolved, leaving nothing but a few thready fibres. You now strain it through a sieve into a shape or mould. When cold, it will turn out easily, and have all the appearance of a firm blamange. This forms one of the cheapest blamanges that can be served to table; it is also agreeable to the palate, and very nutritious. In cases of a hurry in cooking, six hours' soaking of the moss will do, but this causes a waste.

Gooseberry Fool.—Take a quart of full-grown unripe gooseberries. Pick them, and put them into a sauce-pan with a cupful of water. Cover them, and let them heat very slowly. When the gooseberries are soft and dressed, but not so much heated as to burst, strain the water from them, and put the gooseberries in a dish. Bruise them to a fine pulp, with sufficient sugar to sweeten them. Let them stand till cool, and then mix milk or cream with them. Serve in a hash dish or large bowl.

MEDICINE—HOUSEHOLD SURGERY.

Error in diet, drink, dress—in fine, the erroneous treatment of ourselves as organised beings—is sure sooner or later to be productive of bodily ailment. Even were we perfectly nurtured as to food and clothing, and were we born with perfectly sound constitutions, still are we liable to injury from numerous external causes; hence the necessity for remedial agents, either in the shape of *medicines*, strictly so called, or in the form of *surgical* operations. A man, for instance, may be afflicted with some internal or external malady, and he has recourse to a medicament or healing substance, in the faith that it will remove his affliction, and restore him to health. Again, he may have received such bodily injury, or his malady may have assumed such a form, that a medicament of itself would be unavailing, and he submits to the instrumental operations of the surgeon, which, however, are generally accompanied with medicinal administrations. Thus it is customary to distinguish between the surgeon, physician, and apothecary or chemist; and such distinctions, though unnecessary for our humble purpose, are not without their advantages. In the following pages, therefore, while separating Medicine from Surgery, we follow no technical distinction farther than seems likely to facilitate the ordinary reader's comprehension of an art as necessary to his wellbeing as those which relate to his food and clothing. Our utmost aim is to convey to the class whom we more especially address a general notion of the science; those who seek for more will find themselves disappointed. To adopt the language of a recent medical writer—'No one who reads herein is to expect that he is to find a whole body of surgery, or that he will be fitted thereby to set up for an amateur surgeon, capable of practising upon himself or his neighbours, for a vast deal must be passed by. Not that there are any "secrets of the prison-house" to be kept, because we are of those who think it would be well if people generally understood something about how they were treated, and what they were treated for, as they would then be less open to the tricks of cunning knaves, whether enjoying the honour of a diploma or not, and more capable of estimating the value of honourable and upright practitioners; but everything cannot be told, usefully at least, to general readers, for this simple reason—that were it set forth, they could not rightly comprehend it. Still, there is much to be mentioned which may be of good service at a pinch, without interfering with the doctor.'

MEDICINE.

All those drugs which in some form or other are applied to the alleviation or cure of bodily ailments are known by the name of medicines; and they consist for the greater part of substances prepared from vegetable and mineral bases, a few only being of animal origin. The introduction of medicine has afforded much ground for discussion, but the question is really of little importance. The rudest tribes of the present day direct their attention in their own way to the cure of those complaints incident to their climate and situation; and we may safely conclude, that before society had advanced far in civilisation, the aborigines of the world cultivated the art of medicine. On looking around on the face of nature, they would perceive numberless plants and substances unfitted for food, and equally so, to appearance, for any other useful purpose of life. Chance would probably determine, in the lapse of time, the uses of many of these; and indeed, at no very distant period, one of our most valuable medicines was discovered by mere accident. A quantity of Peruvian bark had been thrown as useless into a small well, out of which some soldiers afflicted with the ague had the good fortune to drink. To their own surprise, as well as that of others, they became rapidly well, and the cure happily was attributed to the right cause. In the same manner a knowledge of many important medicinal articles might be attained, and occasionally some bold inquirer might arrive at the same end by actual experiment. As among the African and North American tribes of the present day, however, a great portion of the medical art of our forefathers lay in working on the fears and imaginations of the patients by means of pretended charms and incantations.

The medicinal preparations of the ancients were taken almost entirely from the vegetable kingdom, though the Arabian school of medicine, which arrived at great eminence while the Saracens were masters of Spain, was well acquainted with several metallic remedies. The researches, however, of the chemists, or rather alchymists, of the dark ages, first brought fully to light the great value of the metals in the hands of the physician, and this credit these ingenious individuals are at least entitled to, though we may smile at their absurd attempts to transmute baser minerals to gold, or to find out the elixir of life. They made thus a most important addition to the number of medicines, and effected a change in the healing art which is felt to the present time. The liability of herbs to spoil by keeping, whether in the state of roots, leaves, or seeds, gave a great superiority to the mineral preparations, which retain their powers for a long period. At the time when they were first introduced, the sensation excited was so great, that the numerous believers in their virtues were called, in contradistinction to the admirers of vegetables, the chemical school. This sect went so far as to refer all the functions of the body to chemical processes, and to treat all diseases upon chemical principles. The discovery of the circulation of the blood founded a new set of philosophers, who maintained that the body was entirely framed upon, and regulated by, mathematical laws. Though this doctrine was supported by some eminent men, and for a short time superseded the chemical theory, yet its total failure to account, upon mechanical principles, for all or for any of the vital actions, soon caused it to fall into disrepute.

It is scarcely necessary to mention any other changes in the progress of the science of medicine, and indeed those taken notice of are of consequence only from their effects on the nature of the remedies for disease. During the eighteenth century, anatomy was prosecuted with deep attention, the nature of medicinal preparations closely investigated, and their number increased; the result of which was, the reduction of the practice of physic to principles more agreeable to reason and to truth. Men, too, partaking of the wide spread of knowledge during the period mentioned, began to object to nostrums when labouring under illness, and became reluctant to swallow a dose without being informed of the nature of the action and the effects expected. Hence medicines, instead of being applied indiscriminately to every species of disease, were arranged into some sort of order, and classified according to their known operation. This is the most simple method of viewing the range of medicinal substances, and it is the one we shall adopt in the present instance, though it will be impossible to enumerate any other medicines than those principally in use.

Some substances employed in the cure of disease act *mechanically*, and others *chemically*, on the system; but by far the greater proportion of them act *vitally*. A medicine is said to act mechanically when its effect on the body is the same as that which it exerts over inanimate matter. Demulcents, for instance, or remedies taken to remove the acrid effects of some other substance, operate simply by coating the stomach with a gummy fluid, an action which is entirely mechanical. The chemical operation of medicines may be thus explained: When an acid and an alkali are mixed in a glass of water, they unite together, and form a third substance, a salt, having new properties altogether. The same chemical process takes place when sourness, or an acid, is neutralised in the stomach by soda, or any alkali. The vital action of medicines differs totally from the two former. In this case the substances are absorbed into the blood, and are conveyed by the vessels of the heart to the quarter whither their nature determines them. Diuretics, or medicines which stimulate the urinary organs, may form an example of vital action. From the stomach the diuretic is absorbed into the blood-vessels, and carried to the kidneys, stimulating them to the secretion of urine, though by what process of separation from the rest of the blood we know not. Under these three divisions, mechanical, chemical, and vital agents, all the articles used in medical practice—technically, *materia medica*—are comprehended. After this general explanation, and before proceeding to examine the nature of the more important substances, it will be necessary to allude to the forms and manner in which medical preparations are usually administered.

Forms and Modes of Preparation.

Some medicines are prepared in a liquid, others in a solid form, according as they may be soluble or insoluble, or according to the remedial state in which it may be desirable to administer them. In general, the more finely a substance can be divided, the more rapidly is it taken up by the system, and the more instantaneous its effect; hence, instead of administering the crude vegetable or mineral, the necessity of preparing infusions, decoctions, tinctures, and the like. Another reason for adopting such preparations is, that the active or medicinal principle of a substance may constitute but a small portion of its bulk; while the greater portion may be of no value whatever, or may be even positively detrimental.

Infusions of vegetable substances are common and convenient forms: they are prepared by pouring boiling water upon the materials in a lightly-covered vessel, and allowing it either to cool directly, or to continue at a gentle heat for a few hours; then straining, filtering, and bottling for use. Boiling water has sometimes the disadvantage of dissolving ingredients which we may not be in search of; hence the use of cold water by way of percolation or displacement. In addition to this advantage, cold infusions are found to have less tendency to decay. Infusions by the ordinary method may be preserved, however, for months, by pouring them, while boiling hot, into bottles up to the top, and quickly forcing in strong corks of good quality.

Decoctions differ from infusions in being prepared by actual boiling of the substances; and, if possible, in vessels of glass or earthenware. Decoction, though often resorted to on the large scale, is by no means an accurate or scientific mode of preparation; inasmuch as the active principles of many vegetables are destroyed or weakened by prolonged boiling, at the same time that other constituents than those we may be in quest of are apt to be liberated, and mingle with the result. Thus calumba-root, which yields an active and excellent bitter, cannot be boiled without liberating a large amount of starch, which is not only not wanted, but is actually detrimental to the preservation of the active solution. Decoctions, when had recourse to, should be made in covered (not closed) vessels; and the process should be continued no longer than is necessary to extract the principle sought for.

Extracts, which are much valued in pharmacy, are usually prepared by evaporating the expressed juices of plants, or their infusions or decoctions in water or spirits, at a temperature not exceeding 212°, by means of a vapour bath. Many of them, however, may be obtained of superior quality by the process of evaporation *in vacuo*; and the extracts of expressed juices cannot perhaps be better prepared than by spontaneous evaporation in shallow vessels exposed to a current of air. Extracts should be evaporated, according to the Pharmacopœias, till they are of such a consistence as to form a firm pill-mass when cold. In this condition they are thought to keep better and longer, and can also be administered in a more convenient and concentrated form. Though extracts in general keep well, yet all sooner or later deteriorate; hence the necessity of care in their preservation, as well as in examining them before administration.

Tinctures are solutions of vegetable, animal, or mineral substances, in some spirituous fluid—as proof-spirits, rectified spirits, and the like. They are prepared by breaking down the solid mass into fragments, and macerating in the spirit for a week or more without artificial heat. The liquid is then poured off, the residuum subjected to pressure, or further macerated by the addition of new spirit, and the whole fluid so obtained filtered and bottled for use. 'The form of tincture,' says Christison in his Dispensatory, 'is one of the best in pharmacy; for the menstruum is a powerful solvent of the active constituents of drugs; it presents them in a small volume; it preserves them very long unaltered; and it is for the most part a convenient medium for uniting them with other substances in extempore prescriptions.'

Syrups are intended sometimes to cover the disagreeable taste of drugs, but more generally to preserve them in a convenient state for making mixtures, without the risk of their undergoing decomposition. They are prepared sometimes by simply dissolving sugar in a watery solution of the drug, sometimes by concentrating the syrup to a certain density after the sugar has been dissolved. The most desirable density is 1385 at 60°; and to prevent the influences of external heat and cold, it is recommended to keep syrups in a situation where the temperature is stationary at 55°. Instead of sugar, treacle is very commonly used, both on account of its disguising the taste more effectually, and being less apt to crystallise.

Medicated Wines—that is, where wine is used as the menstruum for some vegetable or mineral drug—are now less frequently employed than formerly; partly because they are apt to spoil, and partly because proof-spirit is on the whole a more active solvent. Where still used, the variety taken is sherry, which contains about 30 per cent. alcohol by volume.

When administered in the solid state, one of the most common forms is that of *Powders*. These are prepared by first drying the substance, then pounding it in a mortar, passing it through a sieve to get rid of the grosser particles (which may be again subjected to the pestle), and ultimately preserving in closely-stoppered vessels. Being in a state of fine division, powders act with considerable rapidity, and are administered in admixture with some fluid or conserve.

Conserves, Electuaries, and *Confections*, are intended as vehicles to impart a convenient form to other drugs, and especially as adhesive menstrua, to give them the form of pills. When the dose of any insoluble medicine is bulky, or when it is of disagreeable taste, such adjuncts are of considerable importance.

Pills are regarded as the most convenient of all officinal forms, both for preservation and for administration; but in many instances not the most efficient in point of activity. 'The making of a good pill-mass,' says Dr Christison, 'is a more difficult problem than it may seem at first sight. The mass must be of such consistence as to cohere strongly, and firm enough to retain the globular form: it should be so composed as not to be liable to grow mouldy: it ought not to contract moisture; and yet it ought not to be apt to harden quickly by undergoing desiccation. The materials for securing these objects, or Excipients, as they are technically called, must vary in some measure with the active ingredients of the pill. Those in common use are bread-crumb, hard soap, extract of liquorice, mucilage, syrup, treacle, conserve of red roses, and conserve of hips. For extempore use, the most common solid excipients are bread-crumb and liquorice-extract; and the liquids generally employed are syrup and mucilage. These substances answer very well when the pills are not to be kept above a few days; but pills so composed become very hard, in which state their activity is greatly impaired. In this respect treacle, and conserve of red roses, or hips, but especially the two conserves, are greatly superior. When pills contain a large proportion of resinous matter, one of the most simple and effective methods of keeping them long soft is to use a little rectified spirits for softening them sufficiently in the first instance. Pills are covered with a great variety of substances, to prevent them from adhering, or to obscure their taste. At one time it was the custom to cover them with gold-leaf or silver-leaf; and some physicians have lately proposed to revive this absurd practice. Liquorice-powder, wheat-flour, and wheat-starch, are now most commonly employed. . . . Inveterate custom and economy have sanctioned the practice of keeping pills in boxes of wood or pasteboard. They retain their activity better—because they are preserved soft much longer—if they be kept by the patient in small bottles. There is reason to suspect that the officinal pills are in general too large. Five-grain pills often pass through the body apparently but little altered; and it has occurred to me to observe that four colocynth and henbane pills, of one grain each, will operate as effectually as two five-grain pills, and more mildly.'

Lozenges or *Troches* is another solid form in which drugs are now administered. Whatever the active principle, the basis consists of sugar, gum, and sometimes liquorice-extract. Care must be taken in preparing them to avoid too much heat, otherwise they may be rendered unpleasantly empyreumatic, or their active ingredients may undergo decomposition.

Besides the preceding liquid and solid forms, there are others of a mixed nature which are equally common and important. Thus *Cerates*, *Ointments*, and *Liniments*, are preparations for external use, differing chiefly in their consistence—cerates being the firmest, ointments softer, and liniments softer still, or even liquid. In compounding these, the wax, resin, or fatty matters employed are to be melted with a gentle heat. When removed from the fire, they are to be diligently stirred till they concrete; and meanwhile any dry substance to be added should be sprinkled in a state of very fine powder into the melted mass. As ointments are of use merely to protect wounds from their coverings, from the air, and from filth, the simpler they are the better. The same rules are to be observed in preparing *Plasters*, which have a similar basis spread equally on cloth, leather, or other tissue.

Poultices are well-known external applications. They are described by Abernethy as of three kinds—the evaporating or local tepid bath, the greasy, and the irritating. The first is thus made:—'Scald out a basin, for you can never make a good poultice unless you have perfectly boiling water; then having put in some hot water, throw in coarsely-crumbled bread, and cover it with a plate. When the bread has soaked up as much water as it will imbibe, drain off the remaining water, and there will be left a light pulp. Spread it, a third of an inch thick, on folded linen, and apply it when of the temperature of a warm bath.' The linseed-meal or greasy poultice is, on the same authority, to be made in the following manner:—'Get some linseed powder, not the common stuff, full of grit and sand. Scald out a basin; pour in some perfectly boiling water; throw in the powder, stir it round with a stick, till well incorporated; add a little more water, and a little more meal; stir again, and when it is about two-thirds of the consistence you wish it to be, beat it up with the blade of a knife till all the lumps are removed. Then take it out, lay it on a piece of soft linen, spread it the fourth of an inch thick, and as wide as will cover the whole inflamed part; put a bit of hog's-lard in the centre of it, and when it begins to melt, draw the edge of the knife lightly over, and grease the surface of the poultice.' The irritating poultice, to be used in cases where a blister is unnecessary or inconvenient, is made simply of mustard and water, mixed as if for the dinner-table, and put within the folds of a piece of fine muslin, so that only the watery part, oozing through, touches the skin.

Mixtures and *Emulsions* are extempore preparations, of such strength, consistence, or quality, as each particular case may demand. The same may be said of *Fomentations*, which are warm fluids applied to the skin; and of *Lotions*, or washes, which are similarly applied either cold or warm.

Enemas, or *Clysters*, are drugs administered in the form of injections; they vary in composition and volume according to the object to be effected.

Volatile Oils are obtained chiefly from the flowers, leaves, fruit, barks, and roots of plants, by distilling them with water, in which they have been allowed to macerate for some time. A few, as the oil of orange, lemon, and bergamot, are obtained by expression. They are of various densities, and exist in various states of fluidity under the ordinary temperature of the atmosphere. All of them should be preserved in dark bottles, carefully stoppered, and nearly full.

Distilled Waters or *Essences* consist of the volatile oils of odoriferous vegetables dissolved in water. They are either obtained by distilling the crude vegetables (fresh or dried), or by agitating pure volatile oils with distilled water until sufficient admixture has been procured. Of the various *Salts* obtained from the mineral and vegetable kingdom it is unnecessary here to speak, as they are all administered in one or other of the liquid or solid forms already mentioned.

In whatever form medicinal preparations may be administered, the quantity is invariably regulated by weight or by measure. Though differing in nomenclature and mode of subdivision, both of these are based on the imperial standard of the country. Thus the imperial pound is divided into ounces, drachms, scruples, and grains; and the imperial gallon into pints, fluid ounces, fluid drachms, and minims. In detail—12 ounces make 1 pound, 8 drachms 1 ounce, 3 scruples 1 drachm, and 20 grains 1 scruple. Again, 8 pints make 1 gallon, 20 fluid ounces 1 pint, 8 fluid drachms 1 fluid ounce, and 60 minims 1 fluid drachm. The different denominations of weights and measures are denoted in the language of prescriptions by the following signs:—Pound, ℔; ounce, ℥; drachm, ʒ; scruple, ℈; grain, gr.; Gallon, C; pint, O; fluid ounce, f℥; fluid drachm, fʒ; and minim, ♏. Medical prescriptions are generally written in Latin, which, conjoined with these signs, Roman numerals, and a large amount of contractions, gives them a very formidable and mysterious aspect. Thus, ℞ (*Recipe*) *Nitratis Potassae* gr. xv.; *Aquae destillatae* f℥iss; *Syrupi Limonum* fʒij. *M* (*Misce*). *Fiat haustus, ter in die sumendus*, is but the technical form of ordering the patient to 'Take fifteen grains of the nitrate of potass; one and a-half fluid ounces of distilled water; and two fluid drachms of syrup of lemon. To mingle and form a drink of them, and take it three times a day.' Further, each university of importance has a list of medicinal preparations drawn up for the guidance of its own members and pupils, and this list is termed its *Pharmacopœia*; with the enumeration is given a full account of the processes by which the various substances are prepared for use. Thus London, Edinburgh, and Dublin have their respective Pharmacopœias; differing occasionally in particulars, but rarely or ever in essentials.

With these preliminary explanations, we now proceed to examine the more important remedial agents, as exhibited in modern and approved practice—classifying them according to their ultimate effects, and arranging the classes in alphabetical order, for the sake of perspicuity and facility of reference:—

Characters, Uses, and Effects.

Antacids, as the name imports, are those medicines which correct acidity of the stomach and digestive organs. The stomach of many individuals is liable to a continued conversion of their food, particularly vegetable food, into a species of acid, which produces the annoying feeling called heartburn. This acid may be neutralised by any of the earths or alkalies, and the process of relief is as purely chemical as if it were performed in a glass of water for experiment. The three alkalies, potass, soda, and ammonia, the alkaline earth magnesia, and carbonate of lime (chalk), are the most useful medicines of this description. The relief obtained from them is, as might be expected, merely temporary, since they do not prevent the generation of the acid anew. Antacids should in general be prescribed along with vegetable tonics, and in no case ought their administration to be long persisted in without occasional interruptions. It is further necessary to observe in what condition, and in what region, the acidity more particularly manifests itself, as all antacids have not precisely the same properties and modes of action. Thus the best corrective for *gaseous* acidity in the stomach is found to be the ammonia and its carbonate; for acidity in the lower bowels, lime and magnesia; and where acid exists in the urinary organs, potass and soda are preferable. Calcined magnesia is one of the simplest and best known of the antacids. It is employed in indigestion, attended with acidity of the stomach and constipation; in which cases it is generally preferred to the alkalies, as being less irritant, and as the combinations which it forms with the free acids of the stomach are gently laxative. In gastrodynia and heartburn, given in combination with some aromatic, a short time before the meals, it seldom fails to prove beneficial. It is also administered with much advantage in the acidity attendant on infantile diseases, and to persons of a gouty and rheumatic tendency. Carbonate of magnesia is also used; but it is less active.

Anthelmintics, also known as *Vermifuges*, are those drugs possessing the property of destroying worms, or expelling them from the intestinal canal. Other medicines, as the more active cathartics (which see), may also effect this purpose, but not specifically, as the class now under review. Among the more common vermifuges may be mentioned powder of tin, oil of turpentine, pomegranate bark, powdered fern root, Corsican moss, and worm-seed. 'As the action of these remedies is merely temporary,' says Dr Neligan, 'it will be requisite, as soon as the worms are expelled, to employ means calculated to restore the digestive organs to a healthy state, and to correct that peculiar character of them which promotes the generation of intestinal worms. The means best calculated for this purpose are:—Keeping the surface of the body warm by proper clothing; a light but nutritious diet, with a moderate use of common salt; and at the same time the administration of bitter tonics, with gentle aperients; and if anemia be present, the preparations of iron.'

Antiseptics, though still ranked as a distinct class of medicines, are very little trusted to in the present day. They were great favourites with the ancients, and were supposed to possess the property of resisting putrefaction, or that tendency to mortification which sometimes appears towards the termination of fevers and other complaints. Peruvian bark is commonly believed to have antiseptic qualities, and, with the exception of alcohol and vinegar, is perhaps the only drug of this class worthy of notice.

Antispasmodics are used to remove spasms or convulsive contractions of the muscular fibre in the body, and are very similar in their action to the class Narcotics. Opium, camphor, ammonia, valerian, galbanum, and assafœtida, with most of the narcotics (which see), are the antispasmodics generally in use. Valerianate of zinc, a recent addition to the list, is a tonic antispasmodic of great power, especially in the treatment of neuralgic affections. It does not seem liable to produce sickness; and as it is used in doses of from one to three grains, it may be conveniently administered in the form of a pill.

Aperients are purgatives of the gentlest kind, for which consult the class Cathartics.

Astringents, as commonly defined, are substances which produce contraction and condensation when they come in contact with living matter; their mode of action, however, is rather obscure. Their power appears to depend in a great measure on the presence of the principle called tannin, and they produce their effect by bringing into closer contact the particles of the body to which they are applied, without in other respects affecting its mechanical structure. They are believed to be often of service in restoring tone to the stomach, and it is evident that their astringency will be of great advantage when any laxity of the surface of that organ exists; hence in many instances the most powerful tonics will be obtained from the class astringents. All the vegetable astringents contain tannin; and those most generally employed are preparations from gall-nuts, catechu, kino, oak-bark, logwood, and creasote. A number of the acids, and some of the salts, those particularly in which the acid preponderates over its base, as in alum, which is a compound of vitriol and the earth alumina, possess astringent properties, although they contain no tannin. Some of the metallic salts, as superacetate of lead (sugar of lead), and sulphate of zinc (white vitriol), are ranked in this class. Cold is also a direct astringent, and is often employed in this character with great advantage in checking bleedings. 'All the astringent medicines taken from the vegetable kingdom,' says Gregory, 'are so mild and safe, that they may be taken inwardly, and the use of them long continued without difficulty or danger, in larger or smaller doses, according to the strength of each; but those from the mineral kingdom cannot always be so employed, indeed they are fitted more for external than for internal application.'

Carminatives are those medicines which produce the discharge of flatulence from the alimentary canal. This malady is more annoying than dangerous, though it rises occasionally to a most painful height. The warm essential oils, such as caraway, anise, or peppermint, and some aromatic stimulants, as cinnamon and ginger, are the carminatives in greatest repute.

Cathartics is the general term for those numerous medicines which quicken or increase the alvine evacuations. As they differ considerably in their effects, they are usually spoken of as *laxatives* or *aperients*—that is, gentle evacuants; *purgatives* when more powerful; and *drastics* when they are particularly powerful and energetic. Whatever be their energy, they may be arranged under three heads:—those of an oily or saccharine nature; those which are derived from vegetables, such as resins and extracts; and those formed by a combination of acids with earths, alkalies, and metals, termed neutral and metallic salts. The operation of all these three is of the character of an irritation upon the mucous or inner membrane of the bowels, though in their effects they differ considerably from each other. The first-mentioned seem simply to discharge the contents of the bowels; the second appear to increase the quantity of matter evacuated, by stimulating the mucous membrane, and increasing the natural flow of mucus; while the third class produce evacuations of a watery consistence:—

The principal purgatives of the *first* kind are, castor-oil, olive-oil (seldom used), manna, tamarinds, honey, and so forth; croton-oil, an essential oil, (that is to say, procured by distillation, not by expression, as the castor-oil is), is scarcely to be included in the class of oils, as its great strength prevents its being used except in desperate cases. The medium dose of the castor-oil is one ounce, of the croton-oil a fraction of one drop. The former is imported in immense quantities into this country annually. It is one of the most useful and safe medicines of the purgative class. The rest mentioned are exceedingly mild in their operation, and are generally employed merely to palliate or disguise the bad flavour of some stronger drug.

The *second* kind of purgatives includes aloes, scammony, jalap, colocynth, senna, and rhubarb. The general character of all these has been given above, though the rhubarb possesses one remarkable distinction from the others. It is supposed to act on the muscular membrane of the bowels, producing a natural discharge simply, without altering the character of the fæces.

The principal neutral and metallic salts, which form the *third* order of purgatives, are sulphate of soda, Epsom salts (sulphate of magnesia), cream of tartar (supertartrate of potash), phosphate of soda, and calomel (submuriate of mercury). The latter is the most universal in its application of all medicinal preparations. By proper regulation of the dose, and in conjunction with other drugs, it can be employed with benefit in almost every disease to which man is subject. But in proportion to its usefulness, so is its danger when misapplied. The dose should be very small at first, and cold ought always to be guarded against during its use. With respect to the others, little can be added to the general description already given; it may be mentioned, however, that the pleasantest, though not the cheapest of all medicines, is the phosphate of soda, or *tasteless salts*.

As cathartics of some kind or other are very largely —perhaps too largely—used in this country, where there are so many sedentary and in-door employments, it may be well to transcribe a few remarks from one of the fathers of modern medicine on the subject:—'The operation of cathartics,' says Gregory, 'is dangerous to the weak, the irritable, the slender. It is also to be attempted with great caution, even by the gentlest medicines, in inflammation of the stomach and intestines, or when these are in a delicate state, as in dysentery or protracted diarrhœa. Too frequent repetition of purging, though at first necessary, does great injury, both to the whole system, which it weakens exceedingly, and especially to the intestines themselves, which it sometimes renders preternaturally feeble, tender, and irritable, but more frequently torpid and slow; whence proceeds constipation, and a necessity of having habitual recourse to cathartics. It also renders the blood thin and pale, in the same manner as too frequent bloodletting. . . . But where necessary, due allowance should be made for the patient's idiosyncrasy, not only in regard to the nature of the medicine, but also to its quantity, mixture, preparation, and time of taking it. It is often of advantage not to take the whole of the medicine at once, but by little and little, in equal portions, at proper intervals; for by this means neither is the stomach unnecessarily loaded, nor does vomiting come on, nor is too large a dose taken, nor are the intestines so severely irritated, while the effect is more easily, and indeed more certainly produced. When there is a tendency to nausea or vomiting, it becomes necessary not only to give the cathartic in small doses, but along with it, or a little before, to try an anodyne for composing the agitation of the stomach. During the operation of cathartics, patients are very easily injured by cold, possibly not more by reason of the body being then weakened, than on account of the current of fluids being drawn off more than usual from the external parts: it is therefore proper at such a time to guard carefully against exposure.'

Caustics are a class of substances employed to create artificial sores or ulcers, for the purpose of relieving some deep-seated malady. The operation of caustics is considered chemical, being the result of some attraction between the animal body and the substance employed. The same action takes place on the application of caustics to a portion of the dead subject. Where suppuration is going on in any internal part, they are exceedingly useful in creating a drain on the surface of the body. The principal caustics employed in medicine are potass, blue vitriol, nitrate of silver, arsenic, and some preparations of mercury. The nitrate of silver, or lunar caustic, is the substance in most common use, chiefly on account of its great manageableness, in consequence of its solid form, its property of not deliquescing, and its mild but effectual action—the pain produced by it being but of short duration.

Counter-irritants—known also as vesicants, rubefacients, and epispastics—are substances which produce redness, vesication, or inflammation, when applied to the skin. The extremities of the vessels which convey the blood from the heart over the body are supposed, when they terminate on the skin, to divide into minute tubes, one kind of which carries the red globules, and another the colourless serum of the blood. When strong stimulants, such as mustard or Spanish flies, are applied to the skin, they are supposed to excite these minute vessels so powerfully, that those which contain serum become filled with red globules; hence the term *rubefacients*. This can only be produced during an extraordinary flow of blood to the part, and is the cause of the redness consequent on the application of mustard cataplasms or blisters. A blister is simply a rubefacient allowed to remain on the skin until a deeper layer of it becomes affected, and pus or serum exudes. Like caustics, blisters are exceedingly useful in substituting a superficial inflammatory action for one existing in some deeper and more dangerous seat, and they are therefore called *counter-irritants*. The principal substances employed in exciting cutaneous inflammation are Spanish flies, mustard, tartarised antimony, ammonia, turpentine, and a few other drugs of a stimulant nature. The Spanish flies are almost exclusively used in blistering, and mustard, as a rubefacient, is held in a similar degree of estimation. Latterly a new and improved method of employing Spanish flies, or cantharides, has been introduced into practice. It consists in applying an extract which contains the essential powers of the material to the skin, by spreading it on paper. The blister so formed, which bears the name of *tela vesicatoria* (blistering tissue), produces a much more rapid effect than the common fly blister, and does not give the same pain to the patient. 'Cantharides should not be employed to produce vesication where any irritation or inflammation of the urinary organs is present, in consequence of their peculiar tendency to produce strangury. In infants and young children, blisters should be used with great caution, as they are liable to produce troublesome sloughing, which in many instances has caused death. As a general rule, they should only be left on until redness of the surface is produced, when the application of a warm poultice to the part will produce vesication.'

Demulcents—known also as *emollients*—are a class of medicinal agents the operation of which seems entirely mechanical. A poultice is applied externally to soften an inflamed or irritated part, and with exactly the same views are demulcents used to soothe any irritation of the alimentary canal. Solutions of gum, and syrups, with barley-water, rice-water, and other farinaceous drinks, are employed for this purpose. Iceland moss (lichen Islandicus), liquorice root, almonds, figs, sugar, marshmallow, linseed, and others, are included in the class of demulcents.' 'Of the non-medicinal used as emollients,' says Neligan, 'warm water is the most important, and the higher the temperature at which it can be applied without the actual production of pain, the greater will be its emollient power; for this reason it will be found productive of most advantage when employed in the form of vapour.'

Diaphoretics are those remedies which promote the insensible perspiration; *Sudorifics* such as produce profuse perspiration or sweating. These two classes of remedies are very closely connected, and scarcely, if at all, admit of being distinguished; since the same means may, by the mode of administration, produce either the one or the other effect—while these effects differ rather in appearance and degree than in nature. With regard to their action, it has been questioned whether there exist any medicines possessing any specific quality of stimulating the skin, or exciting to more vigorous action the vessels which exhale the perspiration. The action seems to be sympathetic rather than direct: nausea and vomiting produce profuse sweating; sudden fears and other mental emotions do the same thing; and all the diluents, stimulants, sedatives, and emollients act less or more in this way. Among the simplest diaphoretics may be ranked whey, gruel, barley-water, and other warm drinks and infusions. For those of a more energetic character see *Sudorifics*. 'Among the most excellent and salutary diaphoretic remedies,' says Dr Gregory, 'is deservedly reckoned proper bodily exercise; for when moderate, it accelerates the circulation, and eminently promotes perspiration: when more violent, it generally induces a profuse sweat, even in those persons who can scarcely be compelled to sweat by the medicines commonly used. In cases which do not admit of exercise, diligent friction may in some measure supply its place.' In fine, bathing, change of dress, quality of dress (see CLOTHING), are all favourable to this end.

Diluents, as water, and all weak liquids of which water forms the greater part, are generally ranked as medicinal agents. Being drunk in large quantity, and conveyed by the lacteals into the blood, they have a powerful effect in attenuating the fluids when these are preternaturally thickened. In health they are as necessary as the air we breathe, for by no other means can we maintain the due equilibrium of the circulating medium, upon which all the vital functions depend.

Diuretics are those medicines which operate in promoting the flow of urine, by stimulating the action of the kidneys, the organs which secrete it. This class is very numerous, though the manner of their operation, like that of all the other vital agents, is not thoroughly understood. 'Some act,' says a recent medical authority, 'as direct stimulants to the secreting vessels of the kidney, being taken into the current of the circulation, and carried, without undergoing any decomposition *in transitu*, to the urinary organs; others are partially acted on by the digestive organs, and some of their component parts thus alimented are carried by the circulation to the kidneys, which are thereby stimulated to increased action; while a third class of substances acts primarily on the stomach, the action they excite being secondarily communicated by sympathy to the urinary organs. In whatever manner the action of diuretics is produced, the general effect is to diminish the watery part of the blood, and by this means promote the absorption of fluid effused into any of the cavities or into the cellular membrane. Hence dropsy is the disease in which they are principally employed; and when the discharge of urine can be excited by their administration, the effused fluid is in general removed more speedily from the system, and with less injury to the patient, than by any other method.' The diuretics chiefly employed in practice are squills, foxglove, juniper-berries, potash, cream of tartar, acetate of ammonia, nitric ether, and Spanish flies. All these act powerfully on the urinary organs—those in highest repute being squills, foxglove, juniper, and cream of tartar. The first and the last of these are the most efficient, being more certain in their effects than the others. The action of diuretics is much affected by the state of the skin; hence the common rule, during their exhibition, to keep the surface of the body cool, and to promote the operation of the dose by the use of simple diluent drinks. Further, from the nature of the above-enumerated substances, it is sufficiently clear that some of them are decidedly heating, others refrigerant; some considerably increase the acrimony of the urine, others diminish and blunt it: so that it is quite evident that all of them cannot be equally adapted to every disease. 'Though diuretics are rarely given in such a way as to do the system much injury'—we quote the 'Theory of Medicine'—'it is nevertheless very evident that some degree of prudence is requisite in the administration of them; the abuse of them being attended with considerable danger, as some have found from experience, whether they had been given of too acrid a quality or too often repeated. For in this manner the whole body is weakened; and, in particular, the kidneys are so injured, that either through torpor they become inadequate to their functions in future, or being softened and relaxed, they excern an excessive quantity of fluid, and that very different from healthy urine. Besides, the irritation of more acrid medicines may seriously injure the urinary passages and bladder, and deprive them of their mucus, whence comes perhaps strangury, and similar complaints, especially in aged people, who, by the ordinary course of nature, also become very obnoxious to disorders of this kind.'

Drastics are the most powerful and energetic of the class Cathartics, which consult.

Emetics are substances administered for the purpose of producing vomiting. It may be supposed, from their being received into the stomach, and acting directly and speedily upon it, that there is no absorption into the blood necessary. Tobacco, for instance, taken into the stomach, excites vomiting; but it is from its reception into the circulation; because, if the tobacco be laid on the arm, the same effect will be produced. Some emetics, indeed, appear to act principally on the muscular covering of the stomach, exciting it to contraction, and thereby causing the expulsion of the contents. Most of them, however, simply produce nausea, which causes the inversion of the receptacle of the food. The most active emetics employed in medicine are tartar-emetic, ipecacuan root, chamomile flowers, mustard, sulphate of copper, and sulphate of zinc. The two first of these are most commonly used; the latter being the gentlest, and perhaps on that account the safest, in ordinary cases. 'Emetics should be employed with great caution where there are symptoms of determination of blood to the cerebral organs, in consequence of the obstruction of the circulation which is occasioned during the act of vomiting; for the same reason also they ought not to be administered in diseases of the large arteries, as in aneurism. From the violent action of the abdominal muscles which is caused, the act of vomiting is attended with great risk in the advanced stages of pregnancy, in hernia, and the like.' Frequent vomiting is very injurious to the body, as it weakens the stomach, of course spoils the digestion, and thus in some measure becomes necessary. The operation is more easy with a full than with an empty stomach: hence the advantage of drinking pretty copiously during the exhibition of emetics. It is often of advantage, especially in very infirm patients, or those who have been much agitated, to give an anodyne after vomiting, to compose such agitation, procure sleep, and recruit the health.

Emollients, already noticed under the head *Demulcents*, are generally ranked under two great classes—the oleaginous and mucilaginous. Whether taken internally, or applied externally as Fomentations (which see), their action is simple and easy to be understood: the solid parts are rendered elastic or resisting, but more flexible; and of consequence some parts, which previously hardly admitted of motion, are afterwards moved with much greater ease. 'Of all medicaments of this kind, by far the most powerful and certain is pure water, especially when warmed; for the innumerable decoctions, fomentations, and infusions which are so frequently prescribed, and so much celebrated for their emollient qualities, are generally nothing else, and have no other virtue than pure warm water. And indeed many experiments instituted for the purpose of investigating this matter, afford sufficient proof that the greater part of the oils, juices, and other substances commonly so highly extolled for their emollient qualities, possess them in a much less degree than water itself. However, it would not be reasonable to conclude, on that account, that those oily and mucilaginous substances which we commonly use do no good; for it is very certain that they render the solid parts of animal bodies more soft and flexible, by moistening, and, as it were, besmearing them with oil, facilitating the motion of the particles among themselves by diminishing or removing the friction which impeded it. Besides, pure water and very many aqueous liquors, whether applied warm or cold, are soon dissipated by evaporation, and by that means leave the external parts which had been fomented with them to dry and stiffen. But oily and mucilaginous applications are generally free of this inconvenience, at least they are much more slowly dissipated. Therefore they are properly mixed with all emollients for softening the external parts.'

Epispastics is the term particularly applied to vesicatories and blistering plasters, already treated under the more general appellation Counter-Irritants.

Errhines, Sternutatories, or *Ptarmics*, are substances which, when applied to the mucous membrane of the nostrils, cause an increased discharge of its natural secretion. The powdered leaves of asarabacca, euphorbium, white hellebore, tobacco and turbith mineral (subsulphate of mercury), are powerful errhines; but they are seldom resorted to in regular practice. Violent sneezing, which these sternutatories occasion, though sometimes of use, as in suspended respiration and suffocation from foreign bodies in the air-passages, is not unattended with danger; especially in plethoric patients, in cases of congestion in the head or lungs, in recent and violent inflammation of the eyes, and in rupture. Though occasionally useful in diseases of the eyes, nostrils, deafness, and torpor of the cephalic functions, the habitual use of errhines (snuffs of whatever name) is alike absurd and pernicious.

Expectorants, or *Pectorals*, as they are sometimes termed, are substances used to promote the expulsion from the lungs of those fluids which are secreted during colds, and lodge there, causing difficult breathing, and sometimes ending in injury of their structure. Thus those remedies which promote expectoration are of great consequence to health, though often neglected. The principal medicines of this class are antimony, squills, ipecacuan, balsam of Tolu, and gum ammoniac. Syrup of squills is the preparation in greatest use, forming one of the best expectorants we possess for the pulmonary affections of children, in doses of from 10 to 30 minims. To these may be added all emetic substances which, by their mechanical action, dislodge accumulated secretions from the respiratory organs, and thus frequently become valuable agents in the treatment of diseases requiring the application of expectoral drugs. Epispastic remedies—as blisters, for example—applied to the breast, side, or back, are also useful in promoting expectoration; and to these may be added all Diaphoretics, the inhalation of steam of warm water, which acts as an emollient, and riding on horseback, which has been much recommended.

Febrifuges are medicines believed to exert a specific influence in ague and other periodic diseases; they belong to the great division of Tonics and Stomachics.

Fomentations (see Demulcents and Emollients) are warm fluids, applied for the purpose of encouraging perspiration on the skin, and thereby to diminish inflammation, and to render the skin yielding, so that the swelling which accompanies inflammation may be less painful, by the greater readiness with which the skin yields than when it is harsh and dry. The usual practice, therefore, of rubbing, dabbing, or pressing, is improper. The patient must be as well defended as possible from exposure to wet, by having something placed under him; and then a piece of thick flannel, or blanket, after being saturated in the warm fomentation, is to be instantly wrung, and laid liberally on the part of the body affected, and covered with oiled silk or a jack-towel, to keep in the warmth. This process is to be repeated every ten minutes or so, for hours if necessary. The foot or hand may be fomented by mere immersion, the heat of the fluid to be kept up by the addition from time to time of more which is hot. Warm water, as already stated, makes of course the readiest fomentation, and is generally the best.

Laxatives is a common appellation for the milder group of Cathartics already described.

Narcotics—known also as *Anodynes, Soporifics*, and *Hypnotics*—are those substances which diminish the natural degree of action in the body, and tend to remove irritation or pain, inducing in general a state of repose. Before this quieting effect is produced, however, there is a primary excitement of short duration, which is well exemplified in the case of opium. Sedatives, viewed as a separate class, are believed to allay pain and promote sleep, without possessing any stimulating qualities. Unless where excessive pain is present, narcotics may be regarded as a class of medicines only to be used with great caution, and never free from danger. Opium and its preparations, lettuce extract, henbane, foxglove, Indian hemp, hemlock, belladona, and tobacco, are some of the strongest narcotics. It is difficult to say which of these is the safest: 'idiosyncrasy,' says Dr Neligan, 'has a remarkable influence on the effects of narcotics: we meet with some individuals almost insensible to their action; while in others small doses produce a dangerous stupifying effect, or in some instances give rise to a degree of excitement amounting to furious delirium. But habit influences the action of narcotics on the system more than any other circumstance—their power being diminished in an extraordinary degree by repetition. Where, therefore, their continued administration is required, it will be necessary gradually to augment the dose, in order to produce their usual effects. The influence of age on their action must be also borne in mind in their administration, the young being much more susceptible to their influence than individuals of maturer age.'

Purgatives is the generic term in ordinary language for all Cathartic remedies.

Refrigerants, known also as *Temperants*, are substances calculated to diminish the heat of the body when morbidly increased, and to produce a soothing sensation of coolness. Applied externally as cooling or evaporating lotions to any inflamed part, their operation is easily understood, as they serve merely to reduce the temperature by carrying off the excess of heat. Taken internally, their mode of action is not quite so clear, for though they produce the sensation of coolness, they do not in reality reduce the temperature of the body. The most common refrigerants are vinegar, citric acid, tartaric acid, lemon-juice, the fruit of the orange, nitrate and chlorate of potash, and conserve or confection of dog-rose. The principal use of these preparations in practical medicine, is in the treatment of fever and inflammatory affections, in which their direct action on the stomach seems to occasion sympathetically a reduction in the force of the circulation.

Sedatives, to which allusion has already been made under the head Narcotics, are those substances which directly or primarily depress the vital powers without inducing any previous excitement. From their effects, which are directly contrary to those of stimulants, they are sometimes termed *Contra-stimulants;* occasionally *Calmatives*. With regard to the distinction which is made between them and narcotics, Dr Neligan remarks—'Were we merely to theorise on their mode of action, it would be perhaps difficult to draw an exact line of distinction, but when we come to consider the remedial powers of the medicines classed under each head, it will, I think, be at once evident how *practically* essential it is that we should recognise this as an especial class of remedial agents.' Hydrocyanic or Prussic acid, aconite, digitalis, hemlock, tartar emetic, chloride of formyle or chloric ether, and cyanide of potass, are the most energetic of this class. The diseases in which these remedial agents are employed are those of over-excitement of the nervous and vascular systems—some of them, as hemlock, acting more immediately on the nerves; and others, as digitalis, more directly on the vascular organs. It is necessary, therefore, before prescribing, to consider attentively the peculiar action of the different sedatives, in order to obtain the most immediate and efficient result. An important rule to be borne in mind with reference to the operation of contra-stimulants is, 'that the dose must be in general proportioned to the degree of excitement present; this *tolerance* of medicines is remarkably illustrated by the large doses of *tartar emetic*, which are administered not only with impunity, but with advantage, when inflammatory action runs high.'

Sialogogues are a small and but seldom-employed class of substances. Their function is that of a *local* stimulant to the salivary organs, increasing the flow of their secretion. 'By this definition we exclude,' says the authority before quoted, 'the so-called remote or specific sialogogues, as the preparations of mercury, gold, &c. which generally produce an increased flow of saliva when their internal use has been continued for some time; but as their remedial powers do not depend merely on the increase of this secretion, it will, I think, be more practical to confine the term *sialogogue* to those agents which are employed as direct stimulants to the salivary glands.' Horse-radish in a fresh state, mezereon, and pellitory of Spain, are vegetable roots possessing this property—the latter especially so. They are chewed in small fragments, and the saliva assiduously rejected.

Soporifics, a familiar term for the milder agents of the class Narcotics. See also Sedatives.

Sternutatories, as the name implies, are substances which provoke sneezing, and relatively an increased discharge from the mucous membrane of the nostrils: they have been already adverted to under the head Errhines (literally, into the nose).

Stomachics and *Tonics* form another class of medicines, acting by absorption into the blood, or as vital agents, which cannot be ranked either amongst those which excite action or those which repress it. The former increase the digestive powers of the stomach, the latter renovate the tone or contractile energies of the muscular fibre. They are slow in their operation, and augment the strength of the body without materially exciting its actions. As these two kinds of medicines are not very distinctly separable, it may be better to enumerate them together. Good nutriment is the most natural and best supporter of the bodily powers, but to effect this purpose, it is necessary that the function of digestion should be in a proper condition. Gentian root, quassia, chamomile, calumba, and canella, assist powerfully this object. Amongst the tonics, Peruvian, cascarilla, cinchona, angustura, and willow barks, the preparations of iron, the sulphuric and nitric acids, are in greatest repute. 'There is no class of remedial agents,' says a high authority, 'which requires more discrimination in their administration than tonics, nor any the injudicious use of which more frequently produces evil consequences. The diseases in which this class of remedial agents are principally employed must manifestly be those of diminished power. In no case, however, should they be prescribed where there is a tendency to irritation or inflammation of the digestive organs, or where the secretions are in a depraved state, without the previous use of means calculated to remove the former or correct the latter; to effect which, the employment of mild purgatives will in most instances be found best adapted. Tonics have a marked action on the various organs of secretion—their effects being to restore them to a healthy state. They are consequently administered with the view of diminishing secretion when it is excessive, or of restoring it when deficient, if either condition depend, as it frequently does, on inertia or want of tone in the secreting organ.' Independently of their tonic properties, some of the remedies contained in this class possess a specific power in ague and other periodical diseases; hence they have been denominated *Febrifuges*.

As remedial agents, few are more largely employed at the present day than tonics and stomachics, not only for the purpose of renewing tone and strength where debility actually exists, but with the view of imparting additional vigour—hence the term *corroborants*—where the constitution is in ordinary condition. It is needless to say that the latter is altogether a mistaken notion; and that the best and safest of all corroborants are—proper dietary, clothing, exercise, cleanliness, freedom from harassing cares, and those general regulations insisted upon in the article PRESERVATION OF HEALTH. Were those regulations attended to as they ought to be, the class of remedial agents now under review might safely be swept from the lists of medicinal preparations.

Stimulants is the general term for remedies which excite sensation in the sentient parts, or motion in the muscular parts—in other words, any excitement of the vital energies. It is usual to distinguish them as *general* and *special*, according as they affect the whole system, or exert a peculiar influence on individual organs or on the system generally. 'It is difficult, however, to define'—says Neligan, whose account of this class we shall adopt—'what is understood in the practice of medicine by the term Stimulant, excitement of the vital energies being produced by such different means under different circumstances. With no class of remedies, therefore, is it more necessary to bear in mind the truth of the maxim, that medicines act merely *relatively*. In their mode of action when administered internally, General Stimulants resemble in some respects Tonics; thus immediately after their administration a feeling of increased tone or power is produced, which, however, is not permanent, but is almost invariably followed by a corresponding depression of vital power; their effects also are more immediate, and more manifestly perceived by the senses, than those of Tonics. Many of them are also closely allied to Narcotics; for example, alcohol and the ethers, the secondary effect of both of which, particularly if given in large doses, is to produce sleep and coma. This does not, however, appear to be, as with Narcotics, from any direct action on the nervous system, but rather to result from the previous over-excitement of the vital energies. The great number of medicines contained in this class, and the material difference of their action in relation to the particular effects which they produce, preclude the laying down of any general rule for their administration.' The general stimulants usually enumerated are—alcohol, sulphuric ether, preparations of ammonia, camphorated acetic acid, camphor, anise, capsicum, ginger, cardamomum, caraway, cinnamon, oil of cassia, cocculus Indicus, lavender, mint, pepper, nutmegs, oil of turpentine, rosemary, sherry wine, sulphur, chloride of soda, chloride of lime; and to these we may add electricity in its various developments.

With regard to Special Stimulants, 'many of them give rise to some alteration, which is not well understood, in the nature or quality of vital action, when they are called *Alteratives*; while others possess a special influence in the treatment of certain diseases, when they are denominated *Specifics*. Many alteratives and specifics have been already described in other classes of medicines, but the articles contained under this head cannot, with a regard to accuracy of arrangement, be included in any of them; inasmuch as the primary influence which some of them exercise on the animal economy has not been satisfactorily ascertained, and others possess a peculiar influence over *certain organs* or *diseases* merely. As examples of the former, we may refer to mercury, iodine, and gold; of the latter, to nux-vomica, cubebs, and copaiba.' The special stimulants commonly enumerated are—iodide of arsenic, iodides and chlorides of gold, bromine, copaiba, cubebs, numerous preparations of mercury, iodine, nux-vomica, iodide of potass, and some marine substances containing iodine, as sponge and cod-liver oil.

Under this section we have mentioned the therapeutical use of alcoholic liquors; and as much error seems to prevail on this matter, we shall here present in brief the opinions of Drs Christison, Pereira, Neligan, and other modern authorities. We avoid the testimony of the older medical schools, as having an evident bias to the employment of these agents; as much as we avoid the dogmas of those who would altogether discard them:—Alcohol, in all its forms, is a highly valuable therapeutic agent. In moderate doses, properly diluted, it acts as a general stimulant, exciting particularly the vascular and nervous systems; in somewhat larger doses, it produces the well-known effects of intoxication; and in excessive doses, it acts as a powerful narcotic poison, rapidly causing death, preceded by slow pulse, contracted pupils, and coma. This effect is most usually observed when a large quantity of ardent spirits is swallowed at once, as for a wager. As a stimulant, alcohol is employed in medicine to support the vital powers in the advanced stages of fevers, particularly those of a typhoid character; for this purpose brandy or whisky is usually employed, but wine is generally preferred. It is also often used as a household medicine in flatulent colic, in indigestion, in vomiting, and in fainting; but for these purposes it is a perilous remedy when resorted to frequently, because apt to lead to the vice of habitual over-indulgence. Mere alcohol is seldom used as a diuretic in regular practice; but it is a powerful and familiar remedy of the kind when united with certain essential oils, of which combinations the most esteemed is Hollands. As an external stimulant, it is a common ingredient in lotions for sprains and bruises, for many forms of external inflammations, as erysipelas and erythema, for various skin diseases, to prevent excoriations in parts exposed to long pressure, and with friction over the region of the heart in syncope and suspended animation. In consequence of its producing cold by evaporation, alcohol is frequently added to cooling and evaporating lotions. Wines, we have said, are also used internally as stimulants, and for this purpose are often better suited than any other alcoholic liquid. Their use is particularly called for in the advanced stages of typhoid fevers, and where delirium is present, with much sinking of the vital powers. They are also given with advantage in convalescence from acute diseases, in chronic debility, especially when it is caused by excessive discharges, in mortification unaccompanied by inflammatory symptoms, and in tetanus or lock-jaw. When any local congestion or inflammation is present, or may be apprehended, the administration of wine in the treatment of disease is for the most part calculated to do mischief. Although sherry is the only wine officinal in the pharmacopoeia, port is generally employed in medicine; claret and Madeira are also used. When its greater strength and astringency are not objectionable, port wine is always to be preferred. Madeira and claret are often inadmissible, on account of their acidity; but when this is not the case, the former is well adapted for debilitated or broken down habits, the latter when the employment of stronger wines might prove injurious. Sherry is chiefly employed in the preparation of medicated wines; but Cape wine, on account of its cheapness, is usually substituted by druggists. In a dietetical view (see BEVERAGES), sherry is the wine in most general use, and the one calculated to agree best with most constitutions.—Such are the opinions of medical authorities with regard to the medicinal or therapeutic uses of alcoholic liquids; and by their enlightened and unbiassed directions ought unprofessional parties to be implicitly directed. The dietetic, habitual, or conventional employment of these beverages is altogether a different question.

Sudorifics (see *Diaphoretics*) are medicines which increase the cutaneous perspiration. Certain substances received through the stomach into the blood, excite through it the vessels of the skin to action, and increase the natural discharge. The mode in which this result is effected is not well known; all we know is, that, during the operation, the heart, and the blood-vessels which terminate on the surface of the skin, are roused to unusual action. Among the most active sudorifics may be enumerated warm drinks; the warm bath; the preparations of antimony, including James's powder; Dover's powder (compound ipecacuan powder); the preparations of ammonia; and all medicines generally which nauseate the stomach. Probably of all these Dover's powder is the best. Sudorifics, in almost all cases, when early used, prevent the effects of colds, which, when neglected, prove so often fatal in their consequences. During the administration of sudorifics, it is essential that the surface of the body should be kept warm; and for this purpose a bad conductor of heat, such as flannel, should be employed. Care also must be taken to avoid the application of cold, either by exposing the surface of the body to cold air, or by the use of cold drinks while the perspiration continues, or for some time after it has ceased; lastly, when it is wished to check the perspiration, this must be done gradually, by drying the surface of the body with dry warm towels, by diminishing the covering, and by cautiously exposing the hands and arms to the air.

Vermifuges is an old and popular term for the remedies treated under the head Anthelmintics.

Medicine Taking.

The principal medicines employed at the present day for the alleviation or cure of disease have been now enumerated, in an arrangement which may show their several properties and modes of operation. The information will have the effect, we humbly imagine, of dissipating some portion of that veil of mysticism which enveloped the art of medicine, and of showing what are the rational objects to be expected from the action of drugs upon the animal frame. There are at present two injurious opinions prevalent in the world on this subject, both of which are entertained alike by the ignorant and by the enlightened, and which are equally at variance with the truth, and noxious in their consequences. The first of these opinions is, that the science of medicine is from beginning to end a deception; that medical men are as much in the dark as their patients with regard to the cause and nature of disease, and are consequently quite unable to provide a remedy. This opinion is generally to be found in its greatest strength among those who set themselves up as free-thinkers on all subjects, and is the natural result of the mystery which has for ages degraded the art of medicine and obscured its true objects; for wherever there is mystery, a belief in, and dread of, chicanery ensues. Enlightened men are more liable, upon the whole, than the ignorant to imbibe this feeling of distrust. One of the most elegant writers of the day, for example, bitterly and satirically defines medicine to be 'the practice of pouring substances of which nothing is known, into bodies of which still less is known.' This is merely satire, it may be said; but satire is seldom attempted, and never becomes current, unless it be directed against a thing which is supposed to deserve it. An opinion of this kind of course leads the person who holds it to regard the regular physician and the empiric as upon a level, and to look upon the prescriptions of the one as equally contemptible, or, in other words, equally valuable, with those of the other. The second opinion, which we alluded to as being prevalent in the world, is directly the reverse of the first, and is more common amongst the ignorant than amongst the intelligent part of mankind. It is a belief in the boundless powers of medicine, which leads those who entertain it to treat their bodies as if these had been designed by nature merely as receptacles for drugs. This opinion tends also to render those who hold it a prey to every successive nostrum that knavery and quackery can invent. It is based upon the very same foundation as the opposite opinion—namely, the mysticism that obscures the true objects and powers of medicine, for with some minds whatever is dark and mysterious, becomes invested with supernatural qualities.

The persons who thus consider the art of medicine as unlimited in its powers, and believe that the body can never be in a proper state unless under the influence of some drug, are generally those who pore over all the medical books they can get hold of, and imagine themselves successively to be the subjects of every disease described. As it would be too expensive to employ every day of their lives a regular physician, they acquire the habit of prescribing for themselves, or of trusting to the prescriptions of an empiric. If these persons perceive, for example, that inflammation in the side is described as characterised by pain in that region, they immediately become alarmed on account of some pain which has troubled them for some time in that quarter, and fly to bleeding and blistering, while, probably, the pain which they felt was merely the consequence of a little flatulence or wind on the stomach. A regular medical man, or any person acquainted with the subject, would have informed them that a chain of symptoms was necessary to establish the fact of inflammation of the side, pain being more or less a characteristic of almost all diseases. By thus observing a prominent symptom in every disease, and imagining their own weakened frames to present an example of it, it is not uncommon, as we said, for persons of this turn of mind to conceive themselves affected in succession with all the ills that flesh is heir to. Finding an enumeration of remedies accompanying the descriptions of diseases in the books they read, they try medicine after medicine, till they impair their bodily powers, and create diseases where none originally existed. Sometimes this method of self-drugging and self-killing is varied by a mania, equally destructive, that leads them to the trial and use of all the pretended remedies which ignorant empirics foist so unremittingly on the world. Those knavish gentlemen, generally termed *quacks*, know thoroughly the points upon which the success of their gulling depends, and accordingly publish imaginary letters addressed to themselves, descriptive of cases in which their invaluable medicine, in the form of drops, pills, powders, or elixirs, 'has been of incalculable service.' These cases embrace every disease, and every symptom of disease, under the sun; and the infatuated beings who read and trust to them find always some fictitious case of cure, which appears to resemble their own complaint, and accordingly are deceived into the purchase of the 'invaluable medicine.' Were these quackeries simply impositions upon the credulous of a harmless drug as a valuable one, the evil would not be so great; but exceedingly few of them have so much merit as to be innoxious. On the contrary, the records of the criminal courts tell a fearful tale of credulity, punished in many instances by death. The examples of this are so notorious as to need no further notice, and we hope that they will make a lasting impression on the public mind. Were people only to consider, however, how excessively inconsistent with each other are the numerous purposes which these nostrums affect to accomplish, how improbable it is that men ignorant of the structure and diseases of the body should have discovered remedies which have baffled the search of those who have studied the frame deeply, and have mastered all the accumulated knowledge of preceding ages on the subject—if they consider these, and many similar arguments, certainly so much credulity would not be evinced on a subject affecting so deeply the comfort and even the existence of man.

It is not with a view to increase the number of those who tamper, in the way described, with medicines that the preceding pages have been written. If such should be the consequence of the information they contain, no one would deplore it more sincerely than ourselves; but we confidently hope that, as far as their humble influence extends, the result will be very different. Those to whom the action of medicines on the system is a mystery, may fly to the quack for a nostrum, or try to discover one themselves; but those who have given the subject so much attention as to be aware that the action of medicinal substances on the body is as varied as the disorders which they are applied to remedy, and at the same time to a great extent demonstrable and intelligible—those who are possessed of this knowledge will scout the idea of a universal panacea, and despise the quack and his nostrums, while at the same time their confidence in the man who has devoted his days to the consideration and relief of disease will be increased tenfold, since they are assured that his objects and his plans are consonant to the soundest principles of true science, of reason, and of common sense.

We have just one word of advice to give in conclusion, and it is this: When any one feels himself afflicted with a complaint anyway beyond a very slight indisposition, let him at once, and without a moment's delay, send for a regular and skilful medical attendant, to whom let him communicate freely the state of his feelings, as well as what has been his previous course of life. Every hour he postpones the execution of this necessary duty, he increases in an immense ratio the chance of premature dissolution; indeed it is our firm belief, founded on very sad experience, that one-half of the deaths which occur might for the time be averted were proper medical advice to be sought for and attended to at the outset of diseases. The grand error in most people consists in 'putting off sending for the doctor' till it be too late; and hence many valuable members of happy social circles—fathers, husbands, mothers, sons, and daughters—are snatched away in the bloom or prime of life, leaving friends and relatives to mourn over the grave of their disappointed hopes.

To these remarks on *medicine taking* by the adult and responsible, we may add with equal advantage the following observations by Dr Combe on the absurd and too-often fatal practice of indiscriminate *medicine giving* to the young and helpless, who are incapable of taking care of themselves:—'Many mothers are continually administering medicines of one kind or another, and thereby deranging instead of promoting the healthy operation of the infant system. Instead of looking upon the animal economy as a mechanism constituted to work well under certain conditions, and having, in virtue of that constitution, a natural tendency to rectify any temporary aberrations under which it may suffer, provided the requisite conditions of action be fulfilled, they seem to regard it as a machine acting upon no fixed principles, and requiring now and then to be driven by some foreign impulse in the shape of medicine. Under this impression they are ever on the watch to see what *they can do* to keep it moving; and altogether distrustful of the sufficiency of the Creator's arrangements, they no sooner observe a symptom, than they are ready with a remedy. Such persons never stop to inquire what the cause is—whether it has been, or can be, removed—or whether its removal will not of itself be sufficient to restore health. They jump at once to the fact that disease is there, and to a remedy for that fact. If the child is convulsed, they do not inquire whether the convulsions proceed from teething, indigestion, or worms, but forthwith administer a remedy *to check the convulsions*; and very probably the one used is inapplicable to the individual case; and both the disease and the cause being, in consequence, left in full operation, instead of being removed, the danger is increased. . . . I have no hesitation in expressing my conviction that a child can encounter few greater dangers than that of being subjected to the discipline of a medicine-giving mother or nurse; and wherever a mother of a family is observed to be ready with the use of calomel, cordials, anodynes, and other active drugs, the chances are, that one-half of her children will be found to have passed to another world.

Even when the child is under the care of a professional adviser, it is by no means safe from the risk arising from the exhibition of heterogeneous medicines. Whenever a child is seriously ill, there is not only great anxiety on the part of the mother, but much sympathy on the part of friends and neighbours, every one of whom has her own story of what was done with such another child in the same situation, and the great good obtained from such and such medicines. In vain the mother may urge that the physician has seen the patient, and already prescribed a different course. Intreaties are poured in with an earnestness proportioned to the danger, just *to try* the vaunted remedy *without telling the doctor*, or interrupting the use of his medicines. Anxious for the relief of her child, the mother often yields before her better judgment can come into play to prevent her, and in a short time the child perhaps suffers from this abuse of incompatible or dangerous remedies, which aggravate the original disease. Those who are accustomed to reflect before they act, would be amazed if they were to witness the perilous follies sometimes perpetrated in this way, and the perfect self-complacency with which the anticipated results are looked for from the individual doses, no matter how much they may counteract each other. . . . The system of concealment from the family physician, into which the adoption of "everybody's" advice is so apt to lead, is itself an evil of the first magnitude. By inducing him to ascribe effects to wrong causes, it necessarily tends to mislead his judgment, and may thus render him also unwittingly an instrument of mischief. The maternal anxiety which lies at the root of the error is highly natural, and every sensible practitioner will make allowance for its impulses, even where they are ill-directed and annoying to himself. But the fair and proper way for the mother is, not to act upon the suggestions of others without the knowledge of the medical attendant, but to state simply, and in an honest spirit, that certain suggestions have been made, and inquire whether they meet with his approbation or not. If they do, they will then be adapted by him to the necessities and peculiarities of the individual case, and the different parts of the treatment carried on consistently and safely. If, on the contrary, they do not, the physician will have an opportunity of assigning a reason for his disapproval, and of pointing out the greater fitness of the means already employed; and if the parent shall not be satisfied with this explanation, but still insist on the suggestion being tried, he can then either decline farther responsibility, or take care that the trial be made with as much safety and prospect of advantage as possible.'

In regard to the quantities of medicine to be employed as doses, that is a branch of the subject which we leave entirely in the hands of the medical practitioners properly empowered to administer them. It may here, however, be mentioned, as an interesting fact, that the action of the dose by no means corresponds with the quantity. The general rule seems to be, that when a too large dose of a medicine is taken, nature makes an effort to expel it, and it is accordingly vomited without doing the intended good. A dose of a moderate size pushes its way to the bowels, which it irritates, and causes to act with a degree of violence. A dose of a smaller size will act only on the stomach. The action of medicines in the stomach is by absorption into the system; and as the stomach is always less or more filled with fluid materials, it follows that the medicines received are diluted, and have a correspondingly weak, or at least slow influence on the absorbents. Thus it has been found that a few drops of certain medicaments dropped on the tongue, by which they are absorbed at once into the system, have as powerful an effect as twenty times the quantity poured into the stomach. (See also statement in p. 755.)

HOUSEHOLD SURGERY.

We now come to the operations of surgery, and here we again wish it to be understood that our aim is in nowise to interfere with the functions of the legitimate practitioner, but rather to facilitate his success by conveying to the ordinary reader some idea of an art from which it may be his misfortune sooner or later to crave assistance. What we chiefly propose is, to show how to manage in cases of accidents and emergencies when and where the doctor is not to be had, and when delay or non-assistance might prove fatal. An interval must necessarily elapse between the occurrence of an accident and the arrival of medical aid, and for want of presence of mind, and a little knowledge how to proceed during this interval, the future efforts of the doctor are often rendered unavailing. Where medical aid is to be had, however, let it be instantly called for. 'Whoever neglects this advice,' it has been quaintly but forcibly said, 'and doctors himself when he can be doctored, is in much the same case as the man who conducted his own cause, and had a fool for his client.'

As stated in the previous section, medicine and surgery are always less or more combined; and for the successful practice of either, even on the simplest domestic scale, it will be necessary to be possessed of certain articles and appliances. For families, and country families in particular, a medicine-chest, supplied by a qualified druggist, is an almost indispensable requisite. Such a store should always be kept with care and caution, and should contain ingredients for simple poultices and fomentations, for cerates and ointments, liniments and lotions; with a few fresh tonic, antacid, purgative, sedative, stimulant, and other common medicines. In this little store everything should be carefully labelled with the name and the doses for children and for adults, and be kept, if possible, in closely-stoppered bottles. Such medicines as castor-oil, syrup of senna, calcined magnesia, laudanum, rhubarb, gum, lime-water, prepared chalk, croton-oil, quinine, calomel, syrup of squills, and so forth, no household should ever be unprovided with; and as for apparatus, a graduated glass measure, a pair of scales and weights, a lancet, scissors, a cupping-glass, perhaps, and a scarificator, are all that is ever likely to be required. It is supposed of course that in every family there are soft clean linen rags for rollers and bandages, and that there is always at hand salt, mustard, vinegar, sweet oil, treacle, flour, loaf-bread, and we may add, without a shadow of countenance to intemperance, some alcoholic stimulant, as brandy. Possessed of presence of mind and a pair of ready hands, and fortified with the above adjuncts and appliances, we may suppose the reader qualified to comprehend and to understand how to act in the cases we are about to describe. In this description we have specially made use of 'Hooper's Medical Dictionary,' as edited by Grant—a little pocket volume on 'Household Surgery,' by Mr South (Cox, London)—and a map-sheet entitled 'Accidents and Emergencies,' by Mr Alfred Smee (Churchill, London), which should be hung up in every nursery, school-room, and factory:—

Bleeding—Blistering.

Bleeding may occur from an artery, vein, or the small vessels which join the arteries with the veins. Arterial blood is known from its bright scarlet colour, and from its issuing in jerks; venous blood by its dark colour and continuous flow.

The best mode of bleeding to be adopted by an unprofessional person is by *cupping*, which is easily learned, although we have no room for the directions. In the absence of a proper instrument, a common cup, or a tumbler (if of a bellying shape, so much the better), may be turned down upon the part, after the air has been rarefied with lighted tow or paper. The skin rises into this, and is afterwards to be wounded with a lancet or sharp knife in half-a-dozen places. Bleeding in the arm is a delicate operation, owing to the neighbourhood of the great artery, and must be learned from a regular practitioner.

Leeches form a safe and convenient mode of bleeding. When they are inconveniently fastidious in their appetite, the skin may be scratched with a needle-point till the blood comes, which will generally be irresistible. A warm bread-and-water poultice, renewed every half-hour, is better for encouraging the bleeding than sponging with warm water. Never let a person go to sleep while leech-bites bleed, as many persons, especially children, have died therefrom. To stop the bleeding, apply your finger for some time to the wound, or use a piece of linen and bandage.

Bleeding from wounds is stopped by pressure on the part; or, if necessary, the ends of any little artery that may be severed are to be tied with a thread; or when the bleeding is important and continued, the main artery that supplies the limb may be stopped till medical assistance is obtained; in the case of the arm, by pressing the thumb behind the middle of the collar-bone; and in the case of the leg, below the crease of the groin. When the bleeding is below the middle of the upper arm, or thigh, a stick tourniquet will answer the purpose. It is merely a handkerchief passed two or three times round the limb, above the wound, and twisted as tightly as may be necessary by means of a stick. For want of this simple precaution, a considerable number of lives are annually lost on our railways and at our great public works.

When blood is coughed up, it is known to come from the lungs by its frothiness, if in small quantities, and its pure bright redness when more plentiful; and when vomited from the stomach, by its dark colour. In either case, all that non-professionals can do is, to keep the patient cool in bed, with his head slightly raised, to enjoin absolute quiet, and give a tablespoonful of vinegar in sugar and water, or a single drop of oil of vitriol in a wine-glass of sugar and water, every half-hour, until the surgeon arrives. When the discharge is from the lungs, the fainter the patient becomes the less danger is to be apprehended.

In blistering, the chief thing to be attended to is, never to allow the plaster to remain on a child under ten years of age longer than till the skin has become well inflamed, which will be in three or four hours at most; and that if any of the disagreeable effects of blisters are feared, they may be easily avoided by covering the plaster before application with tissue paper.

Cuts—Bruises—Wounds.

An ordinary cut or chop with a knife, chisel, axe, and the like, even if it severs a finger or a toe, is only dangerous to the irritable or intemperate. Do not be in a hurry; carefully clean the wound from all dirt or other extraneous matter, and dab with a sponge, dipped in cold water, till all bleeding stops. If the wound be extensive, you may leave it open for half an hour, then bring the corresponding edges together as perfectly as possible, and while thus held, some strips of plaster are to be laid across the wound, with small spaces between every two, so as to allow the escape of an oozing fluid, which often continues for some hours. The edges of the wound should not be dragged tightly together, but merely kept in place by the plaster; and if the wound be in the finger, arm, toe, or leg, it is better that the ends of the plaster should not overlap. If common sticking-plaster be not at hand, court-plaster will do; or thin bands of tow may be wrapped round the part, and smeared with gum-water. Or if nothing else is at hand, a bit of linen rag, by absorbing the blood, constitutes itself a plaster as the moisture dries. In other cases, the parts may be sewn together with a strong needle and silk, as many single stitches being employed as are necessary for that object, and no more. The needle, well oiled, should be thrust well through the skin, which is about a third of an inch in thickness, and each stitch should be tied into a knot. The stitches may be taken out in about twenty-four hours, by carefully cutting the thread on one side of the knot, and gently pulling the other end.

The dressing is to be left on for several days, unless the wound grow painful and throb; in which case it is to be taken off by the aid of warm water or a soft poultice. If the discharge is inodorous, straw-coloured, and creamy-looking, you may apply the plaster again; if otherwise, the wound must be poulticed till these wholesome signs appear. *A bruised cut* must be poulticed with bread and water to moderate the inflammation, and then with linseed-meal, till new flesh grows instead of that which has been killed by the blow. The latter comes away in appearance like a piece of wetted buff-leather. *Scratches* are often fatal, in consequence of soap, pearl-ash, or filth of any kind getting into them, and should therefore be kept covered. *Pricks* with a thorn, &c. are likewise dangerous, occasionally producing locked jaw. Poulticing, leeching, lotions, &c. must be had recourse to if serious appearances present themselves; with a smart dose of calomel inwardly, and some hours after, castor-oil.

Bruises are often attended with the rupture of small blood-vessels, which bleed internally, and cause discoloration. Put the patient in bed, cover the injured part with a cloth dipped in cold water, or spirit and water, and change the cloth every few minutes. If the bleeding increases rapidly, send off with all possible haste to the surgeon, as life will be risked if the vessel is not tied. Use, if possible, the handkerchief and stick as a tourniquet. In the case of a serious bruise, a dozen leeches may likewise be necessary, but only for an adult, and they may require to be repeated two or three times. With regard to the too frequent bruise technically called 'a black eye,' bathing and patience are the only remedies.

Stabs from sharp or pointed instruments are more dangerous than common wounds. Stop the bleeding by the processes already recommended; do not attempt to bring the edges of the wound together, but rather keep them apart; lay a rag over the wound dipped in cold water, and change it every half-hour. Place the patient at once in bed, and enjoin quiet. Should fainting take place, act as directed under that head.

Scalds—Burns—Frost-bites.

The action on the skin of a hot fluid, as boiling water or melted grease, is called a *scald*; that of a solid body, as red-hot iron, a *burn*. The effects of burns are threefold—either simple redness and pain, blisters, or the total destruction of the parts. For redness, Mr Snoe recommends protection from the air by wet lint or linen covered with oiled silk; or, if oiled silk is not at hand, to cover with several layers of linen, slightly wetted with common water, or Goulard water. The part may also be covered with raw cotton, if it can be procured. If blisters arise, leave them alone, if not very tense; and if they be very tense, puncture with a fine needle, and keep on the lint and oiled silk. Absence of pain over the injured part is a bad sign, and shows that it is destroyed. Apply linen and oiled silk as before, or a bread-and-water poultice. 'The object in treating scalds and burns,' says Mr South, 'is to keep up for a time the great heat or high temperature to which the injured part has been raised by the scalding or burning, and to lower this by degrees to the natural heat of the body. The best and readiest dry materials to be applied are flour, or cotton, or cotton-wadding; the wet are—spirits of turpentine, spirits of wine or good brandy, lime-water and oil, lime-water and milk, milk alone, or bread-and-milk poultice; and all these wet applications must be made of sufficient warmth to feel comfortable to the finger, but not hot.' When the blisters become uneasy, after the lapse of perhaps from thirty to fifty hours (for the pain moderates in a few hours after the accident, unless it has been very severe), they must be carefully cut open and dressed.

When the clothes catch fire, the person should be rolled in the carpet or hearth-rug as quickly as possible, in order to stifle the flames. Firmness and presence of mind are essentially requisite in accidents of this nature; and for want of these, numerous lives are hourly sacrificed. The clothes, if any, over the parts injured should be cut away, but only so far as they will come easily. The patient, if severely injured, must be kept moderately warm; and if he continues to shudder or shiver, a little hot wine and water, or spirits and water, should be administered. If excessive sleepiness or stupor, or difficulty of breathing sets in, or great pain ensues about the stomach, danger exists. The surgeon should be consulted in the case even of the slightest scalds or burns, if large in size; for then, especially in children, there is ground for alarm.

Chilblains and *Frost-bites* are the familiar names given to the effects of excessive cold on the surface of the body. In its action on the skin, extreme cold somewhat resembles burning, producing redness, pain, blisters, or destruction of the parts. In restoring a frozen person, or a frost-bitten part, the object is directly the reverse—that is, to keep the cold, which by its exposure the body has acquired, and to withdraw it by slow degrees till the body has recovered its natural heat. If the person or part be brought suddenly into a hot room, or put in a warm bath, he or it will be killed outright. 'The frozen person,' says Chelius, 'should be brought into a cold room, and after having been undressed, covered up with snow, or with cloths dipped in ice-cold water, or he may be laid in cold water so deeply, that his mouth and nose only are free. When the body is somewhat thawed, there is commonly a sort of icy crust formed around it; the patient must then be removed, and the body washed with cold water mixed with a little wine or brandy: when the limbs lose their stiffness, and the frozen person shows signs of life, he should be carefully dried, and put into a cold bed in a cold room: scents, and remedies which excite sneezing, are to be put to his nose; air is to be carefully blown into the lungs, if natural breathing do not come on; clysters of warm water with camphorated vinegar thrown up; the throat tickled with a feather; and cold water dashed upon the pit of the stomach. He must be brought by degrees into rather warmer air, and mild perspirants, as elder and balm tea (or weak common tea), with Minderer's spirit, warm wine, and the like, may be given to promote gentle perspiration.' Frost-bitten parts should be bathed or rubbed with cold water or snow. A sudden application of heat instantly and irrecoverably destroys the vitality of the parts. For chilblains, employ friction with soap liniment. Various chemicals, such as nitric acid, nitrate of silver, strong sulphuric acid (oil of vitriol), &c. may destroy some parts of the skin. In such cases cover with linen and oiled silk, or bread-and-water poultice, as directed in the case of ordinary burns.

Sprains—Dislocations—Fractures.

Sprains are sudden strainings of the tendons and ligaments, and always require time for their complete recovery. For injuries of this kind warm moist flannels applied to the part, and a bread-and-water poultice on going to bed, are recommended; but this, in our humble and unprofessional opinion, is only adapted to cases in which the patient thinks proper to look forward to weeks of such coddling. We have before now cured ourselves in a few hours of a severe sprain of the ankle-joint, attended with swelling, by fomentations of water as hot as we could bear them.

Dislocations of the joints are common accidents among an active and mechanically-employed population. Severe injuries and sprains are sometimes apt to be mistaken for dislocations; but in the latter case the joint cannot be moved, while its form is manifestly altered. When such an accident occurs, make no attempt at reduction or setting of the joint till the surgeon arrives, or you may make the patient worse. Time is always an important object, as the longer the reduction is delayed, the more difficult is it to be accomplished. A dislocation is reduced by the limb being returned to its place; and the chief difficulty lies in the instinctive or involuntary resistance made by the patient. A great part, therefore, of the operator's dexterity consists in his putting the sufferer off his guard at the critical moment.

Fractures.—People generally themselves know when a bone is fractured, from having felt it snap. There is mostly a distortion of the limb, and upon moving it, the ends of the bone may be felt distinctly to grate. Especial care should be taken not to move the patient roughly, otherwise the ends of the bone may be thrust through the flesh. Procure a door, or a hurdle, and place the patient upon it, and let him be carried carefully, and not in a cart or other carriage. If the patient has to be moved far, it would be a good plan to strap the limb, and apply an apparatus made by rolling a bunch of twigs, the length of the limb, in each end of a piece of thick sheeting tied round, after being applied, by three or four pieces of broad tape. By these means the limb would be kept better in situation. If a surgeon is within an hour's journey, and the day is not cold, it is better to wait and allow him to superintend the moving. In the meantime, if the skin be broken, take means to prevent bleeding; look also to fainting. Broken limbs should not be set—that is, bound up with roller, splints, and pads—for the first three or four days, as for some hours after the accident the part continues swelling, and if bandaged up tightly whilst this is going on, much unnecessary pain is produced; and if the bandages be not slackened, mortification may follow, which I (Dr South) have known to occur. It is best then, at first, only to lay the broken bone in as comfortable a posture as possible, and as nearly as can be in its natural direction; and it may be lightly bound to a single splint, merely for the purpose of keeping it steady. The arm, whether broken above or below the elbow, will lie most comfortably half-bent upon a pillow. The thigh or leg will rest most easily upon the outer side, with the knee bent. In the case of broken ribs, a flannel or linen roller, about six yards long and two hands'-breadth wide, must be wound tightly round the chest. Bleeding should not be had recourse to unless the patient complains of pain, or is troubled with cough. The bowels should be cleared with a purge, and twenty drops of antimonial wine, with a teaspoonful of syrup of poppies in a glass of water, given three or four times a day. After a few days, the person will find himself much more comfortable sitting up than lying in bed. In the special treatment, which must differ according to the parts injured, the patient should in every case be guided by the directions of the practitioner; the less one attempts to doctor himself in cases of this kind the better.

Poisons—Poisoned Wounds, &c.

Poison is the name for that which, when taken into the human body, or applied externally, uniformly effects such a derangement in the animal economy as to produce disease or death. It is usual to divide poisons according to the source from which they are obtained—as mineral, vegetable, and animal; or according to their effects—as irritant, narcotic, or narcotic-acrid. Whatever their nature or effects, those most frequently met with in practice are arsenic, certain salts of lead, oxalic acid, prussic acid, opium, laudanum, nux-vomica, poisonous fish and poisonous vegetables eaten through ignorance. In every case where there exists the least suspicion of poisoning, instantly send for medical aid, and meanwhile excite vomiting either by one of the emetics formerly mentioned, or by tickling the throat with a feather. Most poisons have antidotes or correctives—that is, substances which neutralise or modify their effects. In the case of arsenic, for example, olive-oil, milk, white of egg, or flour and water, should be repeatedly taken, and repeatedly vomited, till the surgeon arrives; in oxalic acid, chalk and water, with emetics, are found to be useful; and in the case of acetate of lead, an active emetic with sulphate of soda, or hydro-sulphuret of potash or ammonia, is likely to prove beneficial. In the case of opium or its extracts, excite to vomiting; dash cold water over the face; administer the strongest coffee after vomiting; make the patient walk between two persons; pull the hair, or otherwise inflict pain to prevent sleep. This treatment must be pursued for many hours. For prussic acid, it is recommended to 'give half a teaspoonful of hartshorn in brandy and water immediately, and repeat every ten minutes till the fourth time. Dash cold water upon the spine and face, to rouse, but not to chill the patient.' In vegetable poisons, emetics, conjoined with exhibition of animal charcoal, are generally adopted.

Under *Poisoned Wounds* may be classed the bites and stings of insects, serpent bites, the bites of mad dogs, or wounds poisoned by the absorption of dead animal matter. For stings, two or three drops of hartshorn are quite effectual; and for the after-irritation of bites or stings, a little spirits and water, or Eau de

Cologne, is said to be efficacious. As to dog-bites, 'not one in ten thousand comes from an animal which is mad. Where any one is bitten by a dog which is unquestionably mad, take a carving fork and break off one prong, and heat the other in the hottest part of a common fire. Apply this thoroughly to the whole of the bite, so as to destroy the surrounding parts. If a surgeon be within half an hour's journey, tie a string tightly immediately above the part, and use all possible despatch to secure his aid. In all suspected cases of madness, keep the dog chained up, for perhaps it may be a false alarm, and the continuance of the dog in health will be a great satisfaction to the party bitten. Wounds which are suspected to be poisoned by absorption should instantly be washed and fomented with warm water, and sucked with a small tube, with a view to remove the poison. When swelling and inflammation ensue, trust everything to the surgeon.'

External Inflammation is characterised by a feeling of heat and pain, redness, swelling, and throbbing, or formation of matter. For the first thirty hours or so use cold applications; after which, hot-water fomentations and poultices are best adapted. When taken in time, inflammation resulting from external injury may in general be subdued before assuming the ultimate stages of suppuration.

Lotions or Washes are employed to lessen the inflammatory condition of a part by diminishing its increased heat, which is one of the signs of inflammation; and they are of two kinds—cooling, and stimulating. The cooling lotion acts by means of evaporation, and should be applied by dipping a single piece of linen in the wash, and laying it upon the part, which of course is to be kept uncovered. As the evaporation goes on, the linen is to be kept moist with the lotion by means of a sponge. A spirit wash is made of half a gill of spirits of wine, or a whole gill of ardent spirits, to a pint of water; and a vinegar wash, by mixing one-fourth of vinegar with three-fourths of water. In case of very severe pain, a tablespoonful of laudanum may be added to a pint of lotion. 'Stimulating washes are employed for encouraging sluggish sores to heal. They are usually applied by dipping lint in them, which, being then put on the sore, is confined with a roller.' Common black wash is the most valuable of this kind, and is composed of a drachm of calomel in half a pint of lime-water.

Liniments are chiefly used to remove swellings, and are applied by rubbing *gently* with the flat of the hand for ten minutes or a quarter of an hour at a time. In the case of a large joint requiring the operation, the two hands are to be used, one at each side, and moved alternately up and down at the same time, making each hand travel half round the joint. One-third of hartshorn to two-thirds of oil make a good liniment for stiff neck and lumbago; another is an ounce of camphor rubbed down in four ounces of olive-oil; and a third, called *opodeldoc*, is composed of three ounces of hard white soap and an ounce of camphor, put into a bottle with half a pint of spirits of wine, or other strong spirit, and as much water, and shaken from day to day till dissolved. But the best is the mustard liniment, made of 'an ounce of fresh flour of mustard put into a bottle with a pint of spirits of turpentine, and shaken daily for two or three days.' After this, the liquid is fit to be decanted for use; and its advantage is, that it may be made to act slightly or severely, according to the length of time it is rubbed; to tickle, prickle, or smart the patient, or take off his skin, whichever he likes.

Fits—Convulsions, &c.

In Fainting, as in all other fits, the face and lips turn pale, the pulse is scarcely to be felt, the senses are lost, or very much diminished, and the power of motion is interfered with or takes place involuntarily. Place the patient flat, and the actions of the system will generally be spontaneously restored in a short time. This is accelerated by the horizontal position, which throws the blood on the brain, and thereby stimulates it to resume its wonted functions. Pungent volatile substances (smelling salts) applied to the nostrils, cold water sprinkled on the face or chest, and the internal administration of gentle stimulants (a little brandy in water) as soon as the patient can swallow, may also be resorted to. If coldness of the extremities continue, apply hot bottles to the feet and legs.

In Apoplexy, which is a sudden deprivation or great diminution of the powers of sense and voluntary motion, the pulse is generally strong; and the patient usually shows symptoms of pain or oppression over the head, which is aggravated when he lies down. Sometimes half the face drops, or half the body becomes powerless. Keep the head well raised; remove the neckcloth; unloose the shirt and all other clothes; and give nothing by the mouth. Send immediately for a surgeon, and if one cannot soon be procured, apply six leeches to the temples, if the pulse be strong.

Under Epilepsy the patient drops momentarily, and often issues a piercing shriek. The epileptic is apt to drop into the fire, under a cart, or other dangerous situation. Usually convulsions occur, especially in the face and limbs. The tongue is often bitten. The pulse is often not much altered. Lay the patient on a bed, with the head slightly raised. Undo neckcloth, unloose the clothes, place a piece of wood between the teeth, to prevent the tongue from being injured. Apply a cloth, dipped in cold water, over the head. The fit generally passes off in a few minutes, though I (Mr Smee) have known it to last for ten or twelve hours. If coldness ensue, apply warm bottles. After the fit, give an emetic if the stomach be gorged.

Hysteria or *Hysterics* appears under such various forms, imitates so many other diseases, and is attended with such a variety of symptoms, that it is difficult to give a just character or definition of it. In general the body is much agitated, and the patient gives way to alternate fits of laughing, crying, and screaming. The pulse is not much altered. 'Place the head over a basin, and pour water from a jug over the head and chest till the patient becomes chilly, and revives. Never use anything but cold water for the hysterical fit, unless the party turn very cold, when you should discontinue it, and apply warmth to the feet.' However dreadful and alarming a hysteric fit may appear, it is seldom accompanied with danger; and the disease never terminates fatally unless it changes into epilepsy, or that the patient is in a very weak reduced state.

Shock is described in Mr Smee's sheet, and recommended to be treated as follows:—A severe accident of any kind, as a bruise, fracture, scald, burn, or a sudden emotion, as that of joy, grief, or rage, or even a sudden attack of a serious disease, prostrates the vital powers. The face and lips turn pale, the pulse becomes scarcely perceptible, the body and extremities turn very cold. Place the patient flat; enjoin absolute quiet; and apply warmth to all parts of the body. Give a small spoonful of brandy and water every two or three minutes, and a few hours afterwards the same quantity of beef-tea. Constant care will alone preserve the patient.

Convulsion Fits, which so frequently carry off children, are usually caused by the constitutional disturbance incidental to their cutting their teeth; and the remedy, or rather the safeguard, against these frightful consequences is trifling, safe, and almost certain, and consists merely in lancing the gum covering the tooth which is making its way through. Lancing the gum is very easily managed; and any intelligent person, after seeing it done once or twice, will do it very effectually. Cline taught a mother of a family to do this; and after lancing her children's gums, she never lost another, at least from that cause; for so soon as the teething symptoms appeared, she looked for the inflamed gum, lanced it, and they ceased. The operation is performed with a gum-fleam, the edge of which must be placed vertically, on the top of the inflamed gum, and moved along, pressing firmly at the same time till the edge of the fleam grate on the tooth, and the business is finished. When the patient is under the fit, the most direct remedy is a warm bath, in which he should be plunged up to the neck.

Intoxication, when carried to excess, produces stupor and insensibility nearly allied to several of the preceding fits. It is recommended 'to place the patient quietly in bed, with the head raised, to loosen the body-clothes, and to keep watch. If the extremities turn cold, warmth may be applied, and as soon as he can swallow, a mustard or ipecacuanha emetic may be administered.' Strong coffee is said to be of service. In many cases nothing will preserve the life of the unfortunate victim except immediate recourse to the stomach-pump.

Choking, by attempting to swallow too large a piece of food, 'may usually be overcome by taking large draughts of water, and making great efforts to swallow. Sometimes, if a bone or pin be near the top of the throat, it may be got out by pushing the finger far down, and hooking it up with the nail. But if below the reach of the finger, the best thing to try for immediate relief is to take some crust of bread, or some hard apple into the mouth, chew it coarsely, get down two or three mouthfuls without swallowing it completely, and then to swallow quickly three or four gulps of water, which acts like a rammer to the bread, and forcing it against the bone or pin, not unfrequently carries it down into the stomach, and there the matter ends.' The buttons and other small matters a child sometimes swallows are rarely attended by any troublesome consequences, although the source of so much alarm to parents.

Suspended Animation.

In cases of apparent or supposed death, there are three things which ought always to engage attention—1*st*, To remove the hurtful cause; 2*d*, To regulate the temperature and circulation; 3*d*, To restore breathing.

In Drowning, which is one of the most frequent causes of suspended animation, the following advice may be of advantage:—Lose no time, but do things orderly and quietly. Avoid all roughness, hurry, and crowding; and observe to regulate the heat and strength of all remedies. Let one intelligent person alone direct, while the necessary assistants implicitly obey. Send for medical aid, and in the meantime act thus:—1. Carry the body carefully with the face upwards, and the head and shoulders a little raised, to the nearest house. If to a distance, especially in summer, previously remove any wet clothes, rub the body dry, and wrap it in a blanket, or the garments of the bystanders. A covering such as a dry coat over even wet clothes will check further chilling from evaporation. 2. The body being removed to a warm room, instantly strip and rub it dry; and then cover it with warm blankets, carpets, or the like. Increase the warmth by hot bottles, sand-bags, bricks, or other substances placed in contact with all parts of the body. A hot bath will also be found of great value. 3. Have several assistants to rub the body with their hands. Clear the mucus from the mouth, hold the nose, and then suck out the foul air with a tube, and blow in fresh air in the same manner. When breathing begins to show itself, assist by gentle compression and friction of the ribs and abdomen; and occasionally apply some pungent scent or other irritant to the nostrils. 4. Nothing should be given inwardly by the mouth, unless the power of swallowing exists; and then only small quantities of warm ginger tea, spiced negus or ale, or weak spirit and water occasionally. 5. Means of recovery should be persisted in for several hours: restoration has been known to follow after eight hours' perseverance. When recovery seems established, rest and quiet should be enjoined; but a strict watch must be kept for some hours, as sinking is apt to happen from subsequent neglect.

In Strangulation or *Hanging*, proceed at once to loose the cord and strip off the clothes. Use the same means to keep up warmth and to restore the circulation and respiration as in cases of drowning, with this addition, that six or eight leeches may be applied to the head with advantage. In cases of this kind, medical aid should always be sent for, as the after-symptoms often require skilful treatment.

For Suffocation from noxious vapours, as carbonic acid or foul air from old wells, coal-pits, brewers' vats, ships' holds, ill-ventilated rooms where stoves are kept burning, and the like, proceed as in drowning. Always remove quickly into the open air; dash a little cold water upon the face, but in such quantities as not to depress the warmth of the body. Where necessary, keep up the heat by bottles, warm blankets, &c.

Sudden Death.—'In every instance,' says Mr Smee, 'where one dies suddenly, without a clear equivalent cause which is irremediable, the heat of the body should be maintained at least twelve hours by hot bottles, and artificial respiration should be attempted as for drowning. Remember that the death may be only apparent, and your care may be repaid by the inexpressible delight of seeing life gradually resumed, and the party restored to his family.' Pulsation is the common test of animation; but when any doubt exists, the ear may be applied to the left side of the chest, where the action of the heart may sometimes be heard, even when the pulse can scarcely be felt.

Medical Power of Nature.

All the appliances, internal and external, which we have above enumerated, are administered upon the faith of *a healing power or principle in nature*, which, for the satisfaction of those who are prone to take a desponding view of the human constitution, we shall now endeavour to illustrate:—

When a man accidentally cuts his finger, or otherwise receives a similar wound in a non-vital part of his body, he does not generally regard it as a matter of serious consequence. He knows that, with a little care, it will heal, and that in a great measure by a power apparently residing in nature herself. This feature of the animal economy is so familiar to us, as to excite little notice; yet it is one of the most wonderful and beneficial of all those arrangements which have been made by a bounteous Creator for our welfare. Without it, the human frame would have been continually liable to destruction; the most insignificant injury would have led to speedy dissolution. A property of such exceeding value is not impressed feebly in the constitution of the person, but is associated with the principle of life itself, and is therefore developed with lesser or greater force through all the stages of existence, and according to the healthfulness of the individual. The property of healing ought to be described as an ever-acting principle in the system—a principle operating to compensate the regular decay of parts, and acting with increased vigour upon emergencies when any injury is sustained. In this latter respect, the healing principle is like a sentinel which is placed on guard over the functions of the body. No sooner does the object of its charge receive damage from an attack, than it flies to the injured part, and sets immediately about effecting a cure. The means which it adopts not only to cure, but to prevent injuries to the person, and expel maladies from the system, may almost be described as something instinct with human reason. Take, for instance, its operations upon a wound or cut. If not prevented by some foul or foreign body, placed or remaining in the wound, it commences by a slight inflammation of both sides of the cut; during the progress of this inflammation, a thin liquid substance, of a glutinous nature, exudes, to form a species of cement. At first the liquid is inorganic, but it in time assumes an organised character, with exceedingly minute blood-vessels interweaved throughout, and communicating with the surrounding vessels. In this manner it gradually puts on the appearance of cellular tissue, and at last, when skinned over, cannot be distinguished from the surrounding parts, unless by the scar which remains when nature is disappointed in effecting a cure in this ready manner, or, as it is called, by the *first intention*, in consequence of the presence of some foreign body in the wound, it goes on more slowly, and on a different plan. It commences by suppurating, or festering, in order to expel the offensive substance; and this being effected, it proceeds to throw up small granulations, or protuberances of a fleshy substance, till by this means—by this growing of matter—the wound is filled up, and healing accomplished. This is called healing by the *second intention*.

Nature is equally ready to act in the case of broken bones. No sooner is the bone broken than the healing principle sets to work to mend it. The chief object to be attained in this case is the repose and close union of the parts. Surgeons, therefore, begin by binding up the broken limb in such a way as to prevent any kind of movement or shifting. Nature is all the time facilitating the same object. It throws out a liquid around the break in the bone, which turns into a cartilaginous substance, and acts the character of a bandage to support the junction. The adhesion of the parts takes place gradually, by the formation of a bony matter, and thus the soundness of the limb is restored. Should the two broken ends of the bone happen not to be placed in juxtaposition, so as to produce adhesion, even in such untoward circumstances nature is not inclined to be baffled. The fractured parts make an effort to push forth a bony connection between the two, and establish a union, at the expense, however, of a slight distortion of the limb.

The vigilance of nature in caring for the comfort of the patient is particularly observable in the case of those who are under the painful necessity of parting with their limbs. The total disjunction of a limb, by sawing through the bone, is a calamity which nature has foreseen may occur, and provision has accordingly been made for its melioration. The bone, after amputation, presents a flat terminating stump, the edge of which is sharp, and calculated to irritate the flesh or muscle drawn over it for protection. It is clear that, in such circumstances, the wound would either never heal, or that the sharp-edged flat stump, in pressing on the muscle, would prevent any use being made of the amputated limb. But see how nicely nature manages this difficulty. Let us suppose it is a leg which is cut off. As soon as the amputation is effected, nature pushes forth a liquid matter, covering the point of the stump; and this gradually increasing in bulk and firmness, at length becomes solid, and rounds off the bone like a ball; wherefore the pressure upon the muscle neither creates irritation nor gives pain.

The intelligence of the healing principle in nature, if such a term may be used, is perhaps still more surprising in cases of internal inflammations and abscesses, or gatherings of purulent matter. It is a remarkable truth in our physical economy, that nature acts upon the principle of expelling disease from the interior to the external surface of the body. Internal inflammation seems to be repugnant to nature, and there is an unceasing effort to eject it. Small-pox, measles, and other similar diseases, are only the external symptoms of bodily inflammations in the course of expulsion. Dr Mackintosh of Edinburgh, whose work on 'Pathology and Practice of Medicine' is well known in the medical world, states 'that every instance of cutaneous affection, whether attended by fever or not, depends on derangement of the functions of some internal organ—sometimes of the brain, or stomach and bowels, at others of the liver, or mucous membrane of the lungs,' &c. He considers all the eruptions, even erysipelas, in the light of natural blisters, established by powers inherent in the constitution, which enable it to translate disease from the internal organs to the skin; and he has no doubt that the frequent observance of these circumstances first led the ancients to blister and make extensive external sores, by means of the application of red-hot iron, in cases of dangerous internal diseases. The eruptions which take place on children in cases of teething and other complaints—such as sores behind the ears, and so forth—are just so many demonstrations of the desire which animates nature to bring disease to the surface; and, as such, ought to be very cautiously dealt with. The effort to expel is not less energetic in the case of local inflammations. A portion of the viscera, not connected with the outer frame of the body, receives an injury or becomes diseased; it inflames, and there is a danger of the inflammation leading to morbid symptoms and death. Nature, however, making a bold push, endeavours to create a connection betwixt the inflamed part and the framework of the body; and this it sometimes actually effects. A junction takes place, and thus a channel is formed for the expulsion of the disease. Inflammations of the liver have been known to be carried off in this manner. When inflammation takes place in a part having already a tolerably direct connection with the surface, the difficulty of expulsion is of course not so great, and the cure is more certain. Natural abscesses, or accumulations of matter, may likewise be considered the result of efforts to expel disease from some internal part of the system, and it is fortunate for the patient in such cases that the constitution possesses strength to cast forth the malady.

In speaking of abscesses, we are put in remembrance of a provision in nature particularly worthy of notice. When the foul matter which is to compose the material of the abscess begins to form, choosing a certain situation for that purpose betwixt the skin and the muscle, nature is on the watch to prevent the possibility of the purulent matter insinuating itself extensively among the adjacent cellular tissue, and thereby doing irreparable mischief. To avert this contingency, it sends out beforehand a thin glutinous liquid, which forms a sac or bag, into which the matter of the abscess is secreted. This thin membranous sac remains in use as long as the abscess exists; but no sooner is the matter evacuated, and nature has effected her purpose in establishing the drain, than it begins to discharge a watery fluid, and the sides of the sac finally come to adhere. Occasionally, when the abscess has been deep or long-seated, nature has a difficulty in freeing itself in this manner; a sinus or cavity remains, secreting a thin serous humour, which may be pressed daily from the orifice; and this dull tedious process of secretion sometimes continues such a length of time, that art is required to step in to relieve the patient—the surgeon ripping up the surface with his appropriate instrument, and exposing the whole of the interior of the sac, by which granulation and healing, by the second intention, are allowed to restore soundness and healthiness to the parts so affected.

A physician once mentioned to us a striking instance of the wonderful efforts which nature makes to preserve life, or, as it may be called, the continued action of the animal mechanism. It was a case of complaint in the bowels, wherein one intestine was projected or drawn so completely into another, that there was an effectual stoppage of all communication. The agonizing death which ere long would have ensued to the patient, was fortunately averted by an extraordinary natural provision. The intestine above the point of obstruction formed a junction with that placed below it, and, by means of inflammation and ulceration, an opening was formed from the one into the other, through which artificial channel the ordinary motion in the bowels was carried on!

Admirable as these provisions in nature are which we have been contemplating, it ought not to pass unnoticed, that we have no right to expect the performance of such kind operations in our systems, unless we afford nature a fair field for exertion. The more sound that our constitutions are from exercise and temperance, the more shall we be benefited by the natural principle of healing; and if, by our own folly or intemperance, or by the folly or intemperance of our progenitors, we be afflicted by constitutional weakness, we must not, in such a case, be surprised to find that outraged nature is unable to lend a helping hand in the hour of need, and allows us to sink, the victims of moral delinquency, into a premature grave.

CLOTHING—COSTUME.

WHETHER inhabiting a tropical, temperate, or arctic region—existing in abject barbarism, or enjoying the highest degree of civilisation and refinement, man is essentially a clothing animal. Some kind or other of covering or decorative appendage he always affects, being instigated to this necessity by motives of defence, shelter, decorum, or vanity. From the simple head-dress and loin-cloth of the South Sea islander, to the elaborate costume of the gay Parisian, the ruling principle is much the same; more rational, perhaps, in the case of the savage than in that of the individual laying claim to superior enlightenment. In obeying this clothing instinct or necessity, attention is always paid not only to the kind and quality of the covering, but to the form and manner in which any particular article of dress shall be worn. Thus originates the distinction between clothing and costume—the one having reference to the fitness of the material for the purposes of shelter or protection, the other having reference to taste or a sense of the becoming, though often marred by the absurdities of vanity and caprice.

CLOTHING.

Admitting the above distinction, and laying aside consideration of all dress or armour of a defensive kind, clothing must be regarded simply in the light of a protection from the extremes of heat and cold, so that the body may perform its functions healthfully and without obstruction. For this purpose a warm climate requires a light and loose covering, a cold climate one of a heavier and denser texture. Such a difference, indeed, is in some degree indicated by the supplies of nature; the tropics yielding the light and flocculent down of the cotton, while higher and colder latitudes furnish abundance of hair, wool, and fur. Other adaptations are rendered imperative, according to the activity or inactivity of a population, the amount and nature of their food, and the kind of dwellings they inhabit—all these modifying less or more the normal or natural amount of heat which seems indispensable to healthy existence. 'The usual temperature of the body,' says a recent authority, 'is about 97°, and its warmth is derived from the decomposition of a certain portion of the food in combination with the air taken in by respiration, which is necessary to supply the continual loss of heat to which we are liable. Clothing checks or prevents in some degree this loss; and it follows of course that the materials which are the best non-conductors form the warmest clothing. But there are several other circumstances to be taken into account in making choice of the materials most suitable for this purpose. The skin, by its structure, performs the functions of regulating the temperature; by perspiration through its pores the excess of heat is carried off; and hence, when this function is deranged, and the insensible perspiration obstructed, fever is the consequence. In addition to this use, the pores of the skin serve as an outlet for getting rid of matters no longer necessary in the animal economy, and which, if retained, would prove injurious. Besides this *excretory* function, the skin has likewise an *absorbing* power, by which it takes up matters in contact with it; and we may also observe that it is abundantly supplied with minute nerves, which are the source of feeling, and which demand a certain degree of warmth to preserve their vital action. From these facts, it is easy to deduce that clothing should be of such a nature as not to impede the necessary escape of perspirable matter, but to suffer it to pass through its texture; that it should be of such a non-conducting quality as to confine the heat generated by the blood sufficiently to preserve the activity of the nervous system; and that, by its lightness, softness, and pliancy, it should permit the free motion of the limbs.' Clothing which would subserve all these purposes, and which, moreover, would absorb or reflect the solar or external heat as required, would be nearly perfect in its hygienic properties; and such an attire we could readily assume, were it not that considerations of economy, special avocations, and the like, are always interfering less or more to disturb the equilibrium. With these preliminary remarks, and referring the reader for further information on the general hygiene of dress to the article PRESERVATION OF HEALTH, we shall now consider the peculiar characteristics of British clothing, as manifested in the various fabrics prepared, as detailed under TEXTILE MANUFACTURES, from wool, cotton, linen, silk, fur, and leather.

Quality of Clothing.

Woollen fabrics, as articles of clothing, have several advantages over other materials. They are bad conductors of heat; hence their warmth by preventing the heat of the body from escaping, and their utility in preserving the equability of its temperature, though exposed to sudden changes. From their filamentous texture and elasticity they are light and pliable; and yet, from their peculiar property of being *felted*, they can be prepared to any degree of weight and thickness. They possess also the property of not being easily wetted, the while they are sufficiently porous either to absorb or to permit the escape of all cutaneous exhalations. Further, when worn next the skin, their rough and uneven surface produces in every motion of the body a gentle friction, which greatly assists and promotes the functions of the minute cutaneous vessels and nerves. 'In a climate like ours, which is so variable, and usually so cold, the article of dress that is worn next the skin ought always,' says Dr Robertson of Buxton, 'to be a bad conductor of heat at all events. In general, flannel of an adjusted degree of thickness and fineness answers this intention sufficiently well, without proving to be too heating, or irritating, or relaxing. In summer time, if the flannel which proved to be well borne in the colder seasons of the year, should be so far irritating and heating as to relax or fever the system, this may be remedied by substituting for it a thinner and finer quality of flannel; or in extreme cases of this kind, an under-garment of calico, of a proper degree of thickness, may be substituted for the flannel at that season of the year. Many prefer wearing chamois leather as the under-garment, because it does not irritate the skin so much as flannel. Leather is chiefly objectionable from its not affording, however well dressed, so ready a passage to the insensible perspiration as flannel or calico. I think that thin and very fine flannel may generally be well borne, and must be always greatly preferable; or that this, lined with calico, or even calico alone, is usually much better than the use of leather for this purpose.'

But strongly as the importance of having a bad conductor of heat next the skin should be impressed on the mind, there is a point connected with it which is almost as important. The inner garment, especially if made of flannel, ought not to be worn during night. It ought invariably to be taken off at night, and as invariably resumed in the morning. In bed it is unnecessary: it is worse than unnecessary, for it does harm: it then stimulates the skin, and produces a preternatural waste of the secretions, and corresponding debility of system—a corresponding liability to suffer from the depressing influence of cold—a corresponding incapability of resisting its influence. But, further, removing this garment during the night relieves it from the scurf, some degree of dampness, and other impurities which it must acquire during a day's wear, and so renders it fresh and more agreeable to the sensations of the wearer. Not wearing it at night renders it more effectual in protecting the surface from the cold by day, on the principle that a greatcoat is not of the same service to the wearer when out of doors, if he is in the habit of wearing it in the house. It would be easy to adduce strong evidence in behalf of the value and importance of wearing flannel next the skin. 'Sir John Pringle,' says Dr Hodgkin, 'who accompanied our army into the north at the time of the Rebellion, relates that the health of the soldiers was greatly promoted by their wearing flannel waistcoats, with which they had been supplied on their march by some Society of Friends;' and Sir George Ballingall, in his lectures on military surgery, adduces the testimony of Sir James Macgrigor to the statement that, in the Peninsula, the best-clothed regiments were generally the most healthy; adding that, when in India, he witnessed a remarkable proof of the usefulness of flannel in checking the progress of the most aggravated form of dysentery in the second battalion of the Royals. Captain Murray told Dr Combe that he was so strongly impressed, from former experience, with a sense of the efficacy of the protection afforded by the constant use of flannel next the skin, that when, on his arrival in England, in December 1823, after two years' service amid the icebergs on the coast of Labrador, the ship was ordered to sail immediately for the West Indies, he ordered the purser to draw two extra flannel shirts and pairs of drawers for each man, and instituted a regular daily inspection to see that they were worn. These precautions were followed by the happiest results. He proceeded to his station with a crew of 150 men; visited almost every island in the West Indies, and many of the ports of the Gulf of Mexico; and notwithstanding the sudden transition from extreme climates, returned to England without the loss of a single man, or having any sick on board on his arrival. It would be going too far to ascribe this excellent state of health solely to the use of flannel; but there can be little doubt that the latter was an important element in Captain Murray's success.'

There can be no doubt that flannel is by much the best article for being worn next the skin when the body has to be exposed to such a temperature, or to such a severe degree of exercise, as increases the perspiration in a material degree. It retains a warm and dry atmosphere next to the body, while, from its porous and fibrous character, it carries off the moisture to the external surface of the flannel. This is well seen when horses are stabled in a state of heat and perspiration after a journey, and covered with the usual clothing. Very soon it will be found that the outside of the woollen clothing is quite wet, and often studded with drops of moisture, whereas the skin of the horse and the inside of the clothing are perfectly dry. The common practice among the workmen in potteries, foundries, collieries, &c. of wearing thick flannel shirts, tends much to preserve their health, under the circumstance of the profuse perspiration caused by the excessive labour they are called upon to undergo, or the extreme heat of their places of work, alternated as this must be with the much colder atmosphere out of doors, amounting, it may be, to a difference of temperature of no less than 60° or 70°. Dr Kilgour, in his Lectures on Therapeutics and Hygiene, says 'that the use of flannel was found to be beneficial in the prevention of cholera, by maintaining the equilibrium of the temperature and the functions of the skin, and thereby preventing that derangement of the bowels which is so general a consequence of cold applied to the surface.' To the preceding excellent testimony, we may add that woollen fabrics, from their ready elasticity, are less liable than any other species of clothing to interfere with the circulation of the vital fluids, or prevent the free and easy motion of the body. When made to fit the person, and not too closely felted, they are exceedingly pliable, yielding to every turn and expansion, and never producing any painful or dangerous constriction. Further, as they are slow conductors of heat from the body, so are they also bad conductors of heat from any external source; and thus subserve the double purpose of preserving natural heat where it exists, and of warding off excessive solar heat where is would be injurious.

Cotton, though greatly inferior, ranks next to wool in non-conducting properties. From its comparative cheapness, lightness, and the facility with which it can be cleaned, it has of late years been gradually superseding the use of flannel as an underclothing. But, though recommending itself for these reasons, it can by no means be considered as a perfect substitute for flannel, whether used in a pure state or when mixed with a certain proportion of wool. Its ultimate fibre is altogether different; being void of that springy softness and elasticity so peculiar to wool, and incapable, moreover, of being felted to any thickness without becoming hard, heavy, and obstructive. Further, it is far from being so absorbent, is more readily wetted, and requires therefore to be more frequently changed and submitted to the laundress. Nevertheless it is a valuable staple of dress, and is in general use both as under and exterior clothing from the tropics, of which it is a native produce, to the limits of the polar circle.

We have said that cotton is inferior in its non-conducting properties to wool; that is, all things being equal, cotton fabrics form a cooler dress than those of woollen. These remarks apply to our own climate; let us hear the opinion of the authority already quoted in reference to the requirements of tropical regions:—'Cotton, from its slowness as a conductor of heat, is admirably adapted for the tropics. It must be recollected that the temperature of the atmosphere, in the open air, in the hot season, exceeds that of the blood by many degrees; and even in the shade it too often equals, or rises above, the heat of the body's surface. Here, then, we have a covering which is *cooler* than linen; inasmuch as it conducts more slowly the *excess* of external heat *to* our bodies. But this is not the only advantage, though a great one. When a *vicissitude* takes place, and the atmospherical temperature sinks suddenly far below that of the body, the cotton, still faithful to its trust, abstracts more slowly the heat *from* our bodies, and thus preserves a more steady equilibrium there. To all these must be added the comparative facility with which it absorbs the perspiration; while linen would feel quite wet, and, during the exposure to a breeze under such circumstances, would often occasion a shiver, and be followed by dangerous consequences. That woollen and cotton should be *warmer* than linen in low temperatures will be readily granted; but that they should be *cooler* in high temperatures will probably be much doubted. If the following easy experiment be tried, the result will decide the point in question:—Let two beds be placed in the same room at Madras, we shall say when the thermometer stands at 90°, and let one be covered with a pair of blankets, the other with a pair of linen sheets, during the day. On removing both covers in the evening, the bed on which were placed the blankets will be found *cool* and pleasant, the other uncomfortably warm. The reason is obvious. The linen readily transmitted the heat of the atmosphere to all parts of the subjacent bed; the woollen, on the contrary, as a non-conductor, prevented the bed from acquiring the atmospherical range of temperature; simply by obstructing the transmission of heat from without. This experiment not only proves the position, but furnishes us with a grateful and salutary luxury, free of trouble or expense. The musical ladies of India are not unacquainted with this secret, since they take care to keep their pianofortes well covered with *blankets* in the *hot season* to defend them from the heat, and prevent their warping.

From this view of the subject, *flannel* might be supposed superior to *cotton*; and indeed at certain seasons, in particular places—for instance, Ceylon, Bombay, and Canton—where the mercury often takes a wider range in a very short space of time, the *former* is a safer covering than the latter, and is adopted by many experienced and seasoned Europeans. 'But in general the use of flannel in the tropics is inconvenient for three reasons:—1. It is too heavy; an insuperable objection: 2. When the temperature of the atmosphere ranges pretty steadily a little below that of the skin, the flannel is much too *slow* a conductor of heat *from* the body: 3. The spiculæ of flannel prove too irritating, and *increase* the action of the perspiratory vessels on the surface, when our great object is to *moderate* that process. From the second and third objections, indeed, even cotton or calico is not quite free, unless of a fine fabric, when its good qualities far counterbalance any inconvenience in the above respects. In some of the upper provinces of Bengal, when the summer is intensely hot and the winter sharp, the dress of the native shepherds, who are exposed to all weathers, consists in a blanket, gathered in at one end, which goes over the head, the rest hanging down on all sides like a cloak. This answers the triple purpose of a *chattah* in summer to *keep out* the heat, of a tent in the rainy season to throw off the wet, and of a coat in the winter to defend the body from the piercing cold.' To this may be added, that no tropical head-dress can compete in point of comfort and safety with the loose, light-coloured turban of calico.

Linen, though inferior both to cotton and wool as a non-conductor of heat, and absorbent of moisture, is now extensively used as an article of inner clothing. In this capacity it has been of essential service to personal cleanliness, rendering the bath less necessary in modern Europe than in any other region of the globe. It is comparatively cheap, is easily kept clean, and its snowy whiteness enables us at once to detect when it is soiled or unfit for wear. It has been said by some one in jest, that 'a change of linen is a luxury;' and really so it is when well washed, bleached, and dried under the open air. There is a freshness and positive feeling of comfort about it not to be found in any other fabric however costly or fine. On the other hand, it must be confessed that linen has many disadvantages as an article of inner-clothing. Being denser in the fibre than cotton, and much more so than wool, it forms a good conductor of heat, and thus rapidly robs the skin of its free caloric; hence the cold feeling experienced when linen is just put on. But though rapidly conducting the heat, it does not readily absorb the insensible perspiration, and thus soon becomes saturated, leaving the pores of the skin clogged and obstructed unless the garment be frequently changed. Having little elasticity of fibre, it forms a smooth and dense fabric, totally void of that stimulating function often so much valued in flannel. From the experiments of Count Rumford, it appears that linen does not attract dampness so readily as wool, hair, or other animal substances; nevertheless, when it is damp, it is more prejudicial than these, and therefore requires to be well dried and aired before being worn.

Silk, as a non-conductor of heat, ranks next to cotton: but its qualities in this respect depend in a great measure upon the kind of fabric into which it is woven. Generally speaking, silken fabrics are light and thin; articles of luxury and ornament rather than of every-day utility. Nevertheless silk possesses several valuable hygienic properties, of which the most curious and least understood is that appertaining to its electric qualities. We have stated under another head (No. 17, p. 272), that on the whole the state of the body when healthy and vigorous is *positive*, or that a surplus of positive electricity tends always to appear on the surface, from the actions of the vital organs; but that, after severe labour, hard exercise, and exhaustion, the state of the free electricity generally changes to *negative*. It was further observed, that when the actions of electricity on the animal system are better understood, it may be possible to use artificial methods of maintaining, under all circumstances, the charge that is identical with health and activity; we have acquired by means of our houses, clothing, and fires, an almost perfect command of the element of heat; and it is to be hoped that we may some day attain an equal command over the element of electricity, and keep at a distance the deleterious negative charge as effectually as we defy the winter cold. On this important subject, so far as the influence of silk—which is an excellent non-conductor of electricity—is concerned, Drs Robertson and Carpenter have the following interesting remarks, which we transcribe at length:—

'However little or unsatisfactory our knowledge of the operations of this remarkable agent in the animal economy, there is no doubt that electricity fulfils important and necessary purposes in the living system, and that a certain amount of positive or negative electricity is being constantly given off from the surface of the body, in greater or less degree, according to sex, temperament, weather, the nature of the clothing, &c. It has been said that the skin and most of the internal membranes are in opposite electrical conditions; and according to a theory of Dr Wollaston, the existence of free acid in the urine and gastric juice marks the prevalence of positive electricity in the kidneys and the stomach; whereas the existence of free alkali in the bile and the saliva indicates an excess of negative electricity in the liver and the salivary glands. Whether this view be tenable or not, it seems that the living body is never in a state of perfect electrical equilibrium with the substances or bodies around it, unless it be maintained by free contact with them; and it is stated, in illustration of this, that if two persons, both insulated, join hands, sufficient electricity is developed to influence the electrometer. Some electric disturbance is manifested by almost every individual, if it be carefully sought for. In men, it is most frequently positive; and irritable men, of sanguine temperament, have more free electricity than those of phlegmatic character; whilst the electricity of women is more frequently negative than that of men. Some individuals exhibit these phenomena much more frequently and powerfully than others. There are persons, for instance, who scarcely ever pull off articles of dress which have been worn next the skin without sparks and a crackling noise being produced, especially in dry weather; this may, however, be partly due to the friction of these materials on the surface, and with each other, as it has been proved to be greatly influenced by their nature. The most remarkable case of the generation of electricity in the human subject at present on record, is one that has been met with in America (American Journal of Medical Science, January 1838). The subject of it, a lady, was for many months in an electric state so different from that of the surrounding bodies, that whenever she was but slightly insulated by a carpet, or other feebly-conducting medium, sparks passed between her person and any object which she approached. From the pain which accompanied the passage of the sparks, her condition was a source of much discomfort to her; when most favourably circumstanced, four sparks per minute would pass from her finger to the brass ball of the stove, at the distance of one and a-half inch. The circumstances which appeared most favourable to the generation of electricity, were an atmosphere of about 80°, tranquillity of mind, and social enjoyment; while a low temperature and depressing emotions diminished it in a corresponding degree. The phenomenon was first noticed during the occurrence of an aurora borealis; and though its first appearance was sudden, its departure was gradual. Various experiments were made, with the view of ascertaining if the electricity was generated by the friction of the articles of dress; but no change in these seemed to modify its intensity. It was no doubt generated, or the electrical equilibrium was disturbed in an undue and very extraordinary degree, by the condition of the nervous system, probably influenced by some deranged condition of certain of the organic functions. It seems to have been proved that electrical manifestations are the invariable consequence of the action of the nerves in producing muscular action; and it is probable that this powerful agency of electricity exercises an important influence on the digestive processes, and perhaps especially in facilitating the decomposition of the food, and so far preparing it to enter into new combinations for the nutrition of the body. But however this may be, and however large, or little important, the influence of electricity may be in carrying on the vital and organic processes of the system, there is no doubt that a certain amount of electrical matter is constantly being given off from the surface of the living body; that the amount of this varies according to the dryness or dampness, the coldness or warmth, of the atmosphere; and that the degree to which it is permitted to escape may be influenced by the nature of the clothes, and particularly according to the nature of the fabric which is worn next the skin; and that the escape of this electricity is so far attended with diminished power and energy of the general economy, and in the same degree to which such escape may be prevented, is the system maintained in a state of more vigorous vitality. The depressing influence of wet and cold weather may be largely referred to the effect of such an atmosphere in carrying off rapidly the free electricity of the system; and the colder and more damp the climate man lives in, the more important is it that he surround the body with such articles of clothing as will check, as far as may be, the escape of this extraordinary agent; and the greater the habitual depression and debility of the economy, the less the degree of its vital energy, the more important does this consideration become.

Silk, as a remarkable non-conductor of electricity, deserves to be made use of more generally than it is in this country, as an article of under-clothing. For this purpose it should be woven entirely of what is called *bright* or *wrought* silk, in contradistinction to what is called *spun* or *spurious* silk; and the under-garment is to be manufactured in a similar way, and of a similar material, to stockings; but woven with much thicker thread into a very thick and heavy fabric.'

Furs and *down* are by far the warmest materials, but in Britain they can scarcely be considered as articles of general clothing. Soft, light, elastic, they constitute excellent adjuncts during the winter months, while their fine colours and markings add greatly to their appearance. When worn, as furs usually are, with the skin attached, they are rather impermeable to exhalations, and are not in this light to be considered as equal to the finer fabrics woven or knitted from wool. *Leather*, unless peculiarly prepared (as chamois), is by no means fit to be worn as an inner garment; in fact, the common application of this material is for boots and shoes, for which it is admirably suited by its strength and durability. Unless made somewhat easy, so as to allow room for a worsted sock or stocking and a certain amount of air, leathern boots form but a cold covering, at the same time that they are all but impermeable to any kind of exhalation. When well manufactured, leather should be soft and pliable; and when fashioned into shoes, these should be rather large and easy. There is, in general, no member of the body more sinned against—the chests of stay-wearing ladies scarcely excepted—than the foot; and the certain penalty is corns, callosities, and deformities, an unspeakable amount of pain, and in the long-run, a partial destruction of the powers and functions of one of the most essential of the bodily organs. The feet, with proper treatment, ought to be as free from disease and pain as the hands; their structure and adaptation to the wants and comforts of man being naturally perfect. 'Thirty-six bones and thirty-six joints,' says a writer on the foot, 'have been given by the Creator to form one of these members, and yet man cramps, cabins, and confines this beautiful arrangement of one hundred and forty-four bones and joints—together with muscles, elastic cartilage, lubricating oily fluid, veins, and arteries—into a pair of boots or shoes, which, instead of forming a protection, produces the most painful and permanent injuries.' These objections as to room cannot be urged with the same force against the numerous *elastic fabrics* now coming into use, as these, to a certain degree, expand and contract according to the requirements of the foot; but then there is this objection—all of them are impermeable to perspiration. The foot while heated perspires, the moisture is not allowed to exhale, and on resuming a state of rest, cold and damp is the result. This objection, indeed, is fatal to all the elastic *waterproof fabrics* now so much in vogue: the insensible perspiration must be absorbed or exhaled, and if not, discomfort and disease are the inevitable consequences. Numerous ingenious attempts have been made to remedy these defects, so as to retain the other valuable properties of elastic and waterproof clothing; but as yet we have seen none completely successful; and for our own parts, we would rather undergo a drenching which can be laid aside with the garment which sustains it, than sit for hours enveloped in effete and offensive exhalations.

Amount of Clothing.

The amount of clothing should be regulated as much as possible in reference to the climate under which we live, the season of the year, the degree of exposure to which we are subjected, the exercise or fatigue we undergo, the food consumed, age, sex, and other constitutional peculiarities. Thus other things being equal, a cold climate requires a heavier and thicker dress than a warm one: in winter we could not wear a light summer dress with impunity; a man undergoing healthful exercise in the open air needs less muffling up than a sedentary dweller within doors; the individual enjoying a full invigorating diet feels comfortable in garments under which an ill-fed man would shiver; and, generally speaking, the young and vigorous require less clothing than the aged and infirm. Regarding the first of these circumstances as axiomatic, let us consider the others in detail:—

1. Although it is proper to adapt the warmth of our clothing to the season of the year, yet change in this respect must be made with caution. The animal constitution is no doubt endowed with considerable plasticity; but that plasticity must be operated upon by insensible gradations. 'Very light clothing during the summer months,' says an able writer on domestic economy, 'exposes the body to the effects of those sudden changes of weather which we experience in our climate. It is safer to wear the same clothing nearly all the year than to make frequent and sudden changes; exercise under too warm a dress occasions violent perspiration, the effects of which are often dangerous. It is remarkable that in some countries custom differs materially from ours respecting clothing. We dress in general somewhat warmer when we go out than when we sit in-doors; the Turks, who seldom have fires in their apartments, keep themselves comfortable within doors by using warmer clothing than when they go out, considering the practice of moving about a source of heat, which it really is: the Chinese of rank, it is said, practise the same mode—putting on an additional garment in the house, which they throw off as the sun ascends to the meridian, and resuming it in the cold of the evening.' 2. As to exercise, there can be no doubt that it is a source of heat: respiration goes on more briskly, the carbon of our food and blood is more rapidly consumed, a greater degree of heat is experienced, and this continues so long as the body is in a healthful vigorous condition. To overload one's self with dress during exercise is but to irritate and fatigue; as the same time care is required on relapsing into a state of rest, that the exhausted frame be properly protected. During exhaustion every function goes on less briskly, little heat is supplied by respiration, and that little requires to be carefully retained. 3. The same remarks are applicable to the case of food. A well-fed man, as explained in No. 46,

has a source of heat within him; and if the doctrines of Liebig and others be correct, food may be said to supplement clothing, and clothing food. If we lose heat through lack of clothing, the food must supply it; and *vice versâ*. 4. The young and vigorous, other things being equal, require less clothing than the old and infirm. While the respiration and circulation of the system is vigorous, and the diet wholesome and full, every function is performed with activity; heat is freely formed; and the exercise generally taken by the young greatly augments the supply. But the young and vigorous must not neglect the ordinary rules of clothing on this account—a neglect they are but too apt to perpetrate, and which, in the case of infancy, is too often perpetrated against them by ignorant nurses, and equally ignorant and foolish mammas. 'Are the little "Highlanders,"' asks Dr Erasmus Wilson, 'whom we meet during three out of the four quarters of the year under the guardianship of their nurserymaids, dawdling about the streets in our public walks or squares, properly protected from the cold? Are the fantastically-attired children whom we see "taking an airing" in carriages in our parks, sufficiently and properly clad? If these questions can be truly answered in the affirmative, then, and then only, my remarks are needless. There can enter into the parent mind no more baneful idea than that of rendering children "hardy" by exposing them unnecessarily to cold, and by clothing them inefficiently. I have known instances wherein parents, acting on this principle, have failed entirely in rearing their offspring. Does nature treat her progeny thus? Does she not, first of all, insure the birth of her young only at a kindly season, and then provide them with downy coverings, warm nests, and assiduous protectors? And we must imitate nature, if we would give to Britain a race capable and worthy of maintaining her independence and honour. The little denizens of a warm nursery must not be subjected, without a carefully-assorted covering, to the piercing and relentless east or north-east wind; they must not be permitted to imbibe the seeds of that dreadful scourge of this climate—consumption—in their walks for exercise and health; they must be tended, as the future lords of the earth, with jealous care and judicious zeal. *One-sixth of the deaths of young children*, it must be remembered, *result from cold*.' 'The large mortality,' says another medical authority, 'among the children of the poor, is to be referred to an undue exposure of their feebly-acting and sensitive surfaces to the influence of the cold.' It by no means follows, however, from what has been said, that the systems of the young are to be overheated, relaxed, and enfeebled by an excessive amount of clothing; an amount disproportioned to the requirements of health and growth.

As to special articles of dress, and the clothing of special parts of the body, there is often injudicious management, partly from mistaken physiological notions, and partly from caprice and fashion. Thus there is nothing more common than to dress heavily when we go out of doors, and put on some thin flimsy covering within doors; to clothe well during one portion of the day, and be in loose, open, undress during another; to wear strong boots or shoes when we take open air exercise, and immediately thereafter to be sedentary and in slippers. Such sudden changes are contrary to all reason, and cannot fail to be prejudicial to sound health and comfort. The human body is not a piece of mechanism, which can be wound up and adjusted at pleasure; and far less is it to be tampered with in direct opposition to the natural laws under which it is constituted. What more preposterous than to dress heavily when under the warming influence of exercise, and to dress loosely and lightly when sedentary, and when all the functions of circulation and respiration are languid and slow! Another error, very common in this country, is the inordinate wrapping of the neck and shoulders with kerchiefs, shawls, and furs. To behold men and women, old and young, all be-muffled and be-boa'd, no matter what the day or what the occasion, a stranger would be apt to imagine the country labouring under one huge epidemic; and yet the truth might be some absurdity of fashion—some monkey imitation of A by B, C, D, and all the other letters of the alphabet. 'Unless when much or unusually exposed to the influence of cold,' says a high medical authority, 'the risk of local relaxation from this practice, and of an unadvisable degree of chill when such extra clothing is removed, deserve consideration, and may lead to greater evils than such extra wrapping is calculated to obviate. It is only justifiable under circumstances of extreme and long-continued exposure to cold, or in the instance of very delicate and susceptible systems.'

Another instance in which very irrational and often fatal errors are committed, is the due protection of the feet. 'Of all parts of the body,' says the same authority, 'there is not one the clothing of which ought to be so carefully attended to as the feet. The most dependent part of the system, this is the part in which the circulation of the blood may be the most readily checked; the part most exposed to cold and wet, or to direct contact with good conducting surfaces, it is the part of the system where such a check is most likely to take place. Coldness of the feet is a very common attendant on a disordered state of the stomach; and yet disordered stomach is not more apt to produce coldness of feet, than coldness of feet is apt to produce disorder of the stomach; and this remark does not apply only to cases of indigestion, but to many other disorders to which man is liable. Yet do we see the feet of the young and delicate clad in thin-soled shoes and as thin stockings; no matter whether the weather is dry or damp, or whether the temperature of the atmosphere is warm or cold. But this is not the whole of the evil. These same feet are frequently, at different times of the day, differently covered as to stoutness of the shoes and their soles, and very often likewise as to the thickness of the stockings. . . . I am sufficient of a Goth to wish to see thin-soled shoes altogether disused as articles of dress; and I would have them replaced by shoes having a moderate thickness of sole, with a thin layer of cork or felt placed within the shoe, over the sole, or next to the foot. Cork is a very bad conductor of heat, and is therefore to be preferred. Its extreme lightness, the remarkable thinness to which it may be cut, its usefulness as a non-conductor not being greatly impaired thereby, and the inappreciable effect it has on the appearance of the shoe, all seem to recommend its use for this purpose in the strongest manner.'

Among the special instances of error as to the amount of clothing, the writer just quoted places pre-eminently that of bedclothes. In Britain, where a great variety of material is used, such as feathers, down, hair, woollen blankets, cotton counterpanes, and linen sheets, this subject is deserving of more attention than it generally receives; and all the more, seeing that while in bed the skin usually throws off much more of its secretions than at other times. What is required is a mere sufficiency to keep the surface warm; everything beyond this is exhausting and detrimental. What is sought for in bed is rest, quietude, and a total avoidance of all excitement; and this most certainly cannot be obtained when half-smothered, heated, and irritated by an undue amount of warm clothing. 'A free and sufficient use of exercise, and particularly walking exercise; a regular exposure to the open air; a daily change of air, as far as may be practicable—walking as far away from home as strength, and time, and weather allow, instead of confining the exercise to a circle near the house; and a regulated diet, are the great means, next to sufficiently frequent ablutions, of keeping the vessels of the skin in a state of efficient activity, and preserving or restoring the natural temperature of the surface. And this point having been gained, very few and light bedclothes are all that will be required: the system, having been sufficiently exhausted of its vital energies by the day's work, will need no bed of down to lull or soothe it to repose; and a hair mattress, a sheet, a blanket, and a counterpane, will generally suffice to defend the body from the ruder approaches of the cold air, even during sleep, and in the coldest of our country nights.'

Colour of Clothing.

It has been already stated that different bodies part differently with their heat, by *conduction* and by *radiation*. Thus a bit of stick can be held in the hand with impunity till burned almost to the fingers, while a rod of iron must be dropped long before it has become red-hot. A well-polished silver teapot will retain water for a long while almost at the boiling-point; while in one of rough earthenware, the water will quickly lose its heat by radiation to the external air. Not only do substances part with their heat in this way, but they radiate with different degrees of quickness according to the colour of the surface—according to the ray or rays of light which the surface of the heated substance reflects. Of all colours, *black* reflects least, and absorbs more of the heat that strikes upon it than any other colour, which warmth it communicates to the body; but, on the other hand, it radiates more than any other colour, and of course gives out more of the heat which it receives from the skin, producing a counteracting effect. On the contrary, *white* is the least warmed by the sun, but is more effectual in confining the heat of the system by its imperfect radiation. The difference between them with respect to warmth is, that black clothes are the hottest when the sun is most powerful, and white the warmest when the sun has the least power; in other words, white is the coolest in summer, and black the coolest in winter. The delicate and the invalid should thus generally prefer white or light-coloured clothes, whether as summer or winter wear; and as winter clothing, the light-coloured greatcoat is very much warmer than one of a darker hue. It is to be regretted that we have no very accurate experiments to determine the proportionate radiating and absorbing powers of different colours; but so far as attempts have been made, the *radiating* power of black in one experiment was 21, while that of red was 26, and of white 28. On the other hand, the *absorbing* power was found to be for black 4½, dark-green 5, scarlet 5¼, and white 8. Another important fact connected with the absorbent power of different colours, is the facility of acquiring and retaining odours, and it may be infectious exhalations. So far as experience goes, black is in this case not only the most absorbent but the most retentive.

COSTUME.

Dress may be said to consist of three generic forms—the simple attire of savage life, in which a skin, blanket, or some other loose covering is nearly all that is employed; the flowing and elegant dress of the East; and the precise and more closely-fitting clothing of modern European nations. Of the first-mentioned little need be said. In the absence of manufactured articles, savage tribes in all countries are, and have been, in the habit of attiring themselves in such rude materials as nature has placed within their reach. The Indian of North America clothes himself in skins on which the fur is left, or with a blanket procured from the wandering trader. His legs and feet he dresses in moccasins made from a species of leather, and in full dress he fancifully paints his skin with pigments. In some of the islands of the Pacific (as also till lately in New Zealand), the inhabitants *tattoo* the surface of the body by puncturing it with an instrument, and inserting coloured juices in the wounds. Such likewise was the barbarous practice and fashion of the original inhabitants of the British islands.

Throughout Asia, in North Africa, and in Turkey, the dress is generally of a loose and flowing form; that of the common people in China being least so. The *turban* is almost universal. It is a male head-dress, composed of muslin swathed in folds, for the most part round a cap; and by presenting a mass of light material to the sun, it is considered to be a suitable covering for the head in Eastern climes. The forms of this head-dress, however, differ considerably; some being more tasteful than others. The first represented in the accompanying figure is the round turban common in Africa; the second an elegant modern Egyptian form.

A crowd in Constantinople, previous to the late modifications of costume, was, says a traveller, a picturesque group: 'there was the graceful Effendi Turk with snow-white turban, jetty beard, sparkling and full eyes, long flowing caftan, scarlet trousers, yellow boots, rich Cashmere shawl round the waist, in which shone the gilded dagger; next was the gay but cunning-looking Greek, with short chin, black turban, enormous but short trousers, bare legs, and black shoes; then the grave Armenian, with his calpac of black felt balloon-like upon his head, his long Turkish robe, silver ink-horn in his girdle, and his feet in the crimson slipper or boot; next was the Jew, with his blue turban and slippers; and with these were seen the high taper calpac of the Tartar, the melon-shaped head-piece of the Nizam Djedid, the gray felt conical cap of the imaum and dervish, and occasionally the ungraceful hat of the Frank, with the be-buttoned and mean-looking costume of Western Europe.'

The dress of the modern Greeks is a mixture of Eastern and European costume, with little to mark the classical origin of the people. The chief article of attire of the poorer Greeks is a *capote*, or large woollen garment, with a hood, shaggy with short threads of yarn; it is heavy when dry, but nearly insupportable when wet; it is as serviceable for home and bed to the wandering Greek as the *bunda* is to the Hungarian shepherd, and it is a perfect defence against cold and dew. All but the poor classes of Greeks, however, dress showily; and even a servant will expend every farthing of his wages in fine clothes. Thus a physician's janissary may be seen in a rich robe of scarlet, his vest of blue velvet trimmed with gold lace, and in his silk girdle a brace of pistols embossed with silver; turban, short petticoats, and trousers of purest white, and gaiters or 'leggings' of scarlet velvet, embroidered with gold; altogether, a costume that might suit a prince. The general dress consists of a short embroidered jacket, without collar, and with sleeves open from the elbow; an embroidered vest, a cotton shirt, a tunic of several folds, secured by a sash or shawl about the waist, and reaching to the knee; loose breeches or trousers, short socks, and slippers between sandals and shoes. In one corner of the sash, the common people carry their money, which the rich put into purses, and carry, with their handkerchiefs, watches, and snuff-boxes, in their bosoms. The head-dress is various; as the turban, *à la Turque*; the fur-cap, like a muff; the fez or tasseled cloth cap, worn on one side; the plain caps of the peasantry; and skull-caps of velvet or gold, embroidered and tasseled. The young Greeks are the handsomest race in Europe; their long hair falls over their shoulders from under the cap, their embroidered jackets, vests, and buskins, their arms mounted with silver, and even jewels, and their white kilts, compose, on the whole, one of the most graceful and becoming costumes in the world.

The Greek.

The costume of the Greek female more closely resembles that of the Turks. She wears loose trousers of fine calico, embroidered with flowers, a closely-fitting vest, a jewelled zone about the waist, and a long-sleeved gown, flowing off loosely behind, or a veil covering the body; and sometimes a rich pelisse trimmed with fur. Jewellery is worn to excess; and bracelets of gems, or strings of gold coins round the arm and neck, across the forehead, and in the hair, which the younger girls let fall down their backs and over their brows and cheeks. Little caps, similar to those of the men, are also worn by the females, studded with coins, but worn on one side of the crown, the girls wearing in them flowers, and the matrons heron-plumes or jewels. The young women often dye their hair auburn, and the old ladies red, with which colour the nails are also tinged. The females walk abroad in a robe of red or blue cloth and an ample muslin veil.

The dress of modern Europe, and, we may add, that of civilised America, differs little in essentials. With few exceptions, it is well fitted for an active, hard-working, city-dwelling people; it has little cumbrous or unnecessary about it, and if not always so graceful or picturesque as could be wished, it is free at least from the reproach of 'barbaric pomp and ornament.' Climate, business avocations, and conventional usages require it to be somewhat precise; but this precision can never become ridiculous unless through some temporary freak of what the gay world denominates *fashion*. The usual notions concerning flowing or classical costume are more traditionary than rational; for if there be really anything in 'the human form divine,' the less that any costume clogs, and cumbers, and conceals it—consistently with comfort and decorum—the more becoming must it of necessity be. With this much for the too often reviled costume of modern Europe, and without entering into particulars as to the styles it assumes in different countries, we shall now devote the remaining pages to the history and development of

BRITISH COSTUME.

Partly from a wider acquaintance with other countries, partly from the introduction of new pursuits and avocations, and partly from caprice and fashion, the costume of our country has undergone many changes in the course of ages. Among the Southern Britons, at the time when Julius Cæsar landed in the country (55 B.C.), the arts connected with clothing had made some advance; but in the more northern parts, the practice of living half naked, with painted and tattooed bodies, was common, and, notwithstanding the severity of climate, remained till a much later period. Such fanciful decorations are supposed to have given name to the nation of *Picts* (from the Latin word *picti*, painted); but on better authority, the appellation has been referred to a different origin.

Pict.

The usual Roman dress, in the latter period of the Empire, consisted of a tunic, or loose upper garment, with a dress for the lower limbs, called *braccæ*; hence the modern term *breeches*. Over all was occasionally worn by the higher classes the *toga* or mantle. It is believed that these Roman costumes were generally copied by the greater number of British, at least among the more opulent classes. In the dress of the women, however, there was but little change. They appear in two tunics, the one reaching to the ankles, the other having short sleeves, and reaching about half-way down the thigh; in other words, they resemble a round gown, or bed-gown and petticoat, though the latter, distinct from a body and sleeves, is not considered to be ancient. This tunic was called in British *gwn*; hence our word *gown*, of which we still see specimens of short dimensions worn by women of the humbler classes in England, Scotland, and Wales.

Anglo-Saxon and Danish Periods.

The Anglo-Saxon and Danish periods of English history are marked by new peculiarities in costume. Soon after the departure of the Romans and the arrival of the Saxons in 449, fashions of apparel were introduced from Northern Germany, which were copied by the Romanised British, and continued with no material change for several centuries.

The most important improvement in the ordinary dress of the people was the introduction of the *shirt*, a linen garment worn next the skin, for which we are indebted to the Saxon invaders. The common dress of the eighth century consisted, as we find, of linen shirts; tunics, or a kind of surcoat; cloaks fastened on the breast or shoulders with brooches; short drawers, met by hose, over which were worn bands of cloth, linen, or leather, in diagonal crossings. Leathern sandals were worn by the early Anglo-Saxons; but afterwards the shoe became common; it was very simple, and well contrived for comfort, being opened down the instep, and there, by a thong passed through holes on each side of the slit, drawn tight round the feet like a purse. A felt or woollen cap, called *hæt* (hence our modern word hat), was worn by the higher class of Anglo-Saxons; but it is generally believed that the serfs or lower orders were without any other covering for the head than what nature had given them.

Although Sir Walter Scott, with the natural modesty of genius, disclaims pretension to complete accuracy in the costume of the characters in his historical romances, the following portrait of Gurth, the Saxon swineherd in 'Ivanhoe,' is nearly correct: 'His garment was of the simplest form imaginable, being a close jacket with sleeves, composed of the tanned skin of some animal, in which the hair had been originally left, but which had been worn off in so many places that it would have been difficult to distinguish from the patches that remained to what creature the fur had belonged. This primeval vestment reached from the throat to the knee, and served at once all the purposes of body-clothing. There was no wider opening at the collar than was necessary to admit the passage of the head, from which it may be inferred that it was put on by slipping it over the head and shoulders, in the manner of a modern shirt or ancient hauberk. Sandals, bound with thongs made of boar's hide, protected the feet; and a sort of roll of thin leather was bound artificially round the legs, and, ascending above the calf, left the knees bare, like those of a Scotch Highlander. To make the jacket sit more closely to the body, it was gathered at the middle by a broad leathern belt, secured by a brass buckle, to one side of which was attached a sort of scrip, and to the other a ram's horn, accoutred with a mouth-piece for the purpose of blowing. In the same belt was stuck one of those long, broad, sharp-pointed, and two-edged knives which were fabricated in the neighbourhood, and bore even at this early period the name of a Sheffield whittle. The man had no covering upon his head, which was only defended by his own thick hair matted and twisted together. One part of his dress only remains, but it is

Anglo-Saxon Serf.

too remarkable to be suppressed: it was a brass ring resembling a dog's collar, but without any opening, and soldered fast round his neck; so loose as to form no impediment to his breathing, yet so tight as to be incapable of being removed, excepting by the use of the file. On this singular gorget was engraved, in Saxon characters—"Gurth, the son of Beowulf, is the born thrall of Cedric of Rotherwood."'

The Anglo-Saxon females wore under-tunics, with sleeves; another inner garment—the linen kirtle; and over these the long full gown, with loose sleeves. The head-dress was a hood or vail, which, falling down before, was wrapped round the neck and breast; and this was the only head-covering of the women when abroad. The hair was carefully dressed, and golden head-bands, half-circles, neck-bands, and bracelets, were worn; with earrings, necklaces, crosses, and jewelled ornaments too numerous to describe. The hose and shoes resembled those worn by the men. The long sleeves of the gown or the mantle, drawn over the hands, served as gloves, which were not worn before the eleventh century. All classes used on their cheeks a red cosmetic, so that the art of painting the face is not the creature of refinement. The general colours of the dresses were red, blue, and green, sometimes embroidered in patterns; and gold tissue and cloth of gold were worn by princesses and nuns; and the latter embroidered robes, sandals, tunics, vests, cloaks, and veils of enormous cost—for pearls and precious jewels were interwrought with the materials, and sometimes three years were spent in working one garment; and their dresses were often lined with sable, beaver, and fox furs, or the skins of lambs or cats.

In the article of dress, the Danish intruders into Britain were, after a time, equally profuse. The Anglo-Danish kings appear principally to have worn a red habit, embroidered with gold, and a purple robe; and their mantles were richly embroidered with gold and pearls. Upon a manuscript of the reign of Canute, he is, however, represented in a Saxon dress, the mantle being richly ornamented with cords or ribbons, and tassels; and he wears shoes and stockings with embroidered tops. His body, when discovered in Winchester Cathedral in the year 1766, was decorated with gold and silver bands, and a richly-jewelled ring; bracelets were worn by all persons of rank, and invariably buried with them. Canute's queen wore the tunic, mantle, and long veil. The materials of the Danish dresses were cloths, silks, or velvets, procured either from Spain or the Mediterranean, by plundering the Moors.

From the Danish invasion to the Norman Conquest there were few changes in costume, if we except the imitation of Norman-French fashions in the reign of the Confessor, by shortening the tunics, clipping the hair, and shaving the beard, but leaving the upper lip unshorn. Tattooing after the Pictish fashion was practised even to this time, although it had been forbidden by a law passed in the eighth century.

Eleventh till Fourteenth Century.

The Norman Conquest introduced a greater degree of taste and splendour into British costume; but the dress of the common order of people remained long of a comparatively rude fashion, partly from the effect of caste and sumptuary laws, which prevented any decided change. As time advanced, the materials of dress improved, but the fashioning was little different, and, till this day, we have a sample of the Anglo-Saxon tunic in the *smock-frock*, a species of overall linen shirt, very generally worn by the peasantry of England. The *blouse*, a coarse linen shirt of blue instead of white, which is now universally worn by workmen in France, Switzerland, the Low Countries, and part of Germany, had an equally early origin.

In the reign of Rufus many costly changes were made in dress: the tunics were lengthened, and the under garments even trailed upon the ground. The sleeves were also drawn over the whole hand, although gloves were worn, at least by the higher classes. The cloth mantles were lined with rich furs; and one lined with black sables and white spots cost £100. Extravagantly peaked-toed boots and shoes were worn; and a court coxcomb, who caused the points of his shoes to curl like a ram's horn, received the name of *De Cornibus*, or with the horns. The hair, which had been shorn from the back of the head as well as the face by the Norman-French, was now again worn long; and the courtiers in Stephen's reign even wore artificial hair, so that wigs may date from the twelfth century. The long beard also reappeared in the reign of Henry I. (1100-1135).

About this period *gloves*, highly ornamented, appear to have been used by kings and the higher church dignitaries. Gloves, or a clothing of leather for the hands, had not been unknown in early ages; by the Greeks and Romans they were employed as a protection in certain kinds of rough labour. Now they were employed as part of a mailed dress, and also on ceremonial occasions. From the monumental effigy of Richard I., it is seen that he wore gloves ornamented with jewels on the back of the hand. Throwing down a glove became a challenge of defiance to single combat, according to the etiquette of these partially barbarous ages. From being worn only by kings, archbishops, courtiers, and knights, gloves made of various materials gradually became a portion of ordinary dress.

In the course of the thirteenth century, the sumptuousness of apparel increased: rich silks woven with gold, embroidered and fringed, and French velvets, were much used; and a rich stuff manufactured in the Cyclades was made into a dalmatica or super-tunic, called Cyclas, which was worn by both sexes. The furs of ermines, martens, squirrels, the vair, and the minevair or miniever, were added to the list of furs for winter garments.

The general male dress consisted of the cyclas just mentioned; and the tunic open as high as the waist, to show the drawers, with chaussies or stockings. The principal novelty is the super-totus, or overall, worn like the mantle or cloak, and consisting of a kind of large-sleeved shirt, with a capuchon. Long-toed shoes and boots were resumed, with embroidery and colours.

The female costume differed in fashion and name, rather than in form, from those of the twelfth century. The veils were of gold tissue or superbly-embroidered silk, and over them was worn a diadem, circlet, or garland, or a cap-like coronet, by persons of rank, and sometimes a round hat. The head-dresses were very numerous: the wimple covered the head and shoulders, and was fastened under the chin; and the hair was worn in a net or caul of gold thread, which continued in fashion for the next two centuries. A very ugly kind of wimple, called the Gorget, appeared in the thirteenth century; it was a neck-covering, poked up by pins above the ears. The long robe was also worn trailing on the ground; the cloth stockings were embroidered with gold; and trinkets of gold, as buckles, rings, earrings, and chaplets, and jewels, were much worn. In this century, too, we first meet with the surcol, which Strutt calls a corset, boddice, or stays, worn over the rest of the dress, which enlarged in the skirt, and spread into a train: it was made high in the neck, and had long tight sleeves.

The dress of the working-classes may be supposed to have been improved about this period by the introduction of the worsted manufacture: it is stated to have been brought to the country by a colony of Flemings, who in the reign of Henry II. settled at *Worsted*, a village in Norfolk; hence the name of the fabric.

Fourteenth and Fifteenth Centuries.

We now come to the fourteenth century, in which Edward III. and his queen Philippa led the fashion in apparel. As seen from the effigy on his tomb, the costume of Edward is characterised by its dignified simplicity. The dalmatica is low in the neck, falls in straight folds to the feet, and is open in front nearly half its height, being embroidered at the edges of the aperture; the sleeves of the under-tunic have at each wrist a row of buttons, a fashion of the reign of Edward III.; the mantle, embroidered at the edges, is worn over the shoulders, and confined by a jewelled band across the breast; the shoes or buskins are also embroidered, and the hair and beard are patriarchal; the crown has been removed or lost. The effigy of Queen Philippa, also at Westminster, is equally distinguished by its simplicity; the skirt is long and full, the boddice closely fitting, the waist-belt jewelled, and the mantle ornamented on the shoulders, and confined by a diagonal band across the breast; and upon the head is a low crown, jewelled, and from it depends a kind of draped ornament half-way down the cheek. The costume of the nobles in this reign was, however, far less simple than that of the sovereign. In place of the long robe and tunic was worn a close-fitting body-garment (jupon) superbly embroidered, reaching to the middle of the thigh, and confined across the hips by a splendid belt; from the sleeves of this garment hung long slips of cloth, called *tirippes* (tippets), and over the whole was occasionally worn a long mantle, fastened by buttons upon the right shoulder. This dress was, however, the extreme of foppery. The caps were of various shapes, and among them we find the knight's *chapeau*, nearly in the form now used in heraldry. Beaver hats were also worn; but the greatest novelty was a single feather in the front of the cap. The golden chaplets, by the addition of leaves, now assumed the form of coronets. The gay tournaments of this period led to the introduction of many costly foreign fashions; so that, in 1363, expensive dress, beyond the income or rank of the wearer, was forbidden by law; furs of ermine and pearl ornaments (except for head-dress) were forbidden to all but the royal family and the wealthiest nobles; cloths of gold and silver were permitted only to the next in fortune; and persons of small income were forbidden to wear silks, embroidery, or trinkets. But the ladies dressed still more sumptuously, as in the engraving, where the gown fits close in the boddice, and the train is so long in the front as to be held up, and thus display the embroidered under-dress; the sleeveless jacket worn over the gown is also embroidered and trimmed with fur; the hair is worn long, and the cap is low, and resembles a coronet. Tippets from short sleeves, and the jupon, were also worn by ladies as well as by gentlemen; and both sexes wore daggers stuck through pouches in their rich girdles. In this reign *mourning habits* appear to have been first worn, the colours being black and brown.

Lady of 14th Century.

Gentleman of 14th Century.

The reign of Richard II. must have been the high carnival of coxcombry. The sovereign himself, according to Holinshed, had a coat or robe which cost 30,000 merks. Party-coloured dresses were universally worn, and even the hose were of two colours, so as to render the term *a pair* inapplicable: the colours of the king and his court were white and red. Men and women alike wore hoods set with jewels; and their tippets were jagged, and reached to the heels; and the long-peaked shoes, called *crackowes* (from Cracow, in Poland), were fastened to the knees with gold and silver chains. The preceding engraving shows a gentleman of this period, with shoes and hose all in one, the mantle cut into the shape of leaves at the edges, a belt and pouch, and a fantastically-turbaned head-covering. Chaucer has left us the costume of several ranks at this period: his squire wears a short gown, 'with sleeves long and wide;' his yeoman 'a cote and hoode of grene;' his merchant many colours, with a forked beard, and a 'Flaundrish beaver hat,' and clasped boots; the reeve or steward a long surcoat and rusty sword, his beard and head shaven and shorn; the miller wore a white coat and blue hood, a sword and buckler, and red cloth holiday-hose; and the hats, caps, and bonnets of all classes were very fantastical. Knives, ornamented with silver, and purses, were worn by most classes in their girdles; and shoulder-belts, with bells, were a mark of rank. Liveries are also now mentioned as worn by substantial artisans, as well as by menial servants; but the ploughman appears only in a tabard or sleeveless coat, and the mechanic in a tunic. The hair was worn long and curled, and the beard forked.

In the female costume of this reign the fantastic party-coloured dresses were retained, with the embroidered jupons and kirtles, hip-girdles, and long tippets from the elbow; and the *surcot* or external coat, faced with fur, and terminating in a train sometimes so long as to be carried over the arm, or shorter, opened up the side, and bordered with ermine. The head-dress continued as in the preceding reign. The attire of the carpenter's wife in the 'Canterbury Tales,' with a silk girdle and head-fillet, and brooch, indicates the condition of this class of females.

Gentleman of 15th Century.

The costume of the fifteenth century was equally gay and foppish, but perhaps more neat in form. The annexed engraving represents a gentleman of the reign of Henry V.; he is dressed in a short tunic, buttoned in front, with girdle, large loose sleeves, tight hose forming pantaloons, and stockings in a single piece, peaked shoes, and head-cloth or cap. About this period, silks and velvets of divers colours came into use among the higher classes, by whom gold chains were generally worn. The dress of ladies was of the richest kind. Gowns were embroidered, and bordered with furs or velvet; and the boddice, laced in front over a stomacher, now first appeared. But the greatest eccentricity was the lofty steeple head-dress, shown in the annexed portrait; this consisted of a roll of linen covered with fine lawn, which hung to the ground, or was mostly tucked under the arm. Richard III. (1483-85) according to his wardrober's books, was a right royal fop, for we find him wearing a blue cloth-of-gold doublet and stomacher, 'wroght with netts and pyne-apples,' and crimson and purple-velvet robes, embroidered and furred, and crimson satin hose, and tissue cloth-of-gold shoes, at his coronation. The nobles in this reign had their hose tied by points to the doublet, which was sometimes worn open, but laced like a boddice; and over it was worn a long or short-gown, the former hanging loose, and the latter plaited before and behind, and girded about the waist; and both gown

Lady of 15th Century.

and doublet were slashed. The general head-dress was a closely-fitting cap or *bonet* (bonnet), with a single feather in it; and scarlet hats and hoods were worn. The boots had very long-pointed toes, and reached to the middle of the thigh.

Hitherto the authorities for costume have been illuminated manuscripts, tapestry, and monumental effigies, in which there is often perplexing indistinctness. Now painting comes to our aid; and the portraits by Holbein are the best illustrations of the costume of the two succeeding reigns. The male costume of the wealthier classes in the reign of Henry VII. consisted of a fine shirt of long lawn, embroidered with silk round the collar and wristbands. The sleeves of the doublet were slashed at the elbow, as in the reign of Edward IV.; or they were in two or more pieces, fastened at the shoulders and elbows with laces or points, through which the shirt protruded. The doublet was laced over a stomacher and petticoat, the male costume thus resembling that of the females in name as well as form. The outer garment was a long coat or gown, with loose hanging sleeves, and a broad turn-over collar of velvet or fur. The long hose were differently coloured in the upper and lower portions, and in the former slashed or puffed; the shoes were absurdly long and broad-toed, and high boots were worn for riding. In the head-coverings there was great variety. The hoods were abandoned to official habits, and instead were worn broad felt-hats or caps, and bonnets of velvet or fur profusely decked with ostrich feathers; or the large plumed cap was slung at the back, and a smaller cap of velvet or gold net worn on the head. The knave of our playing-cards has a cap peculiar to this period.

In these distracted times party-colours were worn. Thus the family colours of the House of Lancaster were white and red; those of York purple and blue; and those of Tudor white and green. Buttons also bore partisan figures or emblems.

The female costume of the reign of Henry VII. is distinguished by the square cut of the boddice in the neck, and embroidered and jewelled stomachers, belts, and girdles hanging in front nearly to the feet; the sleeves were large and full, and when confined at the wrist, resembled 'the bishops' sleeves' imitated in England, from the French, a few years since. These sleeves were slashed, divided, and joined like those of the men. The head-dresses were close caps and cauls, from beneath which the hair hung down to the waist; and several kinds of capuchons were worn. In the dress of the humbler classes we find mentioned a 'furred flocket and gray russet rocket,' 'kirtle bristow red,' 'blanket hose,' 'Lincoln green,' &c.

At the close of this century the mourning habits had become so sumptuous as to be limited by law; the principal article being a barb or veil, used at funerals, which was tied on above the chin by duchesses and countesses, and lower by all other ranks.

Throughout the above period the principal material of the clothing of the middle classes must have been abundant; for, in the reign of Edward III., our woollen manufacture almost rivalled that of the Flemings, and our exports to the continent were very large; there appears, however, to have been little or no linen made at this period in England.

Sixteenth Century.

In the sixteenth century the upper part of the long hose began to be worn loose, or slashed with pieces of different colours let in, and the arms and shoulders of the doublet or jacket were fashioned in a similar style. Boots were also worn loose on the leg, with the upper part falling down; hence the origin of the buskin. Ruffs or ruffles, collars, and velvet bonnets with feathers, came likewise into use, as may be seen from the paintings of Henry VIII. Hall, the chronicler, describes several of Henry's superb dresses, and among them a *frocke*, or coat of velvet, embroidered all over with gold of damask, the sleeves and breast cut and lined with cloth of gold, and tied together 'with great buttons of diamonds, rubies, and orient pearls.' The cloaks and mantles were of corresponding magnificence. The shirts were pinched or plaited, and embroidered with gold, silver, or silk. The term *hose* continued to be applied to the entire vestment, from the waist to the feet, throughout this century: the material is more distinctly stated, for Henry wore knit silk, as well as cloth hose; the precise period of the separation of the hose into breeches and stockings, is not so clear as the derivation of the latter term from the '*stockying* of hose;' 'that is, adding the lower part that covered the legs and feet to that which was fastened by points to the doublet,' and was called the *stocks*. The shoes and buskins were of the German fashion, very broad at the toes, and of velvet and satin, slashed and puffed. The hats, caps, and bonnets were of almost endless forms and colours.

Henry passed sumptuary laws, directing that cloth of gold and tissue should be used only for dukes and marquises, and that purple should be kept for the royal family. Earls might use embroidery, and commoners of distinction silks and velvets; and it was even thought necessary to restrict the commonalty and serving-men to cloth of a certain price, and lambs' fur, and to forbid them wearing any ornaments, or even buttons, save the badge of their lord or master. The king likewise forbade his courtiers wearing long hair, according to the general fashion, and made them poll their heads, which led to the introduction of the peruke, afterwards written *periwig*, and more shortly *wig*. The masques, or plays in masquerade, in Henry's reign, were very splendid; and in the ladies' dresses worn at one of them, are mentioned 'demy sleeves, naked down from the elbows,' which M. Planché considers to have been the first appearance of bare arms since the time of the ancient Britons.' Gloves were not unknown, for Henry left a pair to one of the executors of his will. They were sometimes finely perfumed, and brought from Spain and Italy as presents. In this and the preceding reign the head-dresses assumed a different character, having long lappets or ear-pieces hanging down below the shoulders, and when made of velvet studded with pearls, jewels, and gold, they were truly superb. Three-cornered caps of minever were also worn throughout the reign; and the close-fitting cap reaching to the ears, and known as 'Mary Queen of Scots' cap,' was first worn about this period. The ladies' hunting-dress differed but little from the riding-habit of the present day; across it was usually slung, from the right shoulder to the left side, a horn resembling a bugle.

In this reign *pins* were first brought from France, and used by Catharine Howard, before which time the different parts of the dress were kept together by ribbons and loopholes, laces with points and tags, clasps, hooks-and-eyes, and skewers of brass, silver, and gold; but the poorer classes used the natural thorn for the above purpose.

The dress of the middle ranks in this reign may be seen in prints of the time: plain russet coats, and white kersey sloppes, or breeches, with stockings of the same piece, were the ordinary suit; and the London apprentices wore blue cloaks in summer, and gowns of the same colour in winter, as badges of servitude; for this appears to have been the age of domestic distinctions — the relics of the feudalism of the middle ages. The women wore sheep, russet, or long woollen gowns, worsted kirtles (hereafter called *petticoats*), and white caps and aprons; and milk-white underlinen came into general wear. The engraving shows a man and woman in the ordinary dress of this period.

Man and Woman of 16th Century.

The principal novelty of the reigns of Edward VI. and Mary was the flat round bonnet or cap, of plain velvet or cloth, worn on one side of the head, and decorated with a jewel and single ostrich feather. The bonnet itself is preserved in the caps worn at the present day by the boys of Christ's Hospital; and their blue coat and yellow stockings are such as were worn by the London apprentices at the date of the foundation of the hospital by the youthful Edward. The gown of the wealthier classes was furred with sables in front and round the broad sleeves. Philip, on his marriage with Mary, brought into England a richer style of dress for the men, particularly the close ruff; the doublet, which fitted exactly under the chin, and the short Spanish cloak—all of which remained for a considerable time in fashion. The preposterously large stocks, or trunk hose, continued to be worn, but the broad-toed shoes were discarded. The armour continued nearly the same as in the preceding reign. To female costume the chief addition was the *fardingale*, an immense hooped petticoat, introduced from Spain under Queen Mary. The entire dress was worn very close, so as to conceal the person as much as possible.

Queen Elizabeth's fondness for dress is well known; she is stated to have left three thousand different habits in her wardrobe. This great number is explained by the royal affectation of wearing by turns the costume of all the nations of Europe, which may be traced to the use of foreign materials made up by foreigners. Bohun, in his character of Elizabeth, tells us that 'when she appeared in public she was richly adorned with the most valuable clothes, set off again with much gold and jewels of inestimable value; and on such occasions she even wore high shoes, that she might seem taller than indeed she was. The first day of the parliament she would appear in a robe embroidered with pearls, and upon her head she had a small crown. She was dressed in white silk, bordered with pearls of the size of beans, and over it a mantle of black silk, shot with silver threads. Her train was very long. Instead of a chain she had an oblong collar of gold and jewels.'

But the glory of the Elizabethan era of female costume, as well as its most remarkable characteristic in the sixteenth century, was the *ruff* of plaited linen or cambric, which now became superb, and rose from the front of the shoulders behind the head nearly to its full height; from the bosom descended a huge stomacher, on each side of which projected the immense fardingale. In this characteristic costume Elizabeth went to St Paul's Cathedral to return thanks for the defeat of the Spanish Armada; though, besides the magnificent ruff, the queen wore a mantle with a large wing-like collar, her hair intertwined with pearls, large pendant jewels on the neck, and a superb lattice-work of pearls over the entire dress.

The ruff must, however, be further noticed: no sooner had its material been changed from Holland to lawn or cambric, than a difficulty arose as to starching or stiffening it, instead of the clumsy mode of supporting it by poking-sticks of ivory, wood, or gilt metal. At length the art of starching was brought from Flanders, and taught in London for a fee of four or five pounds. The fashion next lay in the colour of the starch, of which there were five varieties.

Stockings, which we find mentioned as foreign rarities in the wardrobe accounts of Henry VIII. and Edward VI., became common of home manufacture in the reign of Elizabeth. In the third year a pair of black knit silk stockings, made in England, was presented to her majesty, who was so pleased with the article, that she would never after wear cloth hose. This resolution has been attributed to Elizabeth's desire to encourage English manufactures by her own example, and may be taken as some set-off to her extreme fondness for foreign materials and fashions of dress. Soon after this, a city apprentice having borrowed a pair of knit worsted stockings brought from Mantua, made a pair like them, which he presented to the Earl of Pembroke; and these are the first worsted stockings known to have been knit in England. Mary Queen of Scots, at her execution, wore stockings of blue worsted clocked and topped with silver, and under them another pair of white; and the stockings of this time generally consisted of silk, jarnsey, worsted, crewel, fine yarn, thread, or cloth, of all colours, and with clocks, open seams, &c. The invention of the stocking-frame by Lee at Calverton, near Nottingham, in 1599, must have brought stockings into general use: he or his brother is said to have worked for Queen Elizabeth; but he was driven by the jealousy of the other stocking manufacturers into France, where he died of a broken heart—an end by no means uncommon in the lives of inventors.

The garters of this age were very costly, sometimes of gold or silver, and £4 or £5 a-pair; they are presumed to have been worn by ladies since the time of Edward II., but they must not be confounded with the leg bandages of an earlier date. The ladies wore 'corked shoes, pinsnets, pantoffles, or slippers,' which raised them two inches or more from the ground: these were made of black, white, green, or yellow velvet, or Spanish and English leather, embroidered with gold, silver, or silk, and shaped after the right and left foot, like the Anglo-Saxon sandal. The Elizabethan head-dresses were French hoods, hats, caps, kerchiefs, cauls of net-wire, and lattice caps—the latter, as well as an ermine bonnet, being forbidden by law to all but 'gentlewomen born, having arms.' In Elizabeth's jewel-box is a long list of wigs, or rather head-dresses, among which are cauls of hair set with seed-pearl and gold buttons. The hair was curled, frizzled, and crisped, and under-propped with pins and wires into the most fantastic forms. The finger-rings, earrings, bracelets, and other jewellery, were very splendid; velvet masks and pocket looking-glasses were carried by fashionables, with fans of ostrich feathers set in gold, silver, or ivory handles—the latter introduced from Italy, and used by both sexes.

The male costume in Elizabeth's reign was the large trunk hose, long-waisted doublet, short cloak, hat, band and feather, shoes with roses, and the large ruff; but the great breeches, 'stuffed with hair like woolsacks,' after the separation of the hose into this garment and stockings, appear to have been worn throughout the reign: they were made of silk, velvet, satin, and damask. The doublets were still more costly, and quilted and stuffed, 'slashed, jagged, pinched, and laced;' and over these were worn coats and jerkins in as many varieties as there are days in the year. The cloaks were of the Spanish, French, and Dutch cuts, of cloth, silk, velvet, and taffeta of all colours, trimmed with gold, silver, and silk lace and glass bugles, inside and outside equally superb. The stockings, shoes, slippers, and ruffs resembled those of the ladies.

Hats now began to supersede the bonnets of a former era. Those of beaver were exceedingly expensive, and they were for the most part made of felted wool, dyed. The most remarkable thing about these hats was their numerous shapes: some were steeple-crowned; others were flat and broad, like the battlements of a house; and others with round crowns, and bands of all colours, and ornamented with huge feathers and brooches, clasps, and jewels of great value.

In taking leave of the British costume of the sixteenth century, we may observe that its splendour was almost entirely borrowed from France, 'that country which has since given laws in dress to nearly all Europe.'

Seventeenth Century.

Under James I. the male costume was somewhat more decidedly Spanish, as respects the slashing and ornamenting of the doublet and breeches. Late in the reign, however, the jackets or doublets were shortened, and the breeches reduced in size, and fastened in large bows at the knees; the well-stockinged leg was admired, and the hat worn low in the crown, and with broad brim, as seen in portraits of the date 1619. Beards and whiskers had become almost universal in the reign of Elizabeth; but in that of James, the former was sometimes worn trimmed to a point, hanging down at the division of the ruff.

In the female costume there was little change. The huge fardingale continued to be worn by the nobility; a strong passion for foreign lace was introduced; pearls were the favourite jewels; and the ruff maintained its sway, so as to be anathematised from the pulpit; and the fancies of female costume were glanced at in a sermon preached before the king at Whitehall in 1607–8, as 'her French, her Spanish, and her foolish fashions; her plumes, her fannes, and a silken vizard, with a ruff like a sail, yea, a ruff like a *rainbow*, with a feather in her cap like a flag in her top, to tell which way the wind will blow.'

The dress worn in the reign of Charles I. is unrivalled for picturesqueness and elegant taste. At this we shall not be surprised, if we recollect that it was copied from the habit of Spain, the most becoming of all European costumes. Early in this reign, however, the motley fashion of the time of James I. prevailed; and the Savoy neck-chain, the ruff and cuffs of Flanders, the Naples hat with the Roman hat-band and Florentine agate, the Milan sword, and the cloak of Geneva set with Brabant buttons, gloves from Madrid, &c. were the characteristics of the beau of 1629. The ruff had almost universally given place to the falling band; and collars of rich point lace, large and hanging down on the shoulders, held by a cord and tassel at the neck, and now called *Vandyke*, from its being the most striking part of the dress in which Vandyke at that time painted portraits.

The principal habits were vests and cloaks of velvet, or silk damask, short trousered breeches terminating in stuffed rolls, and fringes and points, and very rich boots, with large projecting lace tops. A dress of Charles is thus described:—A falling band, green doublet (from the armpits to the shoulders wide and loose), zig-zag turned-up ruffles, long green breeches (like a Dutchman's), tied below the knee with yellow ribbons, red stockings, green shoe-roses, and a short red cloak lined with blue, with a star on the shoulder; the king sometimes wore a large cravat, and at other times a long falling band with tassels. The dress of the gay courtiers or cavaliers consisted of a doublet of velvet, silk, or satin, with large loose sleeves, slashed and embroidered; Vandyke collar and band, and short embroidered cloak, worn on one shoulder; the long breeches, fringed and pointed, met the ruffled tops of the boots; the embroidered sword-belt was worn over the right shoulder, and in it was hung a Spanish rapier; and in the flapping beaver hat was worn a plume of feathers confined by a jewel. A buff coat or jerkin was often worn, as a better defence than the doublet, which it sometimes covered. The engraving represents a citizen of this period more plainly attired.

Citizen in time of Charles I.

The female costume of this period was rather elegant than splendid. Gowns with close bodies and tight sleeves were worn, though the fardingale was retained, with a gorget ruff standing up about the neck like a fan. French hoods were still worn, though with little distinction as to rank. The hair was worn in small curls, and the hoods, of all colours, fastened under the chin with curious effect. Earrings, necklaces, and bracelets were much worn; but the Puritans forbade the females to wear lace, jewels, or even braided hair; and they retained the close hood and high-crowned hat.

Towards the close of the reign of Charles I., the cumbrous fardingale disappeared, with the yellow starched ruff and band. These tasteless fashions having disappeared, the female dress became very elegant, with its rich full skirt and sleeves, and falling collar edged with rich lace, and the hair worn in graceful ringlets; but these vanities were condemned by the Puritan party.

With the Restoration of Charles II. came certain tasteless innovations upon the elegant Vandyke costume of the time of Charles I., which were the first resemblance to the coats and waistcoats of the present day. Thus our most picturesque attire lasted little more than a quarter of a century. Its decline was gradual; its chivalric character soon degenerated into grotesqueness, which in its turn changed to stark meanness. Early in the reign of Charles II. the doublet was much shortened, and worn open in front, where, and at the waistband, the rich shirt was shown; and the loose sleeves and breeches were decked with ribbons and points, and from the knee-bands hung long lace ruffles. At the wrists, too, ruffles were worn; but the lace collar was shorn of its points, designated to this day Vandyke. The cloak was retained upon the left shoulder, and the high-crowned and plumed hat remained for a short time; but the crown of the hat was soon lowered.

The petticoat breeches were another absurdity; although ornamented with ribbons at the sides, the lining strangely appeared below the breeches, and was tied at the knees; to match which the sleeves of the doublet only reached to the elbows, and from under them bulged the ruffled sleeves of the shirt, both being ornamented with ribbons. Meanwhile the skirt of the doublet had been lengthened from above the waist nearly to the knees, and had buttons and button-holes in its entire length, thus becoming a *coat*, and so named in an inventory of 1679; wherein also are the items of *waistcoat*, *breeches*, *pantaloons*, *drawers*, and *trousers*, being the earliest mention of these articles. Stockings of various kinds were common; and 'the lower ends of stockings' are understood as socks. Instead of the lace collar was worn the long square-ended cravat, of the same material, from Brussels and Flanders.

The female costume, as if to compensate for the tasteless additions to that of the men, retained much of its elegance in Charles's reign; indeed from this time 'the stronger sex' appear to have left the art of dress to the ladies. The portraits of the beauties of the court of Charles II., in Windsor Castle and Hampton Court Palace, are familiar illustrations, in which we see only a pearl necklace upon the bosom, and the hair falling in luxuriant ringlets from beneath a string of pearls.

Citizen's wife in the time of Charles II.

The gowns are of the richest satin, low in the bosom, and have long trains, so that the wearers could not 'stir to the next room without a page or two to hold them up.' The annexed engraving represents a citizen's wife performing this office herself.

Passing to the reigns of James II. and William III., we find few noticeable novelties in costume. The coats were often of velvet, without collars, with large hanging sleeves, and button-holes of gold embroidery. The petticoat breeches were exchanged for the close-fitting garments tied below the knee, and therefore called *knee-breeches*; the broad-brimmed hats were turned up on two sides, and edged with feathers or ribbons; the fashion lay in the rich long lace cravat and embroidered waistcoat; the band was now narrowed, so as to resemble that worn at the present time by clergymen. The periwig was worn still longer than hitherto, hanging down in front, or flowing upon the shoulders, though the colour was altered from black to suit the complexion; and combing these wigs was a piece of gallantry, for which purpose a comb was carried, whence the origin of our present pocket-comb: and at court, in the walks of Kensington, the Mall of St James's, or the boxes of the theatre, the beaux curled their wig curls over their fingers whilst in conversation; the effect of these wigs flowing over the cuirass will be seen in the portrait of the great Duke of Marlborough.

The female costume was unchanged in the reign of James II.; but it became less luxuriant and more formal in the time of William and Mary, in accordance with Dutch taste. The waists were much lengthened with velvet stomachers, covered with jewels, so as to conceal the bosom, hitherto unsparingly exposed; the sleeve was made tight, and trimmed with lace lappets or ruffles, and long gloves were worn, so as entirely to cover the arm; but the skirts were worn long, full, and flounced; the hair, instead of flowing in ringlets, was gathered up, and strained over a toupee of silk or cotton wool, carried up so high as to be called a tower, covered with a lace scarf or veil that hung in front below the bosom; but this head-dress gradually shrunk into a caul with two lappets, known as a 'mob.' False locks and curls, set on wires to make them stand out, were also worn. Before the Revolution the citizens' wives dressed with becoming plainness, and gentlewomen wore serge gowns, which, after 1688, were rejected by chambermaids.

A few of the fashions and peculiarities of this century may be summed up in conclusion. From the reign of James I., the ladies appear to have dressed their hair in better taste than previously, in curls on each side of the face, and braided in a knot at the back of the head, where it was often ornamented with jewels or pearls, or a single feather. It was next worn in long locks flowing below the shoulders; and the love-lock, ornamented with ribbon and twisted pearls, was worn on one side. From the reign of Charles II. to that of Queen Anne, long hair was much prized, and was often sold by women of inferior fortune to be made into periwigs. About this time the *fontange*, or top-knot, so called from Mademoiselle de Fontange, who first wore it, was driven out of fashion by the fanatical spirit of the time. *Hair powder* was also introduced from France in this century: it was worn of various colours, an absurdity only discontinued at the close of the last century. Towards the close of the century wigs became fashionable, together with false hair; 'a custom contrary to our forefathers, who wore their own hair.'

Under the House of Stuart, the shoe-rose yielded to the shoe-string, the beaux wearing them of silk tagged with silver, and the humbler classes wore laces of plain silk, or even leather thongs—the latter still to be met with in rural life. Shoe-buckles, in size and shape resembling the horse beau, were introduced at the period of the Revolution.

Eighteenth Century.

In the early part of the eighteenth century the costume of the English gentry was greatly affected by that introduced into general usage in France by Louis XIV. About the reign of Queen Anne the new French fashions had been embraced by courtiers, physicians, and other professional persons in England, also the higher order of gentry; and in the following reigns of George I. and II. it became universal.

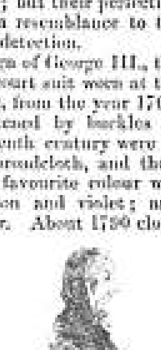
This dress of the old English gentleman, as it afterwards came to be called, consisted at first, during Queen Anne's reign, of a periwig in formal curls, partly contained in a silk bag on the shoulder; a small cocked hat, full bottomed coat, short breeches, blue or scarlet stockings drawn over the knee, and square-toed shoes, with small buckles and high red heels. And this formal costume, relieved only by lace cuffs, ruffles, and neckcloth, and gold or silver clocks in the stockings, remained unmodified through three-quarters of the century. The engraving shows a gentleman of the year 1750, and reminds us that the snuff-box, first carried in the reign of James II., continued indispensable for the 'fine gentleman.' The origin of the cocked-hat is easily explained. The wide flaps or broad brims of the hats in use being found to be inconvenient, they were looped up with a cord and button. At first this was done according to fancy, but latterly there were distinct fashions in cocking the hats. Cocked-hats, richly trimmed with gold-lace and ostrich feathers, occur in Hogarth's pictures, which indeed will furnish a better idea of the entire costume from 1727 to 1760 than many pages of description; and the portraits of Sir Joshua Reynolds will supply the dress of the next forty years.

Gentleman of 1750.

The fashions of wigs were as various as those of hats. A peruke and a plaited and tied tail were called a Ramillies, from the famous battle of that name. The tie-wig became the fashion, from the celebrated Lord Bolingbroke going to court with his wig tied up, upon which Queen Mary observed that he would 'soon come to court in his nightcap,' a royal rebuke which established a fashion. In 1764 wigs went out of wear, and the wig-makers of London petitioned George III. to compel gentlemen to wear wigs by law, for the benefit of their trade! In the present day formal wigs are almost confined to the heads of prelates and law officers; and the latter, to get rid of the powder nuisance, wear wigs made of other materials than hair, as the metal platina. Wigs are, however, much worn, from the greater prevalence of baldness than formerly; but their perfection now consists in bearing so close a resemblance to the natural or living hair as to avoid detection.

Towards the middle of the reign of George III., the male dress took the form of the court suit worn at the present day; the breeches having, from the year 1760, been worn over the knees, fastened by buckles or strings. The coats of the eighteenth century were of velvet, silk, or satin, as well as broadcloth, and their colours very fanciful. Hogarth's favourite colour was sky-blue; Reynold's deep crimson and violet; and Goldsmith rejoiced in plum-colour. About 1790 cloth became the general wear; the waistcoat being of the costlier materials, and embroidered, and sometimes the breeches. Buckles were worn at the knees and in the shoes till the close of the last century; and the large square plaited buckle was the ton until 1791, when shoe-strings became general; though the Prince of Wales and his household endeavoured, by wearing buckles, to retain the fashion.

The female costume of the eighteenth century was as formal and tasteless as that of the men. The most odious piece of attire introduced in the early part of the century was the large whalebone petticoat, which degenerated into the hooped petticoat, and made a lady to appear as if standing in an inverted tub. In the reigns of George I. and II., loose gowns, called *sacques*, and hooded silk cloaks, were worn, and a very small muff, such as have been lately revived. This costume is shown in the annexed portrait of a lady of George II.'s time. Ornamental aprons were also worn, as at the present day, with the watch, necklace, and the fan,



Lady in the time of George II.

which was sometimes from twelve to eighteen inches in length, and beautifully made. Gay sings—

> 'The fan shall flutter in all female hands,
> And various fashions learn from various lands.
> For this shall elephants their ivory shed,
> And polished sticks the waving engines spread:
> His clouded mail the tortoise shall resign,
> And round the rivet pearly circles shine.
> On this shall Indians all their art employ,
> And with bright colours stain the gaudy toy:
> Their paint shall here in wildest fancies flow;
> Their dress, their customs, their religion show.'

Spanish broadcloth, trimmed with gold-lace, was used for ladies' dresses in the reign of George I.; and fur-belowed scarfs were worn from the duchess to the peasant.

Veils of the finest material, as a shroud to the female features, are of great antiquity, and may be traced to Oriental nations, among whom the seclusion of women from general gaze is a point of etiquette. In the eighteenth century, in England, after the disuse of towering head-dresses, veils of an elegant fabric were introduced, and still are not altogether out of date. Female caps of gauze or muslin are of French origin, and have always been multifarious in form. The bonnet, in early times generally made of velvet, cloth, and silk, was in the eighteenth century changed to straw. Gay mentions a new straw-hat lined with green, about 1724, but it was then comparatively rare; for the simple art of plaiting straws together to make bonnets was only practised to any considerable extent about sixty years since; it now employs upwards of 200,000 females in England—Dunstable in Bedfordshire producing the best plait. In our time English straw has been superseded by Leghorn plait, which having declined in fashion, our own straw, silk, and velvet, have been substituted as materials for bonnets; and our home manufactures must have been materially benefited by the change.

Nineteenth Century.

The formalities of the eighteenth century received a terrible blow at the French Revolution; and in the ten years from 1790 to 1800 a more complete change was effected in dress, by the spontaneous action of the people, than had taken place at any previous period in a century. The change began in France, partly to mark a contempt for old court usages, and partly in imitation of certain classes of persons in England, whose costume the French mistook for that of the nation generally. This new French dress was introduced by the party who were styled the Sans Culottes. It consisted of a round hat, a short coat, a light waistcoat, and pantaloons; a handkerchief was tied loosely round the neck, with the ends long and hanging down, and showing the shirt collar above; the hair was cut short, without powder, *à la Titus*, and the shoes were tied with strings.

The comparatively simple form of dress of the Sans Culottes found many admirers in England, and soon became common among young men; the change from antique fashions was also greatly helped by the imposition of a tax on the use of hair-powder, which was henceforth generally abandoned. Pantaloons, which fitted closely to the leg, remained in very common use by those persons who had adopted them till about the year 1814, when the wearing of trousers, already introduced into the army, became fashionable. It is proper, however, to mention that trousers had, for the previous fifteen or twenty years, been used by boys, and were perhaps from them adopted by the army. Previous to the French Revolution, the dress of boys was almost the same as that of men. Although trousers were generally worn after 1815, many elderly persons still held out in knee-breeches against all innovations, and till the present day (1848) an aged gentleman may occasionally be seen clinging to this eighteenth-century piece of dress. The general use of white neckcloths continued, notwithstanding the introduction of the standing collar, till the reign of George IV., when this monarch's taste for wearing a black silk kerchief or stock, and also the use of black stocks in the army, caused a remarkably quick abandonment of white neckcloths, and the adoption of black instead. The year 1825, or thereabouts, was the era of this signal improvement in costume.

While these leading changes were effecting, other alterations of a less conspicuous nature were from time to time taking place. The disbanding of the army after the peace of 1815 led to various transformations besides those we have mentioned. While pantaloons were the fashionable dress, it became customary to wear Hessian boots; these, which had originated among the Hessian troops, were without tops, and were worn with small silk tassels dangling from a cut in front; being drawn over the lower part of the pantaloons, they had a neat appearance, but the keeping of them clean formed a torment that prevented their universal use. When trousers were introduced from the practice of the army, the use of Wellington boots to go beneath them also became common.

Referring to the era of 1815 to 1825, as that in which trousers, Wellington boots, and black neckcloths or stocks came into vogue, we may place the introduction of the surtout in the same period of history. From the time when the collarless and broad-skirted coat had disappeared about the commencement of the century, the fashion of coats had changed in various ways till the above-named era, when the loose frock-coat or surtout was added to the list of garments. We remember seeing French military officers, when in undress, wearing frock-coats as early as 1811; it is probable, therefore, that the modern surtout is only a variety of the loose military greatcoat brought from the continent by the British army; however it originated, it may be allowed to be one of the greatest improvements in the style of dress which has yet occurred in the nineteenth century.

On the whole, the dress of the current age is characterised by simplicity and elegance. The male attire is plain, and in good taste, with the exception of the 'dress-coat' and hat, both of which are as unnatural in cut as they are void of comfort. Female attire was never perhaps more chaste and becoming; the only articles which occasionally merit censure being the square or angular-formed shawl, and the ever-changing but never very classic-looking bonnet. And yet, though convinced of an occasional absurdity in the matter of costume, it is the wiser course rather in so far to follow than attempt to lead in an altogether different direction. 'A man,' says Feltham, and he says wisely, 'ought, in his clothes, to conform something to those that he converses with, to the custom of the nation, and the fashion that is decent and general, to the occasion and to his own condition; for that is best that best suits with one's calling and the rank we live in. And seeing that all men are not Œdipuses, to read the riddle of another man's inside, and that most men judge by appearances, it behoves a man to barter for a good esteem, even from his clothes and outside. We guess the goodness of the pasture by the mantle we see it wears.'

PROVINCIAL PECULIARITIES.

The *Welsh*, as a relict of an ancient Celtic people, possess remarkably few external traits of their original. They have, like the Irish, become Anglicised in costume, and we should in vain search amongst them for the *breacan* or chequered clothing of their Scythian ancestry. The most remarkable part of the Welsh costume is the hat worn by the women. All females in parts of the country not modernised wear round black hats, like those of men; and this fashion is supported to a small extent by ladies of the higher rank. This use of the hat is not Celtic: the fashion is derived from England, and is only two or three centuries old.

The *Irish* at an early period wore the same Celtic fashion of attire as was preserved till recent times in the Scottish Highlands; but, as in Wales, everything of the kind disappeared as the country became Anglicised. A primitive species of attire, including coloured mantles, kirtles, and other fanciful garments, remained in use till the sixteenth century, when laws were passed by Henry VIII. enjoining the use of caps, cloaks, coats, doublets, and hose, of English cut, but of Irish or any other materials. The general dress in Ireland, at the present day, rarely varies from that in England. There are, however, some interesting peculiarities of costume amongst the peasantry of the southern and western counties.

The costume of the Lowland Scotch has generally resembled that of the English in all its changes and vicissitudes. At the present day, Scotland cannot be said to possess any national costume which distinguishes the bulk of the people from their fellow-subjects in South Britain; and however much the fact may surprise the artists and dramatists of England, it is very certain that the inhabitants of Edinburgh, Glasgow, and other cities and towns of Scotland, are dressed in precisely the same fashion of garments as is now seen in the streets of London, Paris, Brussels, or the capital of any other civilised country.

Anciently, the dress of the Scotch, both those of the Highlands and Lowlands, was distinguished by party-colours, woven in cheques, according to taste or ancient usage. By the Celtic race in the Highlands, this species of variegating cloth with colours was called *Breacan*, which signifies spotted, and by the Teutonic population of the Lowlands it received the name of *Tartan*, a word whose origin has defied the researches of etymologists, but which it is not unlikely may have been derived from the ancient Tartar races, who used a similar kind of colouring in their attire. Till the present day, cloths checked in various colours are worn by the Calmucs and other tribes in the north of Europe. Tartan for clothing disappeared in the Lowlands of Scotland in the course of the seventeenth century; but even as late as the beginning of the eighteenth century, party-coloured plaids were pretty generally worn; and young women were in the habit of using a 'tartan screen'—that is, a small plaid of variegated colours. The tartan screen, which was worn in the fashion of a covering for the head and shoulders, so as to combine in some measure the properties of a modern bonnet and shawl, was formed of costly materials; the ladies of the higher classes employing silk, and those of inferior station fine worsted, the colours in each case being remarkably brilliant. Being often employed with a degree of real or affected modesty to conceal a part of the features, it may be said to have performed the office of a veil to Scottish maidens; and hence its appellation of *screen*. Perhaps the use of this species of coif was a consequence of a point of etiquette, which rendered it indecorous for young unmarried women to wear any regular garment on the head.

While tartan disappeared from the Lowlands, except in the screens of the women and the plaids of the shepherds, it continued to be in universal use in the Highlands, where it may be said to have been always associated with the manners of the people; and this leads us to say a few words respecting

Highland Costume.—Originally, the costume of the Highlanders resembled that of other Celtic tribes, and consisted of little else than a woollen garment of variegated colours wrapped round the body and loins, with a portion hanging down to cover the upper part of the legs. In progress of time this rude fashion was superseded by a distinct piece of cloth forming a philibeg or kilt, while another piece was thrown loosely as a mantle or plaid over the body and shoulders. In either case the cloth was variegated in conformity with the prescribed *breacan*, or symbol of the clan; and hence the tartan was sometimes called *cath-dath*, or battle colours, in token of forming a distinction of clans in the field of battle.

According to the author of the 'Vestiarium Scoticum,' the following, in the reign of James VI., was the list of chief and subordinate clans, each possessing its own tartan; among these clans, it will be observed, are included certain Lowland families or houses, who had also adopted the same kind of cognisance:—

Clan Stewart—six colours, chiefly red, chequed with green, purple, black, white, and yellow.
Prince of Rothsay—three colours, chequed with green and white.
Royal Stewart—chiefly white, chequed with green, red, purple, and black.
Macdonald of the Isles—chiefly green, chequed with black, purple, red, and white.
Ranald—chiefly green, chequed with black, purple, red, and white.
Macgregor—chiefly red, chequed with green and white.
Ross—chiefly red, chequed with green and purple.
Macduff—chiefly red, chequed with green, black, and purple.
Macpherson—equal portions of black and white, with small lines of red and yellow.
Grant—chiefly red, with cheques of green and purple.
Munro—chiefly red, chequed with black and white.
Macleod—chiefly yellow, chequed with black and red.
Campbell—chiefly green, chequed with black, purple, yellow, and white.
Sutherland—chiefly green, with black, purple, red, and white.
Cameron—chiefly red, chequed with green and yellow.
Macneil—chiefly green, with purple, black, white, and red.
Macfarlane—very dark, being chiefly black chequed with white.
Machlachlan—chiefly yellow, with cheques of brown.
Gillean or Maclean—chiefly green, chequed with black and white.
Mackenzie—nearly equal portions of green and purple, chequed with black, white, and red.
Fraser—chiefly red, chequed with purple, green, and white.
Menzies—equal portions of red and white.
Chisholm—chiefly red, chequed with purple, green, and white.
Buchanan—chiefly red and white, with small black stripes.
Lamont—chiefly green, chequed with black, purple, and white.
Macdougall—chiefly red, chequed with black, purple, and green.
Mackintyre—chiefly green, chequed with purple, red, and white.
Robertson—chiefly red, chequed with purple and green.
Macnab—chiefly red, chequed with crimson, green, and black.
Mackinnon—chiefly red, chequed with green, black, and white.
Mackintosh—chiefly red, chequed with green, black, and white.
Farquharson—chiefly green, with purple, black, red, and yellow.
Gun—chiefly green, chequed with black and red.
Macarthur—chiefly green, chequed with black and yellow.
Mackay—chiefly a bluish-purple, with black and red cheques.
Macquean—nearly equal portions of red and black, with yellow.
Bruce—chiefly red, with green, yellow, and white.
Douglas—very dark, being equal cheques of black and slate colour.
Crawford—equal portions of red and green, with white.
Ruthven—chiefly red, with purple and green.
Montgomery—chiefly light green, chequed with purple.
Hamilton—chiefly red, with purple and white.
Wemyss—chiefly red, chequed with black, white, and green.
Cumyn—chiefly red, with green, black, and white.
Sinclair—chiefly green, chequed with black, purple, red, and white.
Dunbar—chiefly red, chequed with green and black.
Leslie—chiefly red, chequed with purple, black, and yellow.
Lauder—chiefly green, with purple, black, and red.
Cunningham—chiefly red, with black, purple, and white.
Lindsay—chiefly red, with purple and green.
Hay—chiefly red, with green, yellow, white, and black.
Dundas—chiefly green, with purple, black, and red.
Ogilvie—chiefly green, beautifully chequed with purple, black, yellow, and red.
Oliphant—equal portions of green and purple, with black and white.
Seton—chiefly red, with small lines of green, black, purple, and white.
Ramsay—chiefly red, with black squares chequed with white.
Erskine—red and green.
Wallace—red and black, chequed with yellow.
Brodie—chiefly red, with black and yellow.
Barclay—chiefly light-green and purple, chequed with red.
Murray—chiefly green, chequed with black, purple, and red.
Urquhart—chiefly green, with black, purple, white, and red.
Rose—chiefly red, with small cheques of purple, green, and white.

Colquhoun—green, purple, black, red, and white.
Drummond—chiefly red, with green and dark red.
Forbes—chiefly green, with black, red, and yellow.
Scott—chiefly red, with green, red, and black.
Armstrong—chiefly green, with black, purple, and red.
Gordon—chiefly green, with purple, black, and yellow.
Cranstoun—yellowish-green, with purple and red.
Graham—chiefly green, with black chequers.
Maxwell—chiefly red, with green and black.
Home—dark purple, with black, red, and green.
Johnstone—chiefly green, with purple, black, and yellow.
Ker—chiefly red, with black and green.

To this list the names of other Scottish families who have adopted a peculiar set of tartan as a cognisance could be added, and probably the entire number of tartans now fabricated for indiscriminate sale is not fewer than a hundred. One of the most commonly used patterns of tartan is that adopted by the 42d regiment—dark-green, chequed with purple. Some of what are called fancy tartans are gaudy, but not in good harmony or contrast of colour.

Suddenly in 1747, with the view of breaking the spirit of the clans, a law was enacted proscribing the use of the Highland dress, including the tartan in all its varieties. The following is the provision in the act of parliament on the subject:—'That from and after the 1st day of August 1747, no man nor boy, within that part of Great Britain called Scotland, other than such as shall be employed as officers and soldiers in his majesty's forces, shall, on any pretence whatever, wear or put on the clothes commonly called Highland clothes—that is to say, the plaid, philibeg, or little kilt, trowse, shoulder-belts, or any part whatsoever of what peculiarly belongs to the Highland garb; and that no tartan or party-coloured plaid or stuff shall be used for greatcoats or for uppercoats; and if any such person shall presume, after the said first day, to wear or put on the aforesaid garments, or any part of them, every such person offending, being convicted by the oath of one or more credible witnesses before any court of justiciary, "shall suffer imprisonment, without bail, during the space of six months;" and being convicted for a second offence, shall be transported to any of his majesty's plantations beyond seas, there to remain the space of seven years.' This contemptible law was repealed in the year 1782; but before that time the tartan and the 'garb of old Gaul' had been generally abandoned, except among Highland regiments, and it is chiefly copies from their attire that have guided modern attempts at reviving the costume.

As modernised and improved by the Highland regiments, the 'belted plaid,' worn as the philibeg or small kilt, with a separate drapery depending from the shoulder in imitation of the ancient garb, is one of the most picturesque and graceful costumes to be seen in any part of the world; and although it leaves the legs bare at and a short way above the knee, we are assured that it is by no means too meagre an attire for cold weather. Anciently, the Gael wore no shoes or garments for the legs. The feet were only on occasions covered with pieces of hide, tied with a thong, called *brogs*, which, though slender, were very lasting, and were well suited for walking or running on heathy mountains. The introduction of shoes, and also hose, formed from the same tartan cloth as the kilt, is comparatively modern. The hose of the common men in the Highland regiments are still not knitted or wove like stockings, but cut from the web and sewed. It appears that even in ancient times the Celtic tribes did not always wear the loose garments we have described; but that they also, or at least some of them, wore the *triughas* or *trius*, a species of vestment 'formed of tartan cloth, nicely fitted to the shape, and fringed down the leg.'

The coat, in which the upper part of the body and arms of the Highlanders are now invested, is of course quite modern, having come into use when the old form of the plaid dress was laid aside. Made, as it usually is, with short skirts and small round buttons, it cannot be considered in harmony with the rest of the attire; but it is nevertheless convenient.

The bonnet has for ages been a part of the Highland costume, as it was formerly also of the Lowlanders, and of the English, previous to the introduction of felt hats. The English gave up bonnets sooner than the Scotch; and ultimately the cry that 'the blue bonnets had come over the Border,' was equivalent to saying that a party of Scotch marauders had entered England on one of their usual hostile excursions. The Highlanders, with whom the bonnet has remained longest as a part of ordinary dress, have adopted very many shapes and modes of ornamenting their head-gear. The heavy plume of black feathers used in the army is quite modern, and in exceedingly bad taste, besides being totally unconformable to the idea of a primitive and light costume. The true bonnet of the Highlands is small, either round or peaked in front, as in the adjoining cut, dark blue or gray in colour, and without any tartan or chequering. In fancy dress, however, the bonnet is somewhat larger, and occasionally has a band of tartan. Highland chiefs were distinguished by three pinion feathers of the native eagle stuck in the bonnet; and those who enjoyed the rank of gentlemen were entitled to wear a single feather. It was customary also for the members of each clan to wear in the bonnet a peculiar badge formed of some native shrub. Authorities differ as to the precise shrubs worn for this purpose. The Buchanans used a sprig of bilberry; the Camerons, crowberry; the Campbells, fir-club-moss; the Forbeses, broom; Frasers, yew; &c.

The full dress of Highland chiefs and gentlemen has always been liberally ornamented with sword, baldrick, dirk, large brooches, buckler, shot pouch, and purse. The purse or sporan is a most important part of the costume; it is formed of the skin of a wild animal with the hair on, and tied to the waist by a band, hangs down in front, so as to fall easily upon the lap, and not incommode the legs in walking. It is usually ornamented with silver tags and tassels, and a flap covering the mouth of the purse is sometimes decorated with the visard of a fox. 'In many cases,' says Logan in his 'Scottish Gael,' 'the purse is composed of leather, like a modern reticule. It is formed into several distinct pockets, in which the Gael carried their money, watch, &c. and sometimes also their shot; but anciently they bore a similar wallet or *baily* at the right side, for the shot, or for a quantity of meal or other provision. This was termed *dorlach*, and was the knapsack of the Highland soldier; and small as that of the present military is, among the Gael it was still more portable. "Those of the English who visited our camp," says an author quoted by Jameson, "did gaze with admiration upon these supple fellows, the Highlanders, with their plaids, targets [shields], and dorlachs." The purse admits of much ornament, but according to my taste, when too large, it hides the beauty of the kilt.'

After a period of indifference to the preservation of the Highland dress, there has latterly sprung up a better tone of feeling on the subject among Lowlanders as well as Highlanders. At the same time, it is employed only as a fancy costume on festive or gala occasions; and in the Highlands, the ordinary dress of the English is in common use.

INDEX, AND GLOSSARY OF TERMS.

*** The Figures in the columns indicate the pages of the Text in which the particular term or subject is fully explained.

Abacus (Gr. *abax*, a slab), in Architecture, the upper part or crowning member of the capital of a column.

Abbatoir (Fr. *abbatre*, to knock down), a building appropriated to the slaughtering of cattle. See requirements of, 479.

Abdomen (Lat. *abdo*, I hide or cover), the large cavity, commonly known as the belly, containing the organs more immediately concerned in the process of digestion, as the stomach, liver, spleen, bowels, &c.

Abductor (Lat. *abducere*, to lead or draw from), the term given to those muscles which serve to open or draw back parts of the body; their opposites or antagonists are termed Adductor.

Aberration of light (Lat. *ab*, from, and *erro*, I wander), in Astronomy, 13; and in Optics, 249.

Abracadabra, a celebrated term of incantation, used as a spell against fevers. It was written thus,

A B R A C A D A B R A
A B R A C A D A B R
A B R A C A D A B
A B R A C A D A
A B R A C A D
A B R A C A
A B R A C
A B R A
A B R
A B
A

and suspended from the neck of the patient.

Abranchia (Gr. *a*, not—*branchia*, gills), animals destitute of gills, and having no apparent external organs of respiration.

Abstergent, abstersive (Lat. *abstergere*, to cleanse from), having the property of cleansing.

Acanthopterygii, a Cuvierian order of fishes, 157.

Acanthus, acanthads, acanthaceæ, in Botany, 106.

Acaridæ (Gr. *acari*, a mite), the mite family, 172.

Acclimatise, to accustom to a foreign climate; to inure to the temperature of a new climate: a term applied alike to plants and animals.

Achromatic (Gr. *a*, without, and *chroma*, colour), in Optics, applied to lenses, 252.

Acids, in Chemistry, 292; acidulous, slightly acid; acidulated, made slightly acid.

Acotyledon, acotyledonous (Gr. *a*, not—*cotyledon*, seed-lobe), plants whose seeds have no cotyledons or seed-lobes, in Botany, 91.

Acoustics, 254-256.

Acrogens, acrogenous (Gr. *acros*, the point or apex, and *gennao*, I produce), a term applied to those plants which, like the tree-ferns, increase by additions to the growing point, and never augment in thickness after once formed, 111-112.

Actinia or sea-anemone, its structure, 189.

Actinometer (Gr. *actin*, a ray—*metron*, measure), an instrument invented by Sir John Herschel for measuring the intensity of the sun's rays.

Action and reaction, in Natural Philosophy, 203.

Adamant, adamantine (Gr. *a*, not, and *damaō*, I break or conquer), a name given to different minerals of excessive hardness, as diamond and adamantine spar.

Adipocere (Lat. *adeps*, fat, and *cera*, wax), a fatty or waxen substance produced by the decomposition of the flesh of animals in moist situations or under water, resembling in some of its properties a mixture of fat and wax. It is found in damp grave-yards, in peat-bogs where animals have been accidentally entombed, and is also occasionally thrown up on the sea-shore after a storm. It has a chalky aspect, a soapy feel, is inflammable, and swims in water.

Aeliopyle (*Æolus*, the god of the winds, and *pila*, a ball), figured and described, 309.

Aërography (Gr. *aër*, the air, *grapho*, I write), the science which describes the composition, properties, uses, &c. of the air: seldom used as a technical term.

Aërolites (meteoric stones), theories respecting, 48.

Aërology (Gr. *aër*, the air, and *logos*, discourse), the doctrine of air—a term generally applied to medical discussions respecting its salubrity.

Aeronautics (Gr. *aër*, and *nautikos*, of or belonging to ships), the art of sailing in and navigating the air; aëronaut, one who so sails.

Aerostation (Gr. *aër*, and *stao*, I stand), means simply the weighing of the air; but has been employed (incorrectly) in the science of aëronautics, as the art of raising substances into the atmosphere by means of heated air or light gases. Hydrogen gas, or common coal-gas (carburetted hydrogen), is now generally used for this purpose. See p. 240.

Affinity or attraction, in Chemistry, 304.

Aftermath, in Agriculture; grass which is mown after the first crop of hay has been taken away, instead of being eaten off by stock.

Agate, varieties of in Mineralogy, 360.

Agriculture, 481-496; history of British, 481; implements and practice of, 480-485.

Air, laws of, 235; pressure of, 235-237; air-pump, 236; as necessary to health, 705.

Alabaster economically considered, 358.

Albino (Lat. *albus*, white), a term originally applied by the Portuguese to negroes who were born mottled or discoloured with white spots. It is now generally applied to persons and animals of a preternatural whiteness of the skin and hair, and a peculiar redness of the pupil of the eye, which is so weak as to be of little use in broad daylight. The disease appears to depend upon a deficiency or morbid state of the *rete mucosum* over the whole body.

Alcohol, in Dietetics, 736; in Medicine, 760.

Alder-tree, character and cultivation of, 108, 567.

Alembic, in Applied Chemistry, 308.

Alkalies, alkaline substances, in Chemistry, 292.

Alkalimeter, an instrument for ascertaining the proportion of alkali contained in any substance.

Alkanet (Fr.), a kind of reddish-purple dye of a resinous nature, obtained from the roots of the *Anchusa tinctoria*—a native of Southern Europe.

Alligators or caymans, family of, 153.

Alloy (Fr.), in Chemistry and Metallurgy, a term generally applied to all combinations obtained by fusing metals with each other: thus brass is an alloy of copper and zinc; bronze of copper and tin. When mercury is one of the combining metals, the compound is called an amalgam.

All-spice, or Jamaica pepper, in Cookery, the dried immature berry of the *Myrtus pimenta*. It is supposed to possess the mixed flavour of several spices.

Alluvium, alluvial (Lat. *ad*, to, *luo*, I wash); earth, sand, gravel, or other transported matter, which has been washed away and deposited by water upon land not permanently submerged beneath the waters of lakes or seas, is known by this term, 18. Most of the *straths* and *carses* in Scotland, and the *dales* in

Suppuration, the generation of *pus*, a thick diseased secretion, of yellowish hue.

Surgery, Household, 765-768.

Suture (Lat. *sutura*, a seam), in anatomy, the junction of the bones of the head by an irregularly-jagged zig-zag line, resembling the cross stitches of a seam.

Swallow family (*Hirundinidæ*), in Zoology, 146.

Swans, in Zoology, 152; domesticated, 637.

Swarming of the honey-bee, 643, 651.

Swine (Lat. *sus*); hence *Suidæ*, the pig family, 140.

Sword-fish, *Xiphias*, its habits, 157.

Sycamore or plane, nature and culture of, 565.

Syenite (Syene in Egypt), a variety of granite, 22.

Synchronal, synchronous (Gr.), occurring at the same period of time; simultaneous.

Synchronism, a word expressing the simultaneous occurrence of two events.

Synclinal (Gr. *syn*, together, and *clino*, I bend), bending together, or towards one point, such as the sides of a basin towards the bottom.

Syncopé, a faint or swoon, in Surgery, 766.

Synthesis (Gr. a joining or putting together). In chemistry, p. 290, the operation of joining or uniting simple substances; opposed to analysis. Water is proved to consist of oxygen and hydrogen by *analysis*—that is, by decomposing water, and ascertaining its constituents; it may, however, be proved to consist of oxygen and hydrogen by *synthesis*—that is, by uniting the relative proportions of oxygen and hydrogen, which form water.

Syphons (Gr. *siphōn*, a tube), in Pneumatics, 230; syphon-pipes, in supply of water, 467.

Syrups, preparation of, in Medicine, 754.

System (Gr. *systema*), a composition; a composition of many things acting harmoniously together. 'In science and philosophy, a system is a whole plan or scheme, consisting of many parts, connected in such a manner as to create a chain of natural dependencies; or a regular union of principles or parts, forming one entire thing. Thus we say the planetary *system*, or the whole of the bodies supposed to belong to each other; a *system* of botany, or that which comprehends the whole science of plants; a *system* of philosophy, or a theory or doctrine which embraces the whole of philosophy. The great utility of *systems* is to classify the individual subjects of our knowledge in such a way as to enable us readily to retain and employ them, and at the same time to illustrate each by showing its connection with all.'

Tabasheer, a siliceous concretion found in the joints of the bamboo, 19.

Table-lands and mountains of the globe, 56.

Tadpole, a young frog, before it has disengaged itself from the membranes, which envelope it in its first or aquatic stage of existence.

Talc and mica, in mineral economy, 361.

Talpidæ (Lat. *talpa*, mole), the mole family, 133.

Talus; when fragments are broken off by the action of the weather from the face of a steep rock, as they accumulate at its base, they form a sloping bank, called a *talus*.

Tannin, and tanning in leather manufacture, 313.

Tape-worm (*Tænia*), in Zoology, 176.

Tapestry, manufacture of, 347.

Tapioca, manufacture and dietetic uses, 725.

Tardigrada (Lat. *tardus*, slow, *gradus*, a pace), the technical term for the sloth family, 139.

Tartans, in Highland costume, 763.

Taste, sense of, physiologically considered, 123.

Tatooing, barbarous practice of, 774.

Taxodon, the name given by Professor Owen to a fossil animal discovered by Mr Darwin in the upper tertiaries of South America. The name is assigned from the curvature of the teeth, which seem to indicate that the animal belonged to the order Rodentia, though fully as large as the hippopotamus.

Tea, in Botany, 94; in dietetics, 735.

Teazle, use of, in woollen manufacture, 346.

Technology (Gr. *technē*, art, and *logos*, a discourse), a treatise on the arts. Hence the epithet *technical*, denoting something belonging to art.

Teeth, of man and other animals, 119.

Telegraph, a word signifying 'writing to or for a distant point, and applied to the various inventions by which news are communicated between distant spots by flags or other means.'

Telescopes, refracting and reflecting, 252.

Tellurium, one of the metallic elements, 301.

Temperaments, physiologically considered, 125.

Temperature, internal, of the globe, 63.

Temperature of the body, in hygiene, 715.

Tempering, the term applied to the hardening of steel by suddenly plunging it while red-hot into cold water. No other metal possesses this property, 376.

Tentacles, tentacula, the organs of feeling, prehension, and motion, in various insects and other animals, and sometimes viewed also as organs of hearing.

Terbium, a recently-discovered metallic element, 300.

Teredo navalis, structure of, in Zoology, 183.

Termites, or white ants, in Zoology, 166.

Terra-cotta, an Italian word signifying baked clay, and applied to a class of relics of art, such as vases and the like, formed from that substance, and found in considerable quantities in Tuscany. In pottery, 327.

Terrier dog, varieties of, 663.

Tertian, an ague of which there are two paroxysms every three days.

Tertiary formation, in Geology, described, 29-30.

Tesselated (*tessera*), formed in little squares or mosaic work, as a tesselated pavement.

Tests and test tubes, in Applied Chemistry, 306.

Testudo, the tortoise tribe of Animals.

Tetanus, the technical term for *locked jaw*.

Textile Manufactures, 337-352.

Thallus (Gr. *thallus*, a green leaf), in botany, a name given to the frond, or leaf-like part, of certain plants. Lichens are stemless, leafless plants, consisting of a tough wrinkled substance, called a *thallus*; hence the term *Thallogens*, in systematic classification.

Theatrical representations as an amusement, 717.

Theca, a spore-case or sheath, in botany, 75.

Theory, 'a doctrine which confines itself to the speculative parts of a subject without regard to its practical application or illustration. An exposition of the principles of any science, as the theory of music. The philosophical explanation of phenomena, either physical or moral, as Newton's *theory* of optics; Smith's *theory* of moral sentiments. *Theory* is distinguished from *hypothesis*, thus: a theory is founded on inferences drawn from the principles which have been established on independent evidence; a hypothesis is a proposition assumed to account for certain phenomena, and has no other evidence of its truth, than that it affords a satisfactory explanation of those phenomena.'

Therapeutics, a term applied to the study of the symptoms of disease and its remedies, and denoting, in short, the healing art generally.

Thermal (Gr. *therme*, heat), warm or hot. Thermal and igneous are sometimes used indiscriminately; but it is more accurate to make a distinction. Thus, in treating of volcanoes, we speak of *igneous agency*; in treating of hot-springs, *thermal* is the more appropriate term. *Thermæ*, hot baths.

Thermometer, principles and construction of, 34.

Theroid animals. The termination *therium* (Gr. *therion*, a wild beast) is adopted in geology to designate certain classes of fossil mammalia whose structure and habits have not yet been fully established by anatomists. The individual animals are characterised by a prefix which applies to some peculiarity of form, the place where found, or the name of the discoverer. Thus we have the *deinotherium* (terrible wild beast); the *palæotherium* (ancient); the *anoplotherium* (unarmed, having no weapons of defence); the *megatherium* (great); the *elasmotherium* (from the laminated structure of its teeth); the *anthracotherium* (found
