INFORMATION FOR THE PEOPLE

EDITED BY

WILLIAM AND ROBERT CHAMBERS

VOLUME I

EDINBURGH

PUBLISHED BY WILLIAM AND ROBERT CHAMBERS

AND W S ORR LONDON

1848

PREFACE.

Six years have now elapsed since the completion of 'THE INFORMATION FOR THE PEOPLE' in its second and improved form. Owing to the rapid advance of almost every branch of science and art, this is a long period in the history of a work of the nature of an encyclopædia. It has therefore appeared proper that these volumes should be recast, so as to adapt them as nearly as possible to the present state of human knowledge.

Designed in an especial manner for the People, though adapted for all classes, the work will be found to comprise those subjects on which information is of the most importance; such as the more interesting branches of science—physical, mathematical, and moral; natural history, political history, geography, and literature; together with a few miscellaneous papers, which seemed to be called for by peculiar circumstances affecting the British people. Thus everything is given that is requisite for a *generally well-informed man* in the less highly-educated portions of society, and nothing omitted appertaining to intellectual cultivation, excepting subjects of professional or local interest. It will be understood, then, that the 'INFORMATION FOR THE PEOPLE' is not an encyclopædia in the comprehensive meaning of the word, but rather one embracing only the more important departments of general knowledge. The ruling object, indeed, has been to afford the means of *self-education*, and to introduce into the mind, thus liberated and expanded, a craving after still farther advancement.

The improvements of the present edition will be found very considerable. All the scientific treatises have been carefully remodelled, with due attention to recent discoveries. Subjects, the interest of which is past, have been omitted or greatly condensed, and others of a more enduring and important nature have taken their place. So much new information has been introduced, that the work is more encyclopædic than it has hitherto been. In the Index to each volume will be found an explanation of, or reference to, almost every subject necessary in ordinary circumstances to be known.

It is proper to mention that, in the preparation of this edition, great assistance has been rendered throughout by Mr DAVID PAGE, to whose varied talents we have on other occasions been in no small degree indebted.

W. AND R. C.

Edinburgh, November 1, 1848.

INFORMATION FOR THE PEOPLE.

ASTRONOMY.

Astronomy (from the Greek, *astron*, a star, and *nomos*, a law) is, comprehensively, that science which explains the nature and motions of the bodies filling infinite space, including our own globe in its character of a planet or member of the solar system. The science may be divided into two departments—1. *Descriptive Astronomy*, or an account of the systems of bodies occupying space; 2. *Mechanical Astronomy*, or an explanation of the physical laws which seem to have produced, and which sustain, the arrangements of the heavenly bodies, and of all the various results of the arrangement and relations of these bodies. *Uranography* is a subordinate department of the science, presenting an account of the methods which have been adopted by astronomers for delineating the starry heavens, and working the many mathematical problems of which they are the subject.

I. DESCRIPTIVE ASTRONOMY.

The early ideas of mankind respecting the objects described by astronomy, proceeded upon appearances which the uninstructed eye placed before them, and were far from being true. It was supposed that the earth was, as it seems, a fixed plain, or, at the most, a fixed sphere, with an outer sphere, forming the heavens, revolving around it once in the twenty-four hours. Even philosophers deemed the earth the central and most important object in the system, and regarded the heavenly bodies—the sun, moon, planets, and stars—as comparatively small objects, fixed in different crystal spheres, each of which observed its own laws of revolution, according to the apparent motions of the bodies fixed in it. It was not till after much study and investigation that even the most enlightened minds arrived at a knowledge of the truth; nor was it for some time longer that the idea of the earth not being in the centre of the system, or anything but a small and subordinate part of it, was generally admitted. There is no room here to trace all the steps by which the truth was ascertained, or to argue the uninstructed mind out of all its first and erroneous impressions. But it may be hoped that when the actual constitution of the heavens has been described, it will be possible to form some notion how the celestial objects in their real character and real arrangements happen to appear as they do to our eyes.

The field contemplated by the astronomer is no less than infinite space. So, at least, he may well presume space to be, seeing that every fresh power which he adds to his telescope allows him to penetrate into remoter regions of it, and still there is no end. In this space, systems, consisting of suns and revolving planets, and other systems again, consisting of a numberless series of such lesser systems, are suspended by the influence of gravitation, operating from one to another, yet each body at such a distance from another, as, though the mind of man can in some instances measure, it can in none conceive. We begin with what is usually called the Solar System—that is, the particular solar system to which our earth belongs, and of which the *Sun* is the centre.

THE SOLAR SYSTEM.

The solar system, so named from *sol* (Latin), the sun, consists of the sun in the centre, upwards of thirty ascertained planets, and an unknown number of bodies named comets. We say *ascertained* planets, because, from the recent discoveries of Leverrier and others, there seems a likelihood that we shall yet discover more bodies of this nature. The word planet is from the Greek, *planao*, I wander, because the few such bodies known to the ancients were chiefly remarkable in their eyes on account of their constantly shifting their places with reference to the other luminaries of the sky. Comets are so named from *coma* (Latin), a head of hair, because they consist of a long brush of luminous matter streaming from a point.

Planets.—Of the planets, there are eight which may be said to rank in the first class, in as far as they move in orbits considerably removed from each other, and are in this respect comparatively independent; while a group of small bodies, at least five in number, may be said to have but one orbitual part in the series, and thus to be only co-ordinate with one of the rest. These thirteen are called *primary* planets, to distinguish them from others which move round certain of the primaries, and which are called *secondaries*, or satellites, from *satelles* (Latin), originally signifying a life-guardsman, but, by a wider application, one who follows and serves another.

The primary planets are—Mercury, Venus, the Earth, Mars, Vesta, Ceres, Pallas, Juno, Astræa, Jupiter, Saturn, Uranus, and Neptune. Most of these names are derived from the fabulous divinities of ancient Greece. The Earth has one satellite, the Moon; Jupiter has four; Saturn, seven; Uranus is supposed to have six; and Neptune has one.

The planets move round the sun on nearly one level or plane, corresponding with the centre of his body, and in one direction, from west to east. The secondary planets, in like manner, move in planes round the centres of their primaries, and in the same direction, from west to east. These are denominated revolutionary motions; and it is to be observed that they are double in the case of the satellites, which have at once a revolution round the primary, and a revolution, in company with the primary, round the sun. The path described by a planet in its revolution is called its *orbit*. Besides this motion of revolution, each planet, secondary as well as primary, and the sun also, has a motion in its own body, like that of a bobbin upon a spindle. An imaginary line, forming, as it were, the spindle of the sun or planet, is denominated the *axis*; and the two extremities of the axis are called the *poles*. The axes of the sun and planets are all nearly at a right angle with the plane of the revolutionary movements. The motion on the axis is called the rotatory motion, from *rota*, the Latin for a wheel. The sun, the primary planets, and the satellites, with the doubtful exception of those attending on Uranus, and overlooking that of Neptune, as yet unascertained, move on their axes in the same direction as the revolutionary movements, from west to east.

The Sun is a sphere or globe, of 882,000 miles in diameter, or 1,384,472 times the bulk of the earth, moving round its axis in 25 days. When viewed through a telescope, the surface appears intensely bright and luminous, as if giving out both heat and light to the surrounding planets. But on this surface there occasionally appear dark spots, generally surrounded with a border of less dark appearance; some of which spots have been calculated to be no less than 45,000 miles in breadth, or nearly twice as much as the circumference of the earth. The region of the sun's body on which the spots appear, is confined to a broad space engirdling his centre. They are sometimes observed to come into sight at his western limb, to pass across his body in the course of twelve or thirteen days, and then disappear. At other times they are observed to contract with great rapidity, and disappear like something melted and absorbed into a boiling fluid. Upon the bright parts of the sun's body there are also sometimes observed streaks of unusual brightness, as if produced by the ridges of an agitated and luminous fluid. It has been surmised that the sun is a dark body, enveloped in an atmosphere adapted for giving out heat and light, and that the spots are produced by slight breaks or openings in that atmosphere, showing the dark mass within. Though so much larger than the earth, the matter of the sun is of only about a fourth of the density or compactness of that of our planet, or little more than the density of water.

The sun is surrounded to a great distance by a faint light, or luminous matter of extreme thinness, shaped like a lens or magnifying-glass, the body of the sun being in the centre, and the luminous matter extending in the plane of the planetary revolutions, till it terminates in a point. At particular seasons, and in favourable states of the atmosphere, it may be observed, before sunrise or after sunset, in the form of a cone pointing obliquely above the place where the sun is either about to appear, or which he has just left. It is termed the *Zodiacal Light*.

Mercury, the nearest planet to the sun, is a globe of about 3140 miles in diameter, rotating on its axis in 24 hours and 5½ minutes, and revolving round the central luminary, at a distance of 37,000,000 of miles, in 88 days. From the earth it can only be seen occasionally in the morning or evening, as it never rises before, or sets after the sun, at a greater distance of time than 1 hour and 50 minutes. It appears to the naked eye as a small and brilliant star, but when observed through a telescope, is horned like the moon, because we only see a part of the surface which the sun is illuminating. Mountains of great height have been observed on the surface of this planet, particularly in its lower or southern hemisphere. One has been calculated at 10¾ miles in height, being about eight times higher, in proportion to the bulk of the planet, than the loftiest mountains upon the earth. The matter of Mercury is of much greater density than that of the earth, equalling lead in weight.

Venus is a globe of about 7000 miles in diameter, or nearly the size of the earth, rotating on its axis in 23 hours 21 minutes and 19 seconds, and revolving round the sun, at the distance of 68,000,000 of miles, in 225 days. Like Mercury, it is visible to an observer on the earth only in the morning and evening, but for a greater space of time before sunrise and after sunset. It appears to us the most brilliant and beautiful of all the planetary and stellar bodies, occasionally giving so much light, as to produce a sensible shadow. Observed through a telescope, it appears horned, on account of our seeing only a part of its luminous surface. The illuminated part of Venus occasionally presents slight spots. It has been ascertained that its surface is very unequal, the greatest mountains being in the southern hemisphere, as in the case of both Mercury and the earth. The higher mountains in Venus have been estimated by some to range between 10 and 22 miles in altitude. The planet is also enveloped in an atmosphere like that of the earth; hence the probability that its surface supports a kindred vegetable and animal existence. Mercury and Venus have been termed the Inferior Planets, as being placed within the orbit of the earth.

The *Earth*, the third planet in order, and one of the smaller size, though not the smallest, is important to us, as the theatre on which our race have been placed to "live, move, and have their being." It is 7912 miles in mean diameter, rotating on its axis in 24 hours, at a mean distance of 95,000,000 of miles from the sun, round which it revolves in 365 days 5 hours 48 minutes and 49 seconds. As viewed from another of the planets, suppose the moon, "the earth would present a pretty, variegated, and sometimes a mottled appearance. The distinction between its seas, oceans, continents, and islands would be clearly marked; they would appear like brighter and darker spots upon its disk. The continents would appear bright, and the ocean of a darker hue, because water absorbs the greater part of the solar light that falls upon it. The level plains (excepting, perhaps, such regions as the Arabian deserts of sand) would appear of a somewhat darker colour than the more elevated and mountainous regions, as we find to be the case on the surface of the moon. The islands would appear like small bright specks on the darker surface of the ocean; and the lakes and mediterranean seas like darker spots or broad streaks intersecting the bright parts, or the land. By its revolution round its axis, successive portions of the surface would be brought into view, and present a different aspect from the parts which preceded."—*Dick's Celestial Scenery*, p. 135.

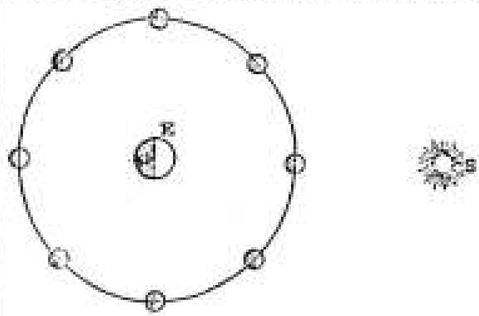
The form of the earth, and probably that of every other planet, is not strictly spherical, but oblately spheroidal; that is, flattened a little at the poles, or extremities of the axis. The diameter of the earth at the axis is 26 miles less than in the cross direction. This peculiarity of the form is a consequence of the rotatory motion, as will be afterwards explained.

The earth is attended by one satellite, the *Moon*, which is a globe of 2160 miles in diameter, and consequently about a 49th part of the bulk of the earth, revolving round its primary in 27 days 7 hours 43 minutes and 11 seconds, at the distance of 237,000 miles. The moon is 400 times nearer the earth than

Telescopic appearance of the Moon.

the sun is; but its diameter being at the same time 400 times less than that of the sun, it appears to us of about the same size. The moon rotates on her axis in exactly the same time as she revolves round the earth. She consequently presents at all times the same part of her surface towards the earth. Inspected through a telescope, her surface appears of unequal brightness, and extremely rugged. The dark parts, however, are not seas, as has been supposed, but more like the beds of seas, or great alluvial plains. No appearance of water, or of clouds, or of an atmosphere, has been detected. The surface presents numerous mountains, some of them about a mile and three-quarters in height, as has been ascertained by measurement of the shadows which they cast on the neighbouring surface. The tops of the mountains of the moon are generally shaped like a cup or basin, with a small eminence rising from the centre, like many volcanic hills on the earth. It has hence been surmised that the moon is in a *volcanic state*, as the earth appears to have been for many ages before the creation of man, and that it is perhaps undergoing processes calculated to make it a fit scene for animal and vegetable existence.

The moon, turning on its axis once in a little more than 27 days, presents every part of its surface in succession to the sun in that time, as the earth does in 24 hours. The *day* of the moon is consequently nearly a fortnight long, and its *night* of the same duration. The light of the sun, falling upon the moon, is partly absorbed into its body; but a small portion is reflected or thrown back, and becomes what we call *moonlight*. The illuminated part, from which we derive moonlight, is at all times increasing or diminishing to our eyes, as the moon proceeds in her revolution round our globe. When the satellite is at the greatest distance from the



Phases of the Moon.

sun, we, being between the two, see the whole of the illuminated surface, which we accordingly term *full moon*. As the moon advances in her course, the luminous side is gradually averted from us, and the moon is said to wane. At length, when the satellite has got between the earth and the sun, the luminous side is entirely lost sight of. The moon is then said to *change*. Proceeding in her revolution, she soon turns a bright edge towards us, which we call the *new moon*. This gradually increases in breadth, till a moiety of the circle is quite filled up; it is then said to be *half moon*. The luminary, when on the increase from *new* to *half*, is termed a crescent, from *crescens*, Latin for increasing; and this word has been applied to other objects of the same shape—for instance, to a curved line of buildings.

In the early days of the new moon, we usually see the dark part of the body faintly illuminated, an appearance termed the *old moon in the new moon's arms*. This faint illumination is produced by the reflection of the sun's light from the earth, or what the inhabitants of the moon, if there were any, might be supposed to consider as moonlight. The earth, which occupies one invariable place in the sky of the moon, with a surface thirteen times larger than the apparent size of the moon in our eyes, is then *at the full*, shining with great lustre on the sunless side of its satellite, and receiving back a small portion of its own reflected light. The light, then, which makes the dark part of the moon visible to us, may be said to perform three journeys—first from the sun to the earth, then from the earth to the moon, and finally from the moon back to the earth—before our eyes are enabled to perceive this object.

Mars, the fourth of the primary planets, is a globe of 4189 miles in diameter, or little more than a half of that of the earth; consequently, the bulk of this planet is only about a fifth of that of our globe. It performs a rotation on its axis in 24 hours 39 minutes and 21⅔ seconds, and revolves round the sun, at a distance of 144,000,000 of miles, in 686 days 22 hours and 18 seconds. Mars appears to the naked eye of a red colour; from which circumstance it was, probably, that the ancients bestowed upon it the name of the god of war. Inspected through a telescope, it is found to be occasionally marked by large spots and dull streaks, of various forms, and by an unusual brightness at the poles. As the bright polar parts sometimes project from the circular outline of the planet, it has been conjectured that these are masses of snow, similar to those which surround the poles of the earth.

Vesta, Ceres, Pallas, Juno, and *Astræa*, are five small globes, revolving between the orbits of Mars and Jupiter, in paths near and crossing each other, and which are not only much more elliptical than the paths of the other planets, but also rise and sink much farther from the plane of the general planetary revolutions. *Vesta* is of a bulk only 1-24,000th part of the bulk of the earth, with a surface not exceeding that of the kingdom of France. It revolves round the sun in 3 years 66 days and 4 hours, at a mean distance of 225,500,000 of miles. Though the smallest of all the planets, it gives a very brilliant light, insomuch that it can be seen by the naked eye. *Juno* is 1425 miles in diameter, and presents, when inspected through the telescope, a white and well-defined appearance. Its orbit is the most eccentric of all the planetary orbits, being 253,000,000 of miles from the sun at the greatest, and only 126,000,000, or less than one-half, at the least distance. In the half of the course nearest to the sun, the motion of the planet is, by virtue of a natural law afterwards to be explained, more than twice as rapid as in the other part. *Ceres* has been variously represented as of 1624 and 160 miles in diameter. The astronomer who calculated its diameter at 1624 miles, at the same time believed himself to have ascertained that it has a dense atmosphere, extending 675 miles from its surface. It is of a reddish colour, and appears about the size of a star of the eighth magnitude. Ceres revolves round the sun, at a distance of 260,000,000 of miles, in 4 years 7 months and 10 days. *Pallas* has been represented as of 2099 miles in diameter, with an atmosphere extending 468 miles above its surface. Another astronomer has allowed it a diameter of only 80 miles. It revolves round the sun, at a mean distance of 266,000,000 of miles, in 4 years 7 months and 11 days. However unimportant it may appear beside the larger planets, it has a peculiar interest in the eyes of astronomers, on account of its orbit having a greater inclination to the plane of the ecliptic than those of all the larger planets put together. *Astræa* revolves round the sun at a mean distance of 247,000,000 of miles in 1521 days. It is evident that these small planets are not distinct and independent in the same degree with Mercury, Venus, and the other primaries. Cosmogonists presume that the matter which in other cases has gone to form one planet of the first rank, has in their case been separated into several parts, assuming various but connected orbits.

These five planets, which are sometimes called *asteroids*, have only recently become known to mankind. Ceres was discovered at Palermo, in Sicily, on the 1st of January 1801, by M. Piazzi, who gave it this name in honour of the tutelary goddess of his native country. Pallas was discovered at Bremen, in Lower Saxony, on the 28th of March 1802, by Dr Olbers. Juno was discovered by Mr Harding, at the observatory of Lilienthal, near Bremen, on the 1st of September 1804. Vesta was discovered on the 29th of March 1807, by the same astronomer who had discovered Pallas. Astræa was not discovered till 1845. Even while we write (August 1847), other two have been announced as an addition to the group, under the names of *Hebe* and *Iris*.

Jupiter is the largest of all the planets. Its diameter is nearly eleven times that of the earth, or 89,170 miles, and its volume or mass is consequently 1281 times that of our globe. The density of Jupiter is only a fourth of that of the earth, or about the lightness of water. It performs a rotation on its axis in 9 hours 55 minutes and 33 seconds, or about two-fifths of our day. It revolves round the sun, at a distance of 490,000,000 of miles, in 4330 days 14 hours and 39 minutes, or nearly twelve of our years. Viewed through a telescope, Jupiter appears traversed by dark lines, or belts, which occasionally shift, melt into each other, or separate, but sometimes are observed with little variation for several months. These belts are generally near the equator of the planet, and of a broad and straight form; but they have been observed over his whole surface, and of a lighter, narrower, and more streaky and wavy appearance. It is supposed that the dark parts are lines of the body of the planet, seen through openings in a bright cloudy atmosphere.

Jupiter is attended by four satellites, which revolve round it, in the same manner as the moon round our globe, keeping, like it, one face invariably presented to their primary. They are of about the same size, or a little larger diameter than our moon; the first having a diameter of 2508, the second of 2068, the third of 3377, and the fourth of 2890 miles. The first revolves round the primary planet in 1 day 18 hours 28 minutes; the second in 3 days 13 hours 14 minutes; the third in 7 days 3 hours 43 minutes; and the fourth in 16 days 16 hours 32 minutes. These satellites frequently eclipse the sun to Jupiter; they are also eclipsed by the primary planet, but never all at the same time, so that his dark side is never altogether without moonlight.

The satellites of Jupiter were discovered by Galileo, being among the first results of the invention of the telescope. They have been of great use in several astronomical calculations of importance, particularly in suggesting the theory of the gradual propagation of light. It having been observed that their eclipses always took place sooner than was to be expected when the earth was near Jupiter, and later when it was at the greatest distance, an astronomer solved the difficulty by supposing that light required some time to travel—a conjecture which was afterwards confirmed by other observations.

Saturn, seen through a telescope, is the most remarkable of all the planets, being surrounded by a ring, and attended by seven satellites. In bulk, this is the second of the planets, being 79,042 miles in diameter, or about 995 times the volume of the earth. Its surface appears slightly marked by belts like those of Jupiter. It performs a rotation on its axis in 10 hours 16 minutes, and revolves round the sun, at a distance of 906,000,000 of miles, in 10,759 days 19 hours 16 minutes, or about 29½ of our years. At such a distance from the sun, that luminary must be diminished to one-ninetieth of the size he bears in our eyes, and the heat and light in the same proportion. The matter of Saturn is one-ninth of the density of our earth.

The ring of Saturn surrounds the body of the planet in the plane of its equator. It is thin, like the rim of a spinning-wheel, and is always seen with its edge presented more or less directly towards us. It is luminous with the sun's light, and casts a shadow on the surface of the planet, the shadow of which is also sometimes seen falling on part of the ring. The distance of the inner edge from the planet is calculated at about 19,000 miles; its entire breadth from the inner to the outer edge is 28,536; the thickness is not more than 100. In certain positions of the planet, we can see its surface at a considerable angle, and the openings or loops which it forms at the sides of the planet. At other times we see its dark side, or only its edge. From observations made upon it in favourable circumstances, it is found to be apparently divided near the outer edge by a dark line of nearly 1800 miles in breadth, as if it were divided into two concentric rings. From other appearances, it has been surmised to have other divisions, or to be a collection of several concentric rings. It is also occasionally marked by small spots. The ring of Saturn rotates on its own plane in 10 hours 32 minutes 15 seconds and a part of a second, being about the same time with the rotation of the planet.

The seven satellites of Saturn revolve around it, on the exterior of the ring, and almost all of them in nearly the same plane. They are so small, as not to be visible without a powerful telescope. The two inner ones are very near to the outer edge of the ring, and can only be discerned when that object is presented so exactly edgeways as to be almost invisible. They have then been seen passing, like two small bright beads, along the minute thread of light formed by the edge of the ring. The three next satellites are also very small; the sixth is larger, and placed at a great interval from the rest. The seventh is the largest; it is about the size of the planet Mars, and is situated at nearly thrice the distance of the sixth, or about 2,300,000 miles from the body of Saturn. The revolutions of these satellites range from 1 to 79 days; and it has been ascertained of some of them that, according to the usual law of secondary planets, their rotations on their axes and their revolutions round their primary are performed in the same time, so that, like our moon, they always present the same face to the centre of their system. The orbit of the seventh satellite is much inclined to the plane of Saturn's equator.

Uranus, or Herschel, is a globe of 35,112 miles in diameter, rotating on its axis in 7 hours, and performing a revolution round the sun, at the distance of 1,823,000,000 of miles, in 84 of our years. It was discovered, on the 13th of March 1781, by Sir William Herschel, at Bath. The sun to this remote planet must appear only a 400th part of the size which he bears in our eyes. Two satellites are known, and other four are suspected, to attend upon Uranus. The two which have been observed circulate round their primary in orbits almost perpendicular to the ecliptic, and are further supposed to move in a direction contrary to that of all the other planetary motions—namely, from east to west.

The existence of *Neptune* was ascertained by calculation by M. Leverrier of Paris, in September 1846, and the planet was consequently detected at the first search for it by M. Galle of Berlin. Having a diameter of 50,000 miles, it ranks as the third planet of our system in point of magnitude; it is nearly 2,900,000,000 of miles distant from the sun, from which it receives only a nine-hundredth part of the light which falls on our sphere. Its year is 167 of ours, or 60,986 days, and it has already been ascertained to be attended by at least one satellite, and to be surrounded by a ring like that of Saturn.

Some idea may be obtained of the comparative size of the principal objects of the solar system, by supposing a globe of two feet diameter, placed in the centre of a level plain, to represent the sun; a grain of mustard-seed, placed on the circumference of a circle 164 feet in diameter, for Mercury; a pea, on a circle of 284 feet, for Venus; another pea, on a circle of 430 feet, for the Earth; a large pin's head, on a circle of 654 feet, for Mars; four minute grains of sand, in circles of from 1000 to 1200 feet, for Vesta, Ceres, Pallas, Juno, and Astræa; a moderate-sized orange, on a circle of nearly half a mile in diameter, for Jupiter; a small orange, on a circle four-fifths of a mile in diameter, for Saturn; a small plum, on a circle of a mile and a-half in diameter, for Uranus; and an ordinary plum, on a circle of two miles and a-half, for Neptune. It is calculated that the united mass of the whole of the planets is not above a 600th part of the mass of the sun.

COMETS.

Comets are light vapoury bodies, which move round the sun in orbits much less circular than those of the planets. Their orbits, in other words, are very long ellipses or ovals, having the sun near one of the ends. Comets usually have two parts—a body or nucleus, and a tail; but some have no tail, while others have no apparent body. The nucleus of some appears opaque and brilliant; in others it is vaporiform, and so thin, that the stars have been seen through it. The tail is a

still lighter luminous vapour, surrounding the body, and streaming far out from it in the direction contrary to its forward motion. A vacant space has been observed between the body and the enveloping matter of the tail; and it is equally remarkable that the tail has in some instances appeared less bright along the middle, immediately behind the nucleus, as if it were a stream which that nucleus had in some measure parted into two.

In ignorant ages, the sudden appearance of a comet in the sky never failed to occasion great alarm, both on account of its threatening appearance, and because it was considered as a sign that war, pestilence, or famine was about to afflict mankind. Knowledge has dispelled all such superstitious alarms; but yet we are not well acquainted with the nature of comets, either as regards their revolutions, or the properties of their physical constitutions.

Out of the great multitude—certainly not less than 1000—which are supposed to exist, about 150 have been made the subject of scientific observation. Instead of revolving, like the planets, nearly on the plane of the sun's equator, it is found that they approach his body from all parts of surrounding space. At first, they are seen slowly advancing, with a comparatively faint appearance. As they approach the sun, the motion becomes quicker, and at length they pass round him with very great rapidity, and at a comparatively small distance from his body. The comet of 1680 approached within one-sixth of his diameter. After passing, they are seen to emerge from his rays, with an immense increase to their former brilliancy, and to the length of their tails. Their motion then becomes gradually slower, and their brilliancy diminishes, and at length they are lost in distance. It has been ascertained that their movement round the sun is in accordance with the same law which regulates the planetary movements, being always the quicker the nearer to his body, and the slower the more distant. In the remote parts of space their motions must be extremely slow.

Three comets have been observed to return, and their periods of revolution have been calculated. The most remarkable of these is one usually denominated Halley's Comet, from the astronomer who first calculated its period. It revolves round the sun in about seventy-five years, its last appearance being at the close of 1834. Another, called Encke's Comet, from Professor Encke of Berlin, has been found to revolve once in 1207 days, or $3\frac{1}{3}$ years; but in this case the revolving body is found, at each successive approach to the sun, to be a little earlier than on the previous occasion, as if, from some retarding cause, its orbit were gradually lessening, and as if the comet might consequently in time fall into the sun. The third, named Biela's Comet, from M. Biela of Josephstadt, revolves round the sun in $6\frac{3}{4}$ years. It is very small, and has no tail. In 1832, this comet passed through the earth's path about a month before the arrival of our planet at the same point. If the earth had been a month earlier at that point, or the comet a month later in crossing it, the two bodies would have been brought together, and the earth, in all probability, would have instantly become unfit for the existence of the human family. Comets are often affected in their motions by the attraction of the planets. Jupiter, in particular, has been described by an astronomer as a perpetual stumblingblock in their way. In 1770, a comet got entangled amidst the satellites of that planet, and was thereby thrown out of its usual course, while the motions of the satellites were not in the least affected by its proximity.

Comets often pass unobserved, in consequence of the part of the heavens in which they move being then under daylight. During a total eclipse of the sun, which happened sixty years before Christ, a large comet, not formerly seen, became visible, near the body of the obscured luminary. On many occasions their smallness and distance render them visible only by the aid of the telescope; on other occasions they are of vast size. The comet now called Halley's, at its appearance in 1456, covered a sixth part of the visible extent of the heavens, and was likened to a Turkish scimitar. That of 1680, which was observed by Sir Isaac Newton, had a tail calculated to be 160,000,000 of miles in length, a space greater than the distance of the earth from the sun. There was a comet in 1744, which had six tails, spread out like a fan across a large space in the heavens. The tails of comets usually stretch in the direction opposite to the sun, both in advancing and retiring.

THE STARS.

The idea at which astronomers have arrived respecting the stars, is, that they are all of them suns, resembling our own, but diminished to the appearance of mere specks of light by the great distance at which they are placed. As a necessary consequence to this supposition, it may be presumed that they are centres of light and heat to systems of revolving planets, each of which may be further presumed to be the theatre of a vital existence.

The stars seen by the naked eye on a clear night are not above a thousand in number. This, allowing a like number for the half of the sky not seen, gives about two thousand in all of visible stars. These are of different degrees of brilliancy, probably in the main in proportion to their respective distances from our system, but also perhaps in some measure in proportion to their respective actual sizes. Astronomers class the stars under different *magnitudes*, not with regard to apparent size, for none of them present a measurable disk, but with a regard to the various quantities of light flowing from them: thus there are stars of the first magnitude, the second magnitude, and so on. Only six or seven varieties of magnitude are within our natural vision; but with the telescope, vast numbers of more distant stars are brought into view; and the magnitudes are now extended by astronomers to at least sixteen.

The stars are at a distance from our system so very great, that the mind can form no idea of it. The brilliant one called Sirius, or the Dog-star, which was supposed to be the nearest, but merely because it is the most luminous, has been reckoned by tolerably clear calculation to give only 1-20,000,000th part of the light of the sun: hence, supposing it to be of the same size, and every other way alike, it should be distant from our earth not less than 1,900,000,000,000,000,000 miles. An attempt has been made to calculate the distance of Sirius by a trigonometrical problem. It may be readily supposed that the position of a spectator upon the earth with respect to celestial objects must vary considerably at different parts of the year: for instance, on the 21st of June, he must be in exactly the opposite part of the orbit from what he was on the 21st of December—indeed no less than 190,000,000 miles from it. The apparent change of position of celestial objects in consequence of this movement is called *parallax*. Now, it has been found that Sirius is so distant, that an angle formed between it and the two extremities of the earth's orbit is too small to be appreciated. Were it so much as one second, or the 3600th part of a degree, it could be appreciated by the nice instruments we now possess; but it is not even this. It is hence concluded that Sirius must be at least 19,200,000,000,000 miles distant, however much more! Supposing this to be its distance, its light would take several years to reach us, though travelling, as it does, at the rate of 192,000 miles in a second of time!

It is ascertained, beyond doubt, that some stars, at one time visible, and registered by ancient astronomers, are not now to be seen; while many instances are on record of stars which have come into sight for a time, and then gradually vanished. A large star suddenly became visible 125 years before Christ, and attracted the attention of Hipparchus, who was thereby induced to draw up a catalogue of stars, the first ever made. In the year 389, a star blazed forth in the constellation Aquila,* and after remaining for three weeks as bright as the planet Venus, disappeared. A star appeared in the region of the heavens between Cepheus and Cassiopeia in the years 945, 1264, and 1572, and is supposed to be one which comes within our sight once every three hundred and nineteen years, or thereby. At its last appearance, it was very attentively observed by the celebrated Danish astronomer Tycho Brahé, who published a volume respecting it. Its appearance was so sudden, that, in returning from his laboratory to his dwelling-house, he found a group of country people gazing at it, and was satisfied it had not been in that quarter of the sky half an hour before. It was then as bright as Sirius, and continued till it surpassed Jupiter when brightest, and was visible at mid-day. It disappeared entirely about eighteen months after being first observed. Another bright star appeared, in the constellation Serpentarius, in October 1604, and remained for a year. It is mentioned by contemporary writers, that at the birth of Charles II., in 1630, a large star, never before observed, appeared in the daytime, as if to mark something extraordinary in the fortunes of the child that day ushered into existence. Other instances have been noticed in still more recent times; but, upon the whole, this is a point in which astronomical observation is defective. It seems, however, to be clearly ascertained that some, if not all of the stars, have periodical motions throughout space, some more rapid than others. In several of the instances where the period is short, there is no want of positive knowledge. It has been ascertained, for instance, that the star Omicron, in Cetus, has a periodical movement occupying 334 days. It is seen as bright as a star of the second magnitude for about a fortnight; then gradually diminishes for three months, till it becomes invisible, in which state it remains for five months, when it again becomes visible, and gradually increases till it regains its former brightness, more or less—for it does not always reach the same degree of lustre. The star Algol, in the constellation Perseus, continues visible during a period of sixty-two hours, when it suddenly loses its splendour, and from a star of the second magnitude, is reduced, in three hours and a-half, to the fourth; after which it begins to increase, and in three hours and a-half resumes its former size. There are eleven other stars which exhibit analogous phenomena, some of them at intervals of five hundred years, to which we may look forward without any danger of mistake. Astronomers have long been of opinion that our solar system might have a motion through space. From recent observations, it is now believed to have such a motion; nay, the whole of the stars of our cluster appear as moving round a fixed point. The situation of this point has been determined by Dr Mädler of Dorpat as in the small group of stars called the Pleiades. The distance of our sun from that point is calculated at 34,000,000 of times that of the earth from the sun. Dr Mädler considers that the stars are crowded immediately round the centre; then a belt of comparatively vacant space; then again a crowded belt; and so on alternately to the extremity. Our sun is supposed to

* It may be stated here, in anticipation of more particular explanations to be given afterwards, that the starry heavens are by astronomers mapped out into a series of constellations, or assemblages of stars, each of which bears the name of some figure or other object—as *Aquila* the Eagle, *Cetus* the Whale, *Castor* and *Pollux*, twin demigods of the Greek mythology, &c. Each particular star in a constellation, in the order of its magnitude, is distinguished by a letter of the Greek alphabet, and when those are exhausted, with a number.

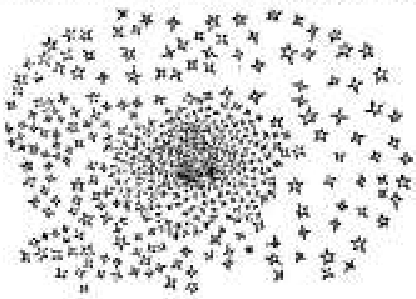
revolve round a central sun, at the rate of 2,200 miles a minute; yet the whole revolution requires 18,200,000 of our years!

Another variety in the nature of these luminaries is their being in some instances not *single* stars, as they appear to the naked eye, but a group of two or more, evidently, from their motions, forming one system. The star Castor, in one of the Twins, is found, when much magnified, to consist of two stars, of between the third and fourth magnitude, within five seconds (a very small space) of each other. Sir William Herschel made observations upon more than 500 stars of this kind, where the distance is not more than half a minute (also a very small space); and to this list a foreign astronomer has added five times that number. Nor is there reason to suppose that, in *all* these instances, one of the stars is at a great distance behind the other, and that they are only brought together by the accident of our position. Many of the double stars, no doubt, are thus accidentally brought together; but of a great number, it has been fully ascertained that they are each a system, with a reciprocal relation to each other. They are therefore called *Binary Stars*. It is generally observed that they move round each other within a certain time, and in elliptical orbits; the revolution of Castor, for instance, is supposed to be accomplished in 252 years; of ξ of Ursa Major, in 58¼ years; of 70 Ophiuchi, in 73 years. In fact, there is the same variety in this branch of the starry system as in its other departments, and the revolutions of the few binary stars that have been accurately surveyed range from 43 to 1200 years. Several of these duplicate stars have made a revolution since they were first observed, and are now advancing in their second period. One, ζ *Herculis*, was seen double, in 1782, by Sir William Herschel; in 1795, it was hardly distinguishable to be double; in 1802, it was double no longer, the one being eclipsed by the other, though a small part of one was still jutting out at the side of the other: astronomers are now watching to observe them once more become separate. Whether one of these stars serves to the other as a sun, or whether both are suns, or whether the organized life with which they are probably stored be of a kind which can endure a perpetual light and heat thrown from the one to the other—or in what other manner these immense worlds are put to use—it would be vain to inquire. One remarkable peculiarity in them is, the variety of tints apparent in the light emitted by a considerable number of them; but no accurate account has yet been given of the reason of this wonderful difference of colour in the stars.

Perhaps the most magnificent of all the starry phenomena is the *Milky Way*. This, as is generally known, is a broad belt, of whitish lustre, which stretches round the whole sky, being parted into two streaks for a large part of the circuit. The ancients formed the mean idea of this light, that it was the milk spilt by the nurse of Mercury, one of the deities; hence its name. When examined by a telescope, it is found to consist entirely of stars, "scattered by millions," as Sir John Herschel beautifully describes them, "like glittering dust on the black ground of the general heavens." The average magnitude of these stars is about the tenth or the eleventh, and hence their invisibility to the naked eye. It is a very remarkable circumstance, that, though the stars of the larger magnitudes are scattered with considerable equality over the whole heavens, there is a notable clustering of the smaller ones towards the body of this ring. Sir William Herschel, by gauging, as it were, the depth of our starry system in this and other parts, arrived at what he believed to be an approximation to the figure of the system itself—namely, an elongated cake-shaped mass, parting flatwise into two at one particular part of the exterior (where the Milky Way is double), and in which our solar system was placed somewhat nearer the one extremity than the other. Where the distance between two stars is so great as we have seen—and we can suppose the distance between all the rest to be no less—what must be the entire extent of this star-system, composed as it is of millions of millions of distinct bodies!

REMOTE STAR-SYSTEMS—NEBULÆ.

Our own star-system, inconceivably vast as it is, is but an item of the heavenly inventory. Far beyond its bounds, the telescope of Herschel has descried similar systems in great numbers, each hanging in some tolerably defined shape in the vast empyrean, and each capable of being resolved, not exactly into stars, though these are in some instances visible, but into what has been expressively called *star-dust*, a collection of small brilliant particles, each of which would probably appear a distinct sun under a stronger power of artificial vision. Observations have been made upon these star-systems chiefly in the direction of the thinner parts of our own system, where the sky is clearest of our own stars, and where of course they are most distinct from other and nearer objects. But even in those limited fields of the sky, very great numbers have been seen—between 1000 and 2000 in the northern hemisphere alone—a number, we must recollect, exceeding that of all the ordinarily visible stars in the same section of the heavens.



Remote Star-System.

They are of various forms, but in general, as has been said, tolerably well-defined. Many appear as spherical clusters, with a crowding of the star-dust towards the centre: of this kind there is a brilliant example in the constellation Hercules. It has been remarked, that in the worlds about the centre of such clusters, the visible heavens must be inconceivably brilliant, though they will have no appearances resembling our Milky Way. There is another spherical class, in which the external parts are the most brilliant: in these cases, the visible heavens of a world near the centre will probably be almost entirely composed of milky way. From our earth these annular clusters are presented in various points of view, some so nearly edgewise, that we can barely see the long line of thin matter in the centre. Several exhibit to Lord Rosse's telescope most remarkable and even startling forms; one being somewhat like an anchor, another like a crab, and so forth. Surprising to relate, there are more than one bearing a strong resemblance to the form which has been presumed as that of our own star-system—namely, a flattened mass, with a brilliant annular exterior, parting flatwise into two at one part! In the *Magellanic clouds*, a nebulous object in the southern hemisphere, there is one remote star-system (30 Doradûs), described by Sir John Herschel as "consisting of a number of loops united in a kind of nuclear centre or knot, *like a bunch of ribbons disposed in what is called a true-lover's-knot!*" "We are," says an astronomer who possesses eloquence worthy of his noble science, "lost in mute astonishment at these endless diversities of character and form. But in the apparent aim of things near and around us, we may perhaps discern some purpose which such variety will also serve. It seems the object or result of known material arrangements, to evoke every variety of creature, the condition of whose being can be made productive of a degree of durability; and perhaps it is one end of this wonderful evolution of firmaments of all orders, that there, too, the law of variety may prevail, and room be found for unfolding the whole riches of the Almighty." The vast general distance of these clusters, their distinctness from our own system, and their relative distances, have been determined by the comparative powers of the telescopes employed in observing them. Some of them are distant from us many thousands of times the distance of Sirius, the nearest of our own stars.

Astronomers have long had under their observation a set of peculiar objects, apparently within the limits of our star-system, and called *Nebulæ*, from their filmy cloud-like appearance. There is one of magnificent appearance in the girdle of the constellation Andromeda, and another still more splendid in the sword-hilt of Orion, both visible to the naked eye. Some of these objects are of irregular form, stretching like a fragment of semi-pellucid membrane over the sky, with patches of brighter matter scattered irregularly throughout their extent. In others, the bright patches are of greater intensity, so as to have the decided appearance of *gatherings* of the matter towards a particular point. Others there are, in which these bright parts seem nearly disengaged from the surrounding thin matter, or only bedded on a slight background composed of it. In a fourth class, we see detached masses, approaching more or less to a spherical form, and with various measures of comparative brightness towards the centre, until they resemble a star with only a slight *bur* around it. When telescopes of high powers were applied to these bodies, many of them were resolved into dense clusters of stars; but others could not thus be resolved, and had such a peculiar appearance, that it was surmised that they were not starry masses, but patches of diffused matter in the course of being condensed to stars and systems—belated portions, so to speak, of the same soft and diffused material, which, countless ages ago, was condensed into the defined bodies forming the remainder of our star-system! This surmise was readily supported by many, on the belief that such uncondensed suns were likely to exist, and that the hypothesis furnished a ready basis whereon to found the history and connection of the solar system. But in 1846, the powerful telescope of Lord Rosse showed that one of the most marked of these nebulæ (that in Orion) did really consist of an immense irregular mass of stars, undiscernible before, from its being situated so remotely in the depth of the starry spaces. It has consequently been pronounced as extremely doubtful if there are any masses of diffused, or, properly speaking, nebulous matter, in the regions of space.

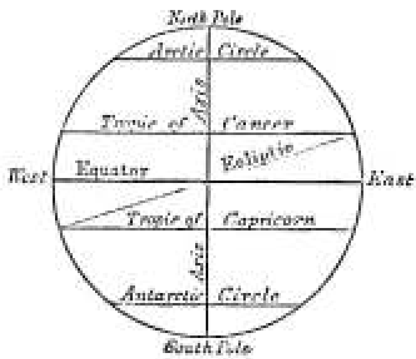
The discovery, however it may affect theories, infinitely exalts our conceptions of the magnitude and extent of the material universe. It teaches us to regard the farthest and filmiest speck which the most powerful telescope can descry, as a mass of worlds melted, by distance, into a dim light, but comprising individualities as perfect, and at the same time as progressive in their natures, as our own. "What mean, for instance," says Professor Nichol in a recent work, "those dim spots, which, unknown before, loom in greater and greater numbers on the horizon of every new instrument, unless they are gleams it is obtaining, on its own frontier, of a mighty infinitude beyond, also studded with glories, and infolding what is seen as a minute and subservient part? Yes; even the six-feet mirror, after its powers of distinct vision are exhausted, becomes in its turn simply as the child gazing on these mysterious lights with awful and hopeless wonder. I shrink below the conception that here—even at this threshold of the attainable—bursts forth on my mind! Look at a cloudy speck in Orion, visible, without aid, to the well-trained eye; *that* is a stellar universe of majesty altogether transcendant, lying at the verge of what is known. Well, if any of these lights from afar, on which the six-feet mirror is now casting its longing eye, resemble in character that spot, the systems from which they come are situated so deep in space, that no ray from them could reach our earth until after travelling through the intervening abysses during centuries whose number stuns the imagination. There must be some regarding which that faint illumination informs us, not of their present existence, but only that assuredly they were, and sent forth into the Infinite the rays at present reaching us, at an epoch farther back into the past than this momentary lifetime of man, by at least *thirty millions of years!*"

URANOGRAPHY.

Under this term (delineation of the heavens) may be comprehended all those arrangements which have been made by astronomers for artificial representation of the heavens, and for the working of the many mathematical problems of which the heavenly bodies are the subject.

The stars, as they appear in their places on the apparent concave sphere of the heavens, are represented in proper arrangement on the *celestial globe*, which is expressly designed as a miniature of that sphere, but bearing also the fanciful figures assigned to the constellations, and the lines necessary for the working of various problems. It is required that, in the first place, we give a brief description of the terrestrial globe, or similar miniature representation of the earth.

Astronomers, for the convenience of their science, have supposed certain lines to pass through and around the globe. One, passing through the centre, between north and south, is called the *axis* of the globe, from a Greek word signifying axle. The two extremities are called the *poles*, from the Greek word *polos*, signifying a pivot. A line girding the globe in the middle, or cutting it into two equal portions, is styled the *equator*; all to the north and south of which are respectively called the northern and southern hemispheres. The circuit of the earth, both in its girth between east and west, and between north and south, is divided into 360 parts, called *degrees*. At the distance of twenty-three and



a-half nearly of these degrees from the equator, in both directions, are two parallel lines called the *tropics*, and at the same distance from each pole is a parallel circle, styled in the one case the *arctic*, and in the other the *antarctic circle*. The space between the tropics is called the *torrid zone*, because the sun, being always vertical in some part of that space, produces a greater degree of heat than what is felt elsewhere. The spaces between the tropics and the arctic and antarctic circles are called the *temperate*, and the spaces within these latter circles the *frigid zones*. Lastly, a line which cuts the equator obliquely, touching upon opposite points of the tropics, is called the *ecliptic*. The ecliptic and equator are called greater circles, because they cut the earth at the thickest parts; the others are called lesser circles.

A series of lines drawn from pole to pole over the earth's surface (like the division lines of a peeled orange), and cutting the equator at right angles, are called *meridians* (from the Latin word *meridies*, mid-day), or lines of longitude. Every place upon the earth is supposed to have one of these passing through it, although only 24 are described upon the terrestrial globe. When any one of these is opposite the sun, it is then mid-day or twelve o'clock with all the places situated on that meridian, and consequently midnight with those on the opposite meridian on the other side of the earth. The exact situation of a place upon the earth's surface, or its latitude and longitude, is determined by means of those circles. They are all divided, as already hinted, into 360 parts, which parts are called *degrees;* these degrees again into 60 equal parts, called *minutes;* the minute into 60 others, called *seconds;* and so on. They are all indicated by certain signs placed behind the figure, and near the top of it—thus 8° 5′ 7″ is 8 degrees 5 minutes 7 seconds. A degree is 60 geographical miles, or about 69 English statute miles; a minute is the 60th part of that; and so on. The *latitude* of a place is its distance measured in that manner from the equator. If it lies north of that line, it is in north latitude; if south of it, in south latitude. There being only 360 degrees in the circumference of the earth, and the distance from the equator to either of the poles being only a fourth part of it, a place can never have more than 90 degrees of north or south latitude. The *longitude* of a place is the distance of its meridian from another, which is called the first meridian. The first meridian is quite arbitrary, and it is a matter of indifference through what point we draw it, provided it be settled and well known which one we adopt, so as to prevent mistakes. Foreigners fixed upon the principal observatories of their respective countries. In Germany, the island of Ferro is generally adopted; in France, the observatory of Paris; and in England, that of Greenwich. Longitude is reckoned either east or west of the first meridian; and 180 is therefore the utmost degree of longitude. Some geographers, however, reckon longitude all the way round the globe. From the shape of the earth, which is flat at the poles, the degrees of longitude decrease as we approach these in either direction. In order to measure latitude, each globe is furnished with a brass meridian circle, on which the degrees are marked. Longitude is measured by a similarly graduated circle, termed the *artificial horizon*, in which the globe is suspended.

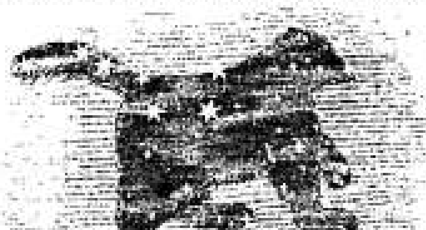
The other great circle, called the Ecliptic, is divided into twelve parts, called signs, which bear the name of the constellations through which this circle passes in the heavens, as shall be afterwards explained. There are other smaller circles which run round the earth parallel to the equator; these are called *parallels of latitude*, because, being everywhere at the same distance from the equator, the latitude of every point contained in any one of them is the same.

The celestial globe, representing that apparent outer sphere, the sky, in the centre of which the earth seems suspended, is marked by lines similar to those upon the terrestrial globe, each line upon the latter being supposed to have a corresponding line opposite to it in the heavens. Thus the celestial sphere is divided into the same number of degrees as the terrestrial. The celestial poles correspond to those parts of the heavens to which the terrestrial poles always point. The point of the heavens directly over our heads, or the very summit of our sky, is called the *zenith*, and is a sort of pole or middle point of the visible half of the heavens; the point which we would see directly beneath our feet, if the earth could be seen through, is called the *nadir*, and forms a pole to the nether half of the heavens. The celestial equator corresponds also to the terrestrial, and is, like it, everywhere 90 degrees distant from the poles. The equator of the earth thus lies directly under that of the heavens: the ecliptic does exactly the same, and cuts the former also at an angle of 23 degrees 28 minutes.

The place where the ecliptic cuts the equator at the vernal equinox is called the first point of Aries; and from this point the distance of all celestial bodies eastward and westward of it is measured. This is called their *right ascension*, and corresponds to the terrestrial longitude. Their latitude is determined by their distance from the equator, and is called their *declination*. The declination of the sun, or other heavenly body, is therefore called north or south declination, according to its proximity to the north or south pole of the heavens; hence it follows, that when the sun's declination is 10 degrees north, he is vertical at a place whose latitude is 10 degrees north. But the right ascensions do not so correspond with the longitudes, simply because the first point of the constellation Aries does not correspond to the first meridian (Greenwich); and because the longitudes are not measured quite round, as the right ascensions are.

The sun, which is always in the ecliptic, has of course no latitude, but he passes through all the degrees of longitude in a year. When any other celestial object has the same longitude as the sun, it is said to be in *conjunction* with him; and when the difference of longitude amounts to 180 degrees, half the circle of the heavens, it is said to be in *opposition* to him. Both these terms are comprehended in that of *syzygy*, which, when applied to any celestial object, means that it is either in conjunction or opposition to him. What is called an *equinoctial colure*, is a great circle supposed to be drawn through the pole of the ecliptic and the points where it intersects the equator. The *solstitial colure* is a similar circle, which passes through the solstitial points at right angles to it. The former colure is a secondary to the ecliptic, and the latter a secondary to both it and the equator. The equinoctial points are Aries and Libra, where the ecliptic cuts the equator. The solstitial points are Cancer and Capricorn; and when the sun is in either of them, he is at his farthest distance above or below the equator.

Allusion has already been made to the constellations or fanciful figures marked on celestial globes, to aid in distinguishing the position of the stars. The earliest astronomers seem to have adopted the idea of thus mapping out the starry heavens, being no doubt at first led to do so by the slight resemblances borne by various groups of stars to familiar terrestrial objects. Thus, a group in the northern part of the sky bears some resemblance to an ancient wain, or to a plough—as also to the hinder part of an animal, with its tail extended; hence it has been variously called *the Plough*, *Ursa Major*, or the Greater Bear, and *Charles's*



Constellation Ursa Major.

Wain—the last term being in honour of the illustrious French king Charlemagne. (In ordinary globes, Ursa Major is alone marked.) Another group, in the southern heavens, conveys the idea of a man's figure, and has been called Orion, from an early Greek semi-divine hero of that name. Some of the names of the constellations were conferred by Chaldean observers several hundred years before our era: others have been given within the last few ages. Particular stars of large magnitude also bear particular names, generally Arabic, having been affixed by Arabian astronomers—as Aldebaran, Dubhe, Alioth, &c. Arcturus and the group of small stars called the Pleiades, are alluded to in the book of Job, which is well known to be one of the earliest of the Scriptural compositions, and probably not less than 3000 years old.

Twelve of the constellations are placed in that part of the heavens which is opposite to the ecliptic in the terrestrial globe; that is to say, the plane of the planetary motions, if extended to the stars, would strike the part occupied by these constellations. This part of the celestial globe is called the *Zodiac*, and these are named the Zodiacal Constellations, or more commonly, the *Signs of the Zodiac*. The zodiac is a zone or belt, extending eight or ten degrees on each side of the ecliptic. It is divided into twelve parts, each of thirty degrees, called the signs of the zodiac. The names of the signs, and the days in which the sun enters them, are as follow:—*Spring signs*—Aries, the Ram, 21st of March; Taurus, the Bull, 19th of April; Gemini, the Twins, 20th of May. *Summer signs*—Cancer, the Crab, 21st of June; Leo, the Lion, 22d of July; Virgo, the Virgin, 22d of August. These are called Northern Signs, being north of the equator. *Autumnal signs*—Libra, the Balance, 23d of September; Scorpio, the Scorpion, 23d of October; Sagittarius, the Archer, 22d of November. *Winter signs*—Capricornus, the Goat, 21st of December; Aquarius, the Water-bearer, 20th of January; Pisces, the Fishes, 19th of February. These are called Southern Signs. Within the zodiac are performed the revolutions of all the principal planets.

II. MECHANICAL ASTRONOMY.

It is the province of Mechanical Astronomy to explain the physical laws which seem to have produced, and which sustain, the arrangements of the bodies occupying space, as well as all the various results of the arrangement and relations of those bodies.

It may, in the first place, be proper to explain what is meant by a *physical law*. In the operations of nature, certain results are invariably observed to take place as a consequence of certain circumstances. This has suggested to the mind of man that there is an *order* in all things, by virtue of which they are regulated to the best general purposes, the authorship of the *order* being no doubt the same as the authorship of matter itself—that is to say, referable to the Divine Being. Any particular regulation which we find imposed upon matter, we term a law of matter, or a physical law.

LAWS OF ATTRACTION AND MOTION.

We have first to consider the laws by virtue of which *particles and masses of matter attract each other*, as far as these are concerned in the province of Mechanical Astronomy.

Particles of matter, when brought close together, or within insensible distances, have a tendency to cohere, or stick together; and this operates in all cases, unless there be opposing influences of superior force. It is termed the *attraction of cohesion*.

Particles of matter have also a tendency to move or be drawn towards each other. This is called the *attraction of gravitation*, because it is what the weight or gravity of an object depends upon.

Under the influence of the attraction of cohesion, particles of fluid matter, when suspended at a proper distance from other objects, arrange themselves round a centre, and take a globular form. The dew-drop, suspended from the point of a thorn or blade of grass, is a familiar example of matter thus acting. If two such drops are brought close together, they will unite; a new and common centre will be instantly established for both, and they will resolve themselves into a new mass equally globular as before.

Under the influence of the law of gravitation, when any two masses of matter are brought within a certain distance from each other, they will, if there be no sufficient obstacle, rush together, and then remain in contact.

We may see this law operating if we take two fragments of cork, no matter how small, and set them afloat on the surface of a cup of water. If kept a considerable way apart, the impediments to their mutual attraction are too strong, and they therefore do not meet. But if brought within a short distance of each other, we shall observe them begin mutually to exercise an influence over each other, and immediately they will rush together, and so remain.

Material laws are equally ready to act on a large as on a small scale, and on a small as upon a large one. The same attraction of cohesion which causes the tear drawn from our eye by sympathetic feeling to be round, produced the spherical form of the vast orbs which people space. These, being originally fluid masses, gathered themselves round a centre, by the irresistible force of the law of the attraction of cohesion. So also are the planets restrained in their position regarding the central luminary, by the force of the same law of gravitation which causes an apple dropping from a tree to fall upon the ground, or two tea-stalks floating in our evening cup to go together, and range themselves as closely side by side as possible.

We have next to consider the laws which regulate the *motion* of masses of matter.

A mass of matter set in motion upon the surface of the earth, or within the compass of the atmosphere, invariably comes sooner or later to a stop. If we roll a ball along the surface, it goes briskly for a while, then slowly, and finally it stops, and remains at rest. What causes it to stop, is the resistance it meets with from the roughness of the ground, and the opposing fluid (atmosphere) in which it moves. It is precisely when as much force has acted in opposition to its motion, as was exerted in setting it agoing, that it comes to a pause. Were it not, however, for this opposing force, the ball, once set in motion, would travel on and on for ever.

Just so the orbs of space, once set in motion, go on and on perpetually, there being nothing whatever to oppose their progress. This applies as well to their spinning or rotatory motion on their axes, as to their progress along their orbits. If a top were set a-spinning on a smooth marble tablet, underneath the exhausted receiver of an air-pump, it would be found to keep in motion for a far longer space of time than in any ordinary circumstances, for then there would be comparatively little air to give resistance to its rotation, and the chief opposition would lie in its friction against the tablet. Could the air be entirely drawn away, and the top be made to spin in a state of suspension, it would be in precisely the same circumstances as an orb revolving on its axis in space, and in that case it would never stop as long as all the circumstances remained unaltered.

But the orbitual revolutions of planets are circular. Why should they be so? Because these orbs are under the influence of both the law of attraction and the laws of motion. Assuming the nebular hypothesis to be true, the impulse which they originally obtained tended to throw them off in a direct line into space, in the plane of the ecliptic. But the law of attraction prevented this result, and caused them to assume a circular course round the parent orb. They were propelled by the one cause (the centrifugal or centre-quitting force), but restrained by another (the centripetal or centre-seeking force, that is to say, attraction), and they therefore settled into paths where the two forces balanced each other.

To explain. If we take any circular body, say a common grinding-stone, and, having first put a few pieces of clay upon its rim, cause it to revolve quickly in a horizontal manner, it will be found that the pieces of clay, one after another, fly off in straight lines from the rim. The cause of this is, that each particular part of the rim of the grinding-stone, at every instant of its revolution, is describing a straightforward movement, and has itself, from the revolutionary motion, a tendency to go straight on, and is only kept in its place by being fixed to the rest of the stone. Every bit of clay that flies off, receives, at the instant of its parting, the force of the straightforward impulse which at that moment affected the part of the rim where it rested;

and hence its going off in a straight line. It is to be observed, however, that the earth immediately begins to act upon the flying piece of clay, and draws it downwards to itself in a bending line, its last movements being, in fact, a part of a circle. This is the power of attraction, which, in this case, is exercised in much greater force by the earth than by the grinding-stone; were the grinding-stone the sole mass of matter near by, and the opposing force of the atmosphere withdrawn, we should see the clay begin to fly round the stone in a circular course.

And this naturally brings us to consider the comparative powers of attraction exercised by different objects. A large mass has a much greater power of attraction than a small one. When two of unequal bulk are brought near each other, we shall only be sensible, perhaps, of the large one drawing the small one to it, and see no attractive power in the small one whatever. In reality, each mass, however small in comparison, exercises a certain degree of attractive power; and this power will depend expressly upon its relative bulk and density, according to fixed regulations of the nicest kind.

One great and important law presides over the attraction which one mass exercises over another. This relates to the *distance* between the two masses. We shall suppose two globes of unequal size. When the small one is removed to as great a distance from the large one as there is space between the surface of the large one and its centre (that is to say, the distance of a semi-diameter of the large one), the attractive force is diminished one-half. When it is removed to twice that distance, or two semi-diameters, the attraction is diminished to a fourth. When it is removed to the distance of three semi-diameters, the force is lessened to a ninth; to four semi-diameters, a sixteenth; to five, a twenty-fifth; and so on; the diminution being always as the squares of the amount of semi-diameters of distance, or these sums multiplied by themselves. The moon is distant from the earth sixty of the earth's semi-diameters; consequently, the attractive power exercised by the earth over the moon is only a 3600th part of what it would exercise at its surface.

In the revolution, then, of a planet round the sun, and of a satellite round a planet, there are various forces at work, all of them in the nicest proportion to each other, and to the mass of each body. There is first the amount of motion resulting from the original impulse; then the amount of attraction exercised by the central and larger over the smaller orb—the one pulling outwards, and the other pulling inwards, but both in union attended with the result of a circular or revolutionary motion.

Gravity has not the same force at all parts of the earth's surface. At the equator, the centrifugal force produced by the rotating motion is greatest; it declines in both directions towards the poles. In proportion as the centrifugal force is greater, the attractive power of the mass of the earth is less, for the first of these forces is directly counteractive of the other. There is of course least attractive power at the equator; and bodies are there drawn with less force towards the centre of the earth than would be found to be the case elsewhere. Yet this difference is not great, for even at the equator the attractive force is 288 times that of the centrifugal. Neither does the difference tell in the weighing of objects, for in that case two equivalents are used, and if a certain object is lighter, so also is the weight put into the opposite scale. The difference was first detected, in consequence of pendulum clocks being found to go slower as they were brought towards tropical latitudes. It was ascertained that the pendulum of a clock which went right at London, required to be one-eighth of an inch shorter (by which means its motion was accelerated) when it was placed upon the equator. This effect, however, is not altogether owing to the increase of centrifugal force, but partly also to the greater distance of the equator from the centre. And it was from a speculation as to the slower movements of pendulums at the equator, that Sir Isaac Newton first conceived the idea of the spheroidal form of the earth, which he ascertained to be of less diameter at the poles than at the equator, as 298 is to 299, or by twenty-six miles.

The orbits of the planets, it has been already seen, are not strictly circles, but rather ellipses, the sun being in each case placed in one of the *foci*—that is, the centre of one end of the ellipse. How should this circumstance affect the revolutionary motion? It might be supposed that, when the planet came to the part of its course where it is nearest to the sun, the attractive force would be greater, and that some derangement might take place. But this is not the case. At that part of the course the planet moves faster than elsewhere, and thus baffles the greater attractive force. This phenomenon is particularly apparent in comets, which have so eccentric an orbit. These bodies move with inconceivably greater speed when near the sun than in the remote parts of their orbits.

It was a discovery of the German astronomer Kepler, in the seventeenth century, that, notwithstanding the increased speed, a revolving orb goes over exactly the same amount of its circuit as when it moves more slowly. Suppose a multitude of lines radiating from the sun, at equal distances from each other, the orb would be found to cross from one to another of these, in exactly the same time, when it was *farthest* from the sun as when it was *nearest*. In scientific language, it describes equal areas in equal times.

Another discovery of Kepler established that there is a relation between the times respectively required by the planets for their revolutions, and their various distances from the sun. At a first glance, we are struck by the fact, that the periods of revolution increase more than in proportion to the distances. For example, the period of Mercury is about 88 days, and that of the Earth 365, being in proportion as 1 to 4.15 (or about 4 1-7th), while their distances, respectively 37,000,000 and 95,000,000 of miles, are in the less proportion of 1 to 2.56 (or a little more than $2\frac{1}{2}$); and a similar remark holds good in every instance. If we take the squares of the distances, we arrive at nothing satisfactory, for it considerably exceeds the proportion of the periods. If, however, we take the squares of the periods of two planets, we find they are in exactly the same proportion to each other as the *cubes* of the mean distances. Some may find a difficulty in understanding the nature of this calculation; but its ingenuity and its results form one of the highest boasts of astronomical science. "When we contemplate," says Sir John Herschel, "the constituents of the planetary system from the point of view which this relation affords us, it is no longer mere analogy which strikes us—no longer a general resemblance among them, as individuals independent of each other, and circulating about the sun, each according to its own peculiar nature, and connected with it by its own peculiar tie. The resemblance is now perceived to be a true *family* likeness; they are bound up in one chain—interwoven in one web of mutual relation and harmonious agreement—subjected to one pervading influence, which extends from the centre to the farthest limits of that great system, of which all of them, the earth included, must henceforth be regarded as members."

The solar system, though composed of many different masses distant from each other, is to be considered with respect to other masses as one mass, having a centre of gravity, by which its position with respect to other masses is regulated. The nearest stars no doubt exercise the force of gravitation upon it, so as to keep it in its position; and it also acts in the same way upon them. It is therefore not strictly correct to speak of the solar system, or any part of it, as *suspended* in space, for that term implies a hanging from a fixed point. It is, in reality, kept at its place by attractive influences exerted all round it by other masses. In like manner, we are to suppose our star-cluster as poised by the same forces in the midst of other clusters; and these, again, poised by others—an idea which leads us on and on through the fields of infinity, till the mind loses itself in an effort beyond its finite powers, and pauses contented to wonder and adore!

DIURNAL AND ANNUAL MOTION OF THE EARTH.

The earth is to be considered as a globe of nearly 8000 miles in diameter, performing a rotatory motion on its axis once every twenty-four hours. This motion is at the rate of 1036 miles an hour to places at the equator, but only 560 miles at London, and a gradually diminishing amount in places nearer to the poles.

From the situation of the earth with respect to the sun, it necessarily follows that only one-half of its surface should be exposed at a time to the light and heat diffused from that body. This is the case with all the planets. When any one part of the earth is presented to the sun, it is day at that part, and all the other heavenly objects are lost in the blaze of the great luminary. When, on the contrary, any part is averted from the sun, it is dark at that part, and the light of the stars is allowed to fall upon our organs. Each part is thus brought once every twenty-four hours towards the sun; in short, this is the cause of what we familiarly know as day and night.

There is a minute difference between the *civil* or *legal day* and what is called the *sidereal day*. The entire orb of the earth, in reality, revolves in 23 hours 56 minutes 4 seconds, or 3 minutes 56 seconds less than 24 hours. This is called a sidereal day, because the earth is then in the same relation to the stars as it was the day before. The fixed stars are so immensely distant from our earth, that its whole orbit is in respect to them but a point; so that no sensible difference is produced by its revolving round the sun. But the sun being much nearer us, any movement made by the earth can be appreciated. The time which elapses from the sun's being on the meridian of any place to its returning to the same spot next day, is exactly 24 hours, and is called an astronomical day. The natural day would always be the same as the sidereal day, if the earth had no other motion than that upon its axis. But in the same time that it has performed one of its daily revolutions eastward, it has also advanced about a degree westward, or in the opposite direction, which is the course it takes round the sun; so that, before the sun can shine exactly upon the same meridian, the earth must make up, as it were, its lee-way, and this it does in 3 minutes 56 seconds, the difference of time between a natural and a sidereal day. If the earth, then, had no other than its diurnal motion, we should have 366 days in the year.

When any spot on earth comes directly opposite to the sun, it is noon at that spot, and at every place in the same longitude. At the same moment, it is an hour before noon at the meridian of longitude fifteen degrees to the west of the same spot, and an hour earlier for every fifteen degrees farther to the west; because, as the earth moves from west to east, it requires so much time to bring those places to the same point—namely, opposite to the sun. In like manner, it is an hour after noon for every fifteen degrees to the eastward of the spot where it is noon, because at those places the sun has already been for so many hours past meridian. Thus the hour of the day varies in every part of the globe where the longitude or meridian line is different. When it is twelve o'clock noon with us in any particular part in Britain, it will be twelve o'clock at midnight in a corresponding point on the opposite side of the globe, near New South Wales; and the intermediate hours, sooner or later, will all lie in the countries between these two points, exactly according to their position or degrees of longitude.

The earth is at a mean distance of 95,000,000 of miles from the sun, and performs its revolution round him in a sidereal year, which is 365 days 6 hours 9 minutes 11 seconds mean solar time. The earth travels at the rate of 68,000 miles per hour. Its orbit is, as already stated, not a circle, but an ellipse, the sun being situated in one of the foci—that is, not in the centre, but near one of the ends of the oval-shaped figure. Neither does the earth go round the sun in an upright or perpendicular position; its axis is slanting or oblique. The degree of obliquity is 23 degrees 28 minutes. The points at which the ecliptic cuts the equator are called *nodes*: the period of time at which it does this, the *equinoxes* (a Latin term, signifying equal nights, for the days and nights are then of equal length all over the world). In consequence of this obliquity, during one part of the earth's course the north pole is turned towards the sun, and the south is dark; and during another part of its course, the south pole is turned to the sun, and the north is dark; and this is the cause of the difference of seasons, which will be better understood by referring to the subjoined figure.

THE SEASONS.

Let S represent the sun, and A B C D the earth at various places of its annual circuit; when the earth is at B or D, these are the periods of the equinox, when the line of the equator intersects or cuts through the line of the ecliptic. At this period, one-half of the globe is illuminated from pole to pole, or there is over all the earth an equal day and night of twelve hours. But

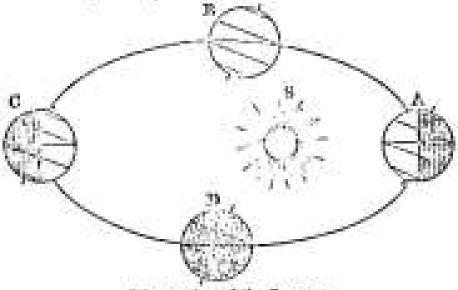


Illustration of the Seasons.

when the earth has proceeded to A, the pole or axis still keeping the same position, or pointing to one particular place in the starry heavens, it will be turned more directly from the sun; a greater proportion of his rays will shine on any particular spot of the southern half of the globe, and the period of day, or sunlight, will exceed that of darkness by the proportion of the light and shade parted in the circle of the earth. It will be observed also, that within the circle of the south pole, the sun will shine continually as the earth revolves on its axis, or, in short, to the inhabitants of that part of the globe the sun will never set for several months. When the earth has proceeded on to B, one-half of its annual course is finished, or this is the spring equinox, or equal day and night. At C, again, the earth has arrived at our longest day in summer, when the axis is turned to the sun, and the regions around the pole are in the light for a greater period, while darkness, or night, prevails for a less. It will be seen, too, that now the pole and circle around it revolve in perpetual light; or to the inhabitants of that region the sun never sets for some months, but they have one continued and uninterrupted day. At the other, or south pole, the same changes take place, only matters are reversed—there it is summer while we have winter, and the winter of the north pole is the summer of the south. In the middle regions of the earth, or around the equator, the sun's place does not suffer a very great change; and, accordingly, there the heat is nearly of the same intensity all the year through; and the length of their days and nights is nearly equal, or nearly the same as at the periods of the equinoxes. But the orbit in which the earth travels round the sun is not an exact circle; it is, as we have already mentioned, an ellipse, and the sun is placed near one end of it, as at the small circle and letter S. In consequence of this circumstance, the sun is much nearer us at one period of the year than another, and this happens in our winter; accordingly, the sun appears about one-thirtieth part larger in January than in June. But in proportion as the earth approaches in her orbit to the sun, her motion is quickened, and she passes over the winter half year in nearly eight days' less time than the summer. It is principally from this circumstance, as well as the shorter period of the day, that although the sun be nearer us in winter, and consequently his power of imparting heat greater, yet the actual quantity imparted is, on the whole, much less in the one season than the other. We have said that the north pole of the earth always points to a particular spot in the heavens; this is not, strictly speaking, correct; the pole or axis makes a circle round the centre of the axis of the ecliptic in a long period of years, and it is this motion that gives rise to the precession of the equinoxes, which will be afterwards described under that title.

ABERRATION OF LIGHT.

Although the most convincing proof of the earth's orbitual motion is not to be found in any circumstance of which the senses can take immediate cognisance, but is afforded by the full development of the planetary system, there is, however, one direct proof of it in a phenomenon discovered by Bradley, an illustrious astronomer. It is called the *aberration of light*, and is manifested by a small difference between the apparent and true places of a star, occasioned by the motion of light combined with that of the earth in its orbit. Vision, it is well known, arises from rays of light proceeding from any object, and entering the eye; and we see the object in the direction in which the rays have come. If both the body giving forth light, and that one which receives it, be at rest, the former will be seen in its true place, at least in so far as aberration is concerned; but let either of the bodies move, and this will not be the case. In order to render this plain, suppose a shower of hail to fall perpendicularly upon a number of tubes—say the pipes of an organ; if the organ remain stationary, the hailstones will descend sheer from the top to the bottom, without any deviation right or left; but move the organ in any direction, and they will strike the side opposite to the direction in which the motion is made. Now, it is just in this way that the eye misses the perpendicular ray, and, meeting an oblique one, receives an impression that the star lies in that direction. The object thus appears displaced, and the amount of displacement is *aberration*. The earth travels at the rate of about nineteen miles per second, and therefore is every instant changing its direction. Time is also occupied by light in traversing space, which it does at the amazing rate of 192,000 miles per second; so that also requires to be calculated for by astronomers. The effect of aberration is to make a star apparently describe a small ellipse in the heavens, in the centre of which it would be seen if the earth were motionless. The reader must carefully distinguish between aberration and refraction; their effects are the same—namely, to displace the ray-projecting object—but they proceed from very different causes. Besides these corrections which astronomers have to make in their calculations, there is another, resulting from what is called *parallax*, which may be as well introduced in this place.

PARALLAX.

The word *parallax*, in its general signification, denotes change of place; but in astronomical books it has a conventional meaning, and implies the difference of apparent positions of any heavenly luminary when viewed from the surface of the earth and from its centre. The centre of the earth is the general station to which all astronomical observations are referred; the situation of a heavenly body, observed from the surface of the earth, is called *the apparent place;* and that at which it would be seen from the imaginary place of observation at the centre of the earth, *the true or mean place*. Hence the altitudes of the heavenly bodies are depressed by parallax, which is greatest at the horizon, and decreases as the altitude of the object increases. This may be rendered very plain, by supposing that two persons placed individually at the end of a straight line, look at a candle removed at, say, 100 yards' distance from them. It is evident that the burning body will appear to be projected upon the wall of an apartment, or any other background, at very different positions to each of the spectators. The angle which this difference of position makes is similar to parallax. The farther they remove from the light, allowing them still to remain at the same distance from each other, the more obtuse the angle would become, and the less the parallax. Thus the fixed stars, being so far removed from us, when viewed from any two positions upon the earth's surface, are seen at the same place upon the celestial sphere, and hence have no perceptible parallax. It is different, however, with the luminaries belonging to our system; and by this means astronomers have been enabled to estimate the quantity of space which separates us from them. For a complete account of the means by which this is accomplished, we must refer the reader to more elaborate treatises than the present. A general and correct enough idea of it may be formed from the familiar example we have given. In the same manner, suppose two observers, one in the northern, the other in the southern hemisphere, at stations on the same meridian, observe on the same day the meridian altitudes of the sun's centre. "Having thence derived the apparent zenith distances," says Sir J. Herschel, "and cleared them of the effects of refraction, if the distance of the sun were equal to that of the fixed stars, the sum of the zenith distances thus found would be precisely equal to the sum of the latitudes north and south of the places of observation; for the sum in question would then be equal to the meridional distance of the stations across the equator. But the effect of the parallax being in both cases to increase the apparent zenith distances, their observed sum will be greater than the sum of the latitudes by the whole amount of the two parallaxes. This angle, then, is obtained by subducting the sum of the latitudes from that of the zenith distance; and this once determined, the horizontal parallax is easily found, by dividing the angle so determined by the sum of the sines of the two latitudes." It may be observed that the angles are determined by means of very nice instruments. The parallax thus obtained is called the *daily* or geocentric, in contradistinction to the annual or heliocentric, by which, in general, is understood the difference of place of a heavenly body, as seen from the earth and from the sun; in particular, however, it denotes the angle formed by two lines from the ends of the diameter of the earth's orbit to a fixed star, which, as we have already observed, from the immense distance of the latter, is inappreciable. Some idea of the importance of parallax may be obtained from the fact, that before the sun's was determined, the distance of that luminary from us was not estimated at within 13,000,000 of miles of its true amount. Its parallax is of course a very minute quantity, only 8″ 6.

OF SOLAR, SIDEREAL, AND ANOMALISTIC YEARS.

There are three different periods at which the sun may, in different senses, be said to return to the same position—when he returns to the same equinox at which he was before; when he returns to the same point in his orbit, or the ecliptic; and when, being in perigee (least distance from the earth), or apogee (farthest distance from the earth), he comes back to either again; or, which is the same thing, when, having been at a given distance from any of these points, he returns to the same point with respect to them. Each of these may be said to be a completion of the revolution of the sun (strictly speaking, it is a revolution of our own earth round him), and a revolution thus performed is called *a year*. The first and shortest is the equinoctial, solar, or tropical year; for his time of returning from tropic to tropic, they being situations holding the same relation to the equinox for the time being, is obviously the same as that from equinox to equinox. The value of this year is 365 days 5 hours 49 minutes nearly. But although the earth has thus returned to the same equinox, it has not made the entire circuit of its orbit, but must travel a little farther to arrive at the same point it was in a year before. This arises from a backward movement of the equinoctial point, as previously explained. The second is the sidereal year, which consists, as we said before, of 365 days 6 hours 9 minutes 9''.6, reckoned in mean solar time, or *a day more*, reckoned in sidereal time. Here, then, there is a remarkable difference between solar and sidereal time, which requires explanation. If the reader will recollect what was said with regard to a solar and sidereal *day*, the discrepancy between the times of the years will become apparent. In the course of twelve months, all the little daily deficiencies, as it were, amount to twenty-four hours, which constitutes the difference between the two years. The sun's apparent *annual* motion among the stars is performed contrary to the apparent *diurnal* motion of the sun and stars; hence the stars gain every day three minutes fifty-six seconds on the sun, which makes them rise that portion of time earlier every day. In the course of a year, the sun will fall behind the stars a whole circumference of the heavens, or one revolution, which deficiency he must make up to complete the number of days in a year. It is evident, then, that the sun apparently, or the earth really, turns 366 times round upon its axis; and had it no other motion, there would be as many days in a year. After the earth or sun has completed a sidereal year, before it can finish an anomalistic year, it must describe a farther arc of 11''.8 to arrive at its original position in perihelion, the latter having moved forward to that amount. In so doing, it occupies 4' 39''.7, which must be added to the sidereal period, making the anomalistic year 365 days 6 hours 13 minutes 49''.3 in length. All these periods have their uses in astronomy; but the one in which mankind are most particularly interested is the tropical year, or that on which the seasons depend, and which is a compound phenomenon, depending chiefly and directly on the annual revolution of the earth round the sun, but subordinately also, and indirectly, on its rotation round its own axis.

MEASUREMENT OF TIME.

Although the sidereal day, from its uniformity, is well adapted for astronomical purposes, yet it is scarcely sufficiently marked for the ordinary wants of life. No person but an astronomer ever attends to the culmination of a star; on this account, the diurnal return of the sun to the same meridian has been universally adopted as the measure of time; and this is called a *civil day*. Most nations reckon the beginning of their day from midnight, but astronomers count from noon to noon. The day thus determined is called the astronomical or solar day, and being regulated by the true motion of the sun, the time which is measured by it is called true or apparent time. Two causes conspire to render astronomical days unequal: first, the variable velocity of the sun in his orbit; and second, the obliquity of the ecliptic. A mean astronomical day, which is independent of any causes of inequality, has been obtained by astronomers introducing into the system two imaginary suns. These two fictitious bodies are supposed to move uniformly, the first in the ecliptic, the second in the equator; and as the circles are both equal, the actual motion of each of the bodies is equal. To those desirous of studying this part of the subject, we would recommend a perusal of the article *Astronomy* in the seventh edition of the Encyclopædia Britannica, page 778, where it is well illustrated. The correction or equation, by which apparent time is reduced to mean time, is technically called the *equation of time*. There are only four days in the year when the apparent and mean time are the same, and the equator of time nothing. In the interval between the first and second of these—that is, December 24th, and April 15th—and, again, in that between the third and fourth—that is, June 15th and September 1st—the apparent is always later than the mean time, or the clock is before the sun; in the other intervals which complete the year, the reverse is the case, and the clock is after the sun. The greatest difference between solar and true time amounts to between fifteen and sixteen minutes. Tables of equation are constructed for the purpose of correcting the differences. For further information on the Measurement of Time, see No. 17 of the present series.

THE MOON.

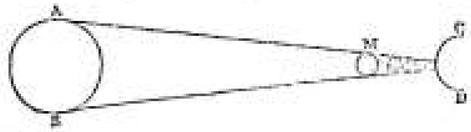
Next to the sun, the moon is to the inhabitants of the earth the most remarkable and important of all the heavenly bodies. The mean horizontal parallax of the moon is 57' 18''; and her mean distance from the earth 236,947 miles. Like the sun, the moon advances in the heavens in a motion contrary to that of the stars. Notwithstanding the vast distance she is from us, it is little more than one-fourth of the sun's diameter, and the globe of that magnificent luminary would nearly *twice* include the whole orbit of the moon! It has various motions; as a secondary planet, it revolves round the earth, which is its primary. Along with the latter, it revolves round the sun, and it has a rotatory motion upon its own axis. Owing to the sun's apparent movement in the heavens being in the same direction with that of the moon, only slower, the latter has to make up for that slowness in the same way as we have mentioned with regard to the earth, and the time it takes constitutes the difference between the sidereal and synodic month or lunation. The sidereal month is 27 days 7 hours 43 minutes 11''.5, in which time the moon performs a complete revolution round her primary; and the other is 29 days 12 hours 44 minutes 2''.87, the time which elapses between two new moons, or two conjunctions of the sun with the moon. It happens that its revolution upon its axis is performed in the same time as its revolution round the earth, so that the same side of her orb is always presented to the latter planet. Although the moon's rotation on her axis is uniform, her motion in her orbit is not so, and we are by this means enabled at times to obtain a peep of the equatorial portions of her eastern and western sides. Her axis, also, is not perpendicular to her orbit, and a small part of each of her poles alternately becomes visible. These phenomena are known by the name of *librations* of the moon, and they are of two distinct kinds, the result of different causes.

The wisdom and beneficence of the Deity are strikingly displayed in the economy of moonlight, as distributed to our globe during various seasons of the year. The remarkable phenomenon of the *harvest* moon is familiar to every one. During the time that our satellite is full, and for a few days before and after, in all about a week, there is less difference between the time of her rising on any two successive nights, than when she is full in any other month of the year. By this means an immediate supply of light is obtained after sunset, so beneficial for gathering in the fruits of the seasons. To conceive of this phenomenon, it must be recollected that the moon is always opposite to the sun when she is full; that she is full in the signs Pisces and Aries, these being the signs opposite to Virgo and Libra, which the sun passes through in September and October, our harvest months. Thus, although, whenever the moon enters the two former signs (and she does so twelve times in a year), the same circumstance takes place with regard to the time of her rising; yet it is not observed on these other occasions, just because she is not *full* at the time. The reason of there being little difference in the time at which she rises on several consecutive nights is, that at these periods her orbit is nearly parallel to the horizon. The harvest moons are as regular in south latitude as with us in north latitude, only they happen at different periods of the year.

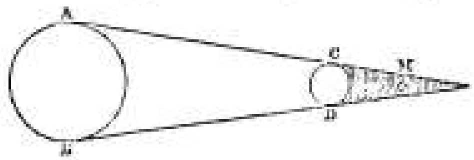
ECLIPSES.

Eclipses are caused by the positions of the earth and moon with respect to each other and to the sun. An eclipse of the sun takes place when the moon is between the sun and earth; and an eclipse of the moon is the result of the earth being between the sun and moon. In other terms, the shadow of the earth cast upon the moon causes a lunar eclipse, and that of the moon upon the earth causes a solar eclipse.

The following figure explains an eclipse of the sun. A B is the sun, M the moon, and C D the earth. The



shadow of the moon falls upon a part of the earth's surface; and there, accordingly, the sun appears in eclipse, the body of the moon being placed between. Another diagram represents an eclipse of the moon. In this instance, A B is the sun, C D the earth, while



the moon appears as a small circle (M) involved in the shadow thrown by the earth.

The planes of the earth's orbit and the moon's do not exactly coincide, but cross or intersect each other; and the consequence is, that in general the moon, when she is in conjunction with the sun, either passes on one side or the other, and therefore does not intercept the sun's rays, or produce an eclipse. An eclipse of this kind can only take place when the earth and moon are in conjunction in that part of their orbits which cross each other (called the nodes), because it is then only that they are both in a right line with the sun. If the orbit of the moon were parallel to that of the earth, an eclipse would happen every month. Partial eclipses, again, are caused when the moon, in passing the earth, is not directly in a line with the sun, but a little on either side; the consequence of which is, the edge of one side of the moon only dips into the sun's disk. When the sun is eclipsed, the total darkness is confined to one particular part of the earth, but the lunar eclipses can be seen from every part of the earth, when the moon is above the horizon; and both circumstances prove that the earth is a good deal larger than the moon. The moon arrives very nearly at the same situation with respect to the earth, after making 223 revolutions, which are performed in eighteen years, of 365 days 15 hours 7 minutes and 43 seconds each; so that, after a period of about eighteen years, the series of eclipses recommences nearly in the same order; a circumstance observed by the ancients. The mean number of eclipses which occur in a year is about four, and there are sometimes as many as seven. There must necessarily be two solar eclipses, but it is possible that there may not be even one lunar. A remarkable eclipse, called an annular (or circular) solar eclipse, happens when the moon, being in conjunction with the sun, the edge of the latter appears for a few minutes as a narrow ring of light encircling all round the dark disk of the moon. A great solar eclipse, visible in England, will take place in March 15, 1858, and a still more remarkable one, when the whole disk will be nearly covered, in August 18, 1887.

THE SATELLITES.

The earth, we have seen, is attended in her annual circuit round the sun by one satellite, the moon, which revolves round her as a centre. Strictly speaking, both move round a common centre of gravity in an elliptic orbit, the regularity of which is disturbed by their mutual attractions, so that it is undulated or waved, thus, ... The number of undulations in a whole revolution is, however, only thirteen, so that the deviation from the ellipse is exceedingly trifling. Jupiter, Saturn, and Uranus, are all attended by satellites, as we have seen; and they form, as it were, each of the primaries with its attendant moons, a sort of miniature system, similar in the laws by which they are governed to the great system to which they all belong, where the sun may be termed the primary planet, and the primary planets the satellites. Their orbits are circles or ellipses of small eccentricity, the primary occupying one focus. Of these systems, that of which Jupiter forms the head has been studied with the greatest attention. The discovery of Jupiter's satellites by Galileo, was one of the first fruits of the invention of the telescope, and forms a remarkable era in the history of astronomy. From it resulted a solution of the great problem of the longitude, and the grand discovery of the velocity of light. It also established completely the Copernican system, and confirmed the laws of Kepler. The satellites of Jupiter revolve from west to east like our moon, but they are much less in comparison with their primary than it, whilst their orbits are of smaller dimensions, and less inclined to the ecliptic of their primary than that of our satellite. The largest of them is about 3377 miles, and the least about 2068 miles in diameter. The satellites of Saturn have been much less studied, and have fewer peculiarities. Those of Uranus, however, are remarkable, inasmuch as their orbits are nearly perpendicular to the ecliptic, and in these orbits they are supposed to have a retrograde motion—that is, from *east* to *west*, instead of from *west* to *east*, like the other planetary bodies. No satisfactory cause for this departure (if it be one) from the general rule can be given. It is by accurate observation of the satellites that the densities of the planets, or their mass as proportioned to their bulks, have been ascertained; as also, by watching their frequent eclipses, that the velocity with which light travels from the heavenly bodies to the earth has been brought within our calculation.

PERTURBATIONS.

The name of *perturbations* has been applied to those inequalities in the lunar and planetary motions which arise from the universality of attraction. Thus not only does the sun attract the earth, and the earth the moon, but the latter attracts the preceding, and both are again influenced in their movements by the great centre of the system to which they belong. Not only is this the case, but every individual planet in the system attracts, and is attracted by, all the rest, although certainly in a very trifling degree when compared with that exercised by the sun over the whole of them. But in those miniature systems—such as the moon and earth, Jupiter and his satellites, &c.—the perturbations thus arising, though insensible in short intervals, become apparent when accumulated, and derange the elliptic motions and relations. The calculation of the effects of these disturbing forces is famous in the history of analysis, under the name of *The Problem of the Three Bodies*. It is so worded, because the Sun, Moon, and Earth, and the Sun, Jupiter, and Saturn, form each separately a system little influenced by the rest. Anything like an attempt to exhibit the method by which these nice calculations are made, is impossible in this place: of its difficulty, some idea may be formed, when we consider, what is apparent to every one, that the bodies under investigation are continually shifting their relative distances from each other, and altering the intensity of the disturbing force, which evidently must materially increase the abstruseness of the calculation. Yet great as the difficulty may be, the effect of these disturbances has been ascertained in many instances with the most rigid accuracy, enabling the astronomer not only to predict positions and revolutions with certainty, but to point, as in the case of the planet Neptune, to the heavens, and to pronounce that there, in such a spot, would a planet appear to the telescope of the observer. One of the principal effects produced on our globe by this play of gravitation is denominated

THE PRECESSION OF THE EQUINOXES.

The equinoctial points, we have already explained, are Aries and Libra, where the ecliptic cuts the equator. They are also termed nodes, and the line which joins the two is called the line of the nodes. The longitudes of the stars, as has been also observed, are counted on the ecliptic from the vernal equinox Aries. Now, if the line of the nodes is invariable, the longitude of the stars will of course remain the same from age to age. But on comparing the actual state of the heavens with the recorded observations of ancient astronomers, it is perceived that the longitudes of the stars have considerably increased; so that, to explain the circumstance, we must either suppose that the whole firmament has moved in the order of the zodiacal signs, or else that the equinoctial points have gone backwards, or retrograded westward; since these points depend entirely upon the motion of the earth, which was far more likely to be disturbed by some cause or other, than that the countless multitude of stars should have a motion relative to these points. Accordingly, the phenomenon has been explained, by attributing to them a retrograde motion from *east* to *west*, in consequence of which the sun arrives at them sooner than if they had remained at rest. Hence the equinoxes, spring and autumn, and the other seasons, happen before he has completed an entire circuit. This motion, however, is extremely slow, amounting only to a degree in about seventy-six years; so that the equinoctial points will take nearly 26,000 years to make an entire revolution of the heavens. This motion was known in very ancient times, and its discovery is ascribed to Hipparchus, who lived about 140 years before Christ. The consequence of this retrograde movement is, that the sun's place amongst the zodiacal signs, at any season of the year, is greatly different from what it formerly was. The vernal equinox now happens in the constellation Pisces; the summer solstice in Gemini; the autumn equinox in Virgo; and the winter solstice in Sagittarius. Astronomers, however, still count the signs from the vernal equinox, which always corresponds to the intersection of the ecliptic with the equator; and on this account it is necessary carefully to distinguish between them.

The cause of precession is to be found in the combined action of the sun and moon upon the protuberant mass of matter accumulated at the earth's equator, the attraction of the planets being scarcely sensible. The attracting force of the sun and moon upon this shell of matter is of a twofold character; one is parallel to the equator, and the other perpendicular to it. The tendency of the latter force is to diminish the angle which the plane of the equator makes with the ecliptic; and were it not for the rotatory motion of the earth, the planes would soon coincide; but by this motion the planes remain constant to each other. The effect produced by the action of the force in question is, however, that the plane of the equator is constantly, though slowly, shifting its place in the manner we have described.

NUTATION.

The action of the sun and moon in producing precession is various, at different periods of the year, according to the relative distance of the earth from them. Twice a-year, the effect of the sun in producing it is nothing; and twice a-year—namely, at the solstices—it is at maximum. On no two successive days is it alike, and consequently the precession of the equinoctial points must be unequal, and the obliquity of the ecliptic subject to a half-yearly variation; for the sun's force, which changes the obliquity, is variable, while the rotation of the earth, which counteracts it, is constant. By this means the plane of the equator is subject to an irregular motion, which is technically called the *solar nutation*. Its amount, however, is so exceedingly small, as not to be appreciable by observation. That resulting from the moon's action, however, is sufficiently so, as to have been discovered by Bradley before theory had indicated its existence. Its period depends upon the revolution of the moon's nodes, which is performed in 18⅔ years, and in about that period of time the axis of the world describes a small circle in the heavens, about eighteen seconds in diameter, contrary to the order of the signs. This apparent vibratory motion is denominated the nutation of the earth's axis. The two phenomena of precession and nutation are intimately connected, or rather are constituent parts of the same phenomenon, and dependent upon the same cause, as noticed above under Precession. It is impossible here to enter more minutely into the subject, or explain it more in detail. For an admirable account of it, we refer the reader to Herschel's Treatise on Astronomy, p. 333. We also would direct the inquirer to the same admirable work for further information upon the subject of perturbations, comprising all the complicated varieties of motion. In general, they may be said to arise from the play of attractions kept up by the whole of the planets amongst themselves, they with the sun, and the sun with them; the distances of the bodies from each other, which are always varying; and the masses of matter, and the shape of the bodies, which are invariable. In concluding this part of our subject, we may remark that it is by means of the perturbations of those planets which have no satellites, that astronomers have arrived at a knowledge of their masses. Every planet produces an amount of perturbation in the motions of any other, proportioned to its mass, and to the degree of advantage or *purchase* which its situation in the system gives it over their movements.

STABILITY OF THE SYSTEM.

It is natural to inquire whether the numerous perturbations which all the heavenly bodies are subject to, are such as, in the long-run, to overthrow the present arrangements of the System. If any cause were at work to diminish steadily the mean distance of a planet, it must of course ultimately fall into the sun. It has, however, been proved, that the total effect of all the mutual disturbances has no such tendency, and that the planets and satellites may revolve for countless ages without any radical change happening to the character of their orbits; they will preserve both their mean distances, and the average shape of their ellipses. The only thing that remains under any suspicion as a means of bringing about a decay in the System, is a resisting medium: that is, if the planetary spaces, instead of being perfectly blank and void, are filled with a very thin gas or ether that would impede the motion of bodies, as our own atmosphere resists any body that is impelled through it. It is at present doubtful whether such an ether exists; it is certain that, if it does exist, it is exceedingly rare, and cannot produce any sensible effect in less than thousands of years. Still, if it exist at all, it must tell some time or other, and will have the effect of lessening the mean distances, and contracting the orbits, so that an end to planetary revolution must be the inevitable consequence. It has been suggested, on the other hand, as probable, that the planetary periods may continue to diminish for thousands of years yet to come, then reach a limit, and afterwards gradually return to their former periods of revolution. This progressive and retrograde, or oscillatory kind of motion, is by no means uncommon in nature, a noted example being found in the magnetic needle, which seems to oscillate between 23 degrees west and 23 degrees east of due north in the course of several hundred years. It is expected, however, that the question of a medium will shortly be decided by a more rigid and extensive study of the comets, which are so light, and so much spread out, that the slightest resistance would soon show itself in contracting their orbits.

GEOLOGY.

Geology (from the Greek *gê*, the earth, and *logos*, discourse), is that science which treats of the materials composing the earth's crust, their mode of arrangement, and the causes which seem to have produced that arrangement. By the earth's *crust* is meant that external shell or covering of solid matter which is accessible to man's investigation; the term being used in contradistinction to the interior mass, respecting the nature and composition of which we can know nothing by inspection. Thin as this crust may seem, it nevertheless presents innumerable objects for investigation; hence the magnitude of the science, which has been ranked in point of importance second only to that of astronomy. The materials which constitute the crust of the globe are exceedingly varied; but whatever their composition, origin, or aspect, they are known by the name of *rocks*. It is with rocks and rock formations which the geologist has to do; arrange and classify them, discover their origin, treat of the organic remains imbedded in them, and thus arrive at some conclusion as to the phases which our planet has assumed during their formation. Geology, therefore, in its widest sense, includes—*physical geography*, which limits itself to the mere surface configuration of the earth, as occupied by land and water, mountains and valleys, and other external appearances; *lithology*, which refers to the composition, order, and relation of the rock masses composing the crust; *mineralogy*, which treats of the individual crystals, or mineral elements, of which rock masses are composed; and *oryctology*, or *palæontology*, which directs itself exclusively to the consideration of the fossil plants and animals that may be found imbedded in the rocky strata. In the present sheet, we shall endeavour to exhibit an outline of the lithology, or rocky structure of the globe, embodying therewith an account of the fossil remains characteristic of the successive steps or formations of that structure; this we may designate *descriptive geology*. Economic geology, as concerns minerals and metals, physical geography, and the other subordinate branches, will form the subjects of separate treatises.

It is necessary, however, before entering upon any analysis of the materials of the earth's crust, to examine the causes which have determined, and which still continue to determine, the formation and arrangement of these materials. We know that some rocky masses are hard and crystalline, others loosely aggregated and earthy; the merest tyro can distinguish between granite, marble, sandstone, and coal, which all differ in composition, and maintain different positions in the crust; some rocks appear always in strata or layers, other in irregular masses, without any determinate arrangement; the petrified remains of land plants and animals are found imbedded in some layers, those of marine animals in others, while many are utterly destitute of such reliquiæ. What, then, are the grand causes for this variety and arrangement of material? Rocks have no inherent vitality, like plants and animals; they cannot add to their material, or transport themselves from place to place; they are inert, lifeless masses, subject in every respect to the physical laws of the universe. Obeying the laws of attraction and gravitation, acted upon by electrical and chemical agencies, worn down by the mechanical effects of winds, frosts, rains, and rivers, borne seaward and strewn in layers beneath the waters, and upheaved again by earthquakes and volcanoes—they are ever being displaced and re-formed, each new formation of material enclosing some relic of vitality, which becomes the test and type of the earth's conditions during the period of its enclosure. Here the ocean encroaches upon the land, there new land emerges from the ocean; what is now dry land and rocky heights, was once loose material beneath the waters; and seas now roll their waves over the surface of ancient continents. Nor is there any cessation of this alternating process: a little shifting of the theatre of activity, periods of greater or less intensity, and a progress in vital development, are the only diversities which mark the onward operation of these ever-modifying causes. As they are the prime sources of all geological phenomena, so a knowledge of their power and mode of action forms the basis of all true geological knowledge.

CAUSES MODIFYING THE EARTH'S CRUST.

These causes chiefly resolve themselves into *degrading* and *elevating*; that is—whether they be mechanical, chemical, or vital in their nature—their effects mainly tend to raise or to depress certain portions of the earth's crust beneath the surface-level of the ocean.

Degrading Causes.—These refer to the wearing down of the elevated portions of the earth's surface, and the transport of the materials to lower levels. The *disintegration* is brought about by certain mechanical and chemical forces, and the *carrying down into low levels* is, in the main, a result of the law of gravitation. Considering that the solid parts of the earth are in their very nature liable to the operation of these forces, it appears quite unavoidable that land should be degraded. The causes of this degradation may be considered under three heads—*meteoric*, or those connected with the atmosphere; *fluviatile*, or those depending on rivers; and *oceanic*, or those in which the sea is the immediate agent.

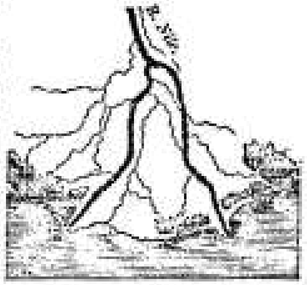
The operation of the atmosphere and its vapoury contents upon the land proceeds in two ways—chemical and mechanical. There is a tendency in the hardest rock to absorb oxygen and carbonic acid from the atmosphere, and to be by that union dissolved. And this is a union which is always occurring, though in some places with more conspicuous results than elsewhere. If the soil on any hill of volcanic rock be examined, we shall first find a fine powdery earth, then a mixture of earth and splinters of rock, next splinters alone, graduating into the hard rock below; and such may be considered as an exhibition of the gradual process by which any rock is disintegrated into soil under the action of the atmosphere. In Jamaica, this disintegration of volcanic rock has taken place to a great depth. In granite, which is considered the most durable of all rocks, one of the component substances (felspar) has a great tendency to be decomposed; hence even this rock is sometimes found to have been reduced to gravel or powder to a considerable depth. A hollow way, blasted through granite, was found in one instance to have been in six years pulverised to the depth of three inches. These are solely *chemical* phenomena.

Again, water percolates through minute fissures in rocks. When frost arrives, the water freezes and swells, and thereby dislodges parts of the rock, which are precipitated into lower levels. Or it may meet some clayey veins or strata, hitherto sufficient to keep various masses together: these veins or strata, being gradually softened by the water, lose their power of cementing the masses; and the upper then fall away or slide into a lower level. A *slide* of rock from the Ruffiberg, in Switzerland, in 1806, filled the bottom of the vale below, destroying many villages, and causing the loss of 800 lives. The impulse of wind and rain on the surface of rock is also of great efficacy in pulverising and wearing it down, sharp parts being rounded, and soft parts hollowed. In Sweden there are some large detached masses of granite, containing perforations produced by this cause, some so very large as to admit of a horse and cart passing through them. These effects may be considered as chiefly *mechanical*.

When water collects into channels, and follows its well-known tendency to find the lowest level to which it has access, it becomes a mechanical instrument of still greater force for wearing down the land. In its smallest rills, as it descends the mountain side, it cuts into the soil, and carries off whatever particles it can disengage. When gathered into brooks, its operations are still more powerful. When one of these is placed amongst mountains, every heavy shower swells it into an impetuous river, by which large quantities of detached rock and soil are brought down. In the upper parts of the courses of almost all rivers, the greater speed of descent makes up for the smaller volume of water, as far as the power of bringing down stones and soil is concerned. Again, in the lower part of the course, the smaller speed is sometimes compensated by the unevenness of the course; in which case the water is incessantly driven from one projection of the banks against another, and by that means wears away a great quantity of solid matter. The mere flowing of pure water would exert little influence on hard rocks; but all rivers carry down sand and gravel according to their velocity;* and these, by rubbing and striking against the sides and bottoms of the channel, assist in scooping out gullies and ravines, which everywhere present themselves. The Nerbuddah, a river of India, has scooped out a channel in basaltic rock 100 feet deep. The river Moselle has worn a channel in solid rock to the depth of 600 feet. Messrs Sedgwick and Murchison give an account of gorges scooped out in beds of the rock called conglomerate, in the valleys of the Eastern Alps, 600 or 700 feet deep. A stream of lava, which was vomited from Ætna in 1603, happened to flow across the channel of the river Simeto. Since that time the stream has cut a passage through the compact rock to the depth of between forty and fifty feet, and to the breadth of between fifty and several hundred feet. The cataract of Niagara, in North America, has receded, according to most authorities, nearly fifty yards during the last sixty years. Below the Falls, the river flows in a channel upwards of 150 feet deep, and 100 yards wide, for a distance of seven miles; and this channel has manifestly been produced by the action of the river.

Sometimes, during floods, rivers produce great changes in very short periods. A flood caused by the bursting of the barrier of a lake in the valley of Bagness, Switzerland, moved at first with the tremendous velocity of thirty-three feet per second. From the barrier burst by the waters to Lake Geneva, there is a fall of 4187 Paris feet; the distance is forty-five miles; and the water flowed over all this space in five hours and a half. It carried along houses, bridges, and trees; and masses of rock equal in size to houses were transported a quarter of a mile down the valley.

The matter carried down by rivers is often deposited at their sides, when it constitutes what is called *alluvial land*. Sometimes it is deposited at the bottom of lakes, when it forms what are termed *lacustrine deposits*. In many instances it has been deposited in large quantities at the mouths of rivers, giving rise to alluvial flats, which, from their resemblance in shape to the Greek letter Δ, have been denominated *deltas*. The triangular form of a delta, like that of the Nile, for example, is produced by the river at a certain point inland, dividing itself into two main streams, which gradually diverge till they reach the ocean, enclosing the space which constitutes the delta. As an instance of the great amount of new land formed at the mouths of rivers, the delta of the Ganges is 220 miles in one direction, by 200 in another.



The matter carried down by rivers, and thus deposited, is nothing in amount compared to that transported to the ocean. The quantity of sand and mud brought down by the Ganges to the Bay of Bengal, is in the flood season so great, that the sea is discoloured with it sixty miles from the river's mouth. Mr Lyell states the quantity of solid matter brought down by this river every day, as equal in bulk to the greatest of the Egyptian pyramids. According to Captain Sabine, the muddy waters of the Amazon river may be distinguished 300 miles from its mouth.

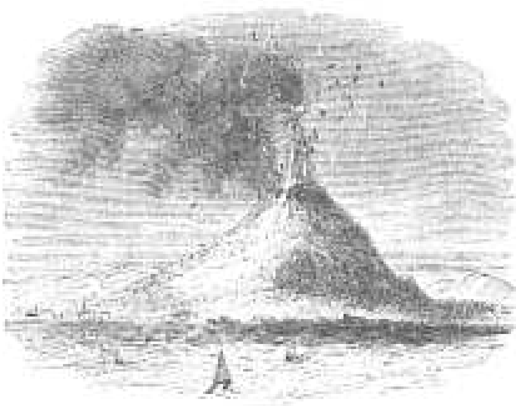
The constant action of the sea upon the land is strikingly apparent to the inhabitants of coasts. Whole islands have been destroyed by the action of tides, waves, and oceanic currents, while the remains of others rise above the surface of the water, like the ruins of some desolated city. Many instances of the encroachment of the sea upon the land have been recorded. An inn on the coast of Norfolk, built in 1805, then seventy yards from the sea, was, in 1829, separated from the coast by only a small garden. A church on the coast of Kent, which, in the reign of Henry VIII., was a mile inland, is now only about sixty yards from the water's edge. The island of Nordstrand, on the coast of Schleswig, was, in the thirteenth century, fifty miles long and thirty-five broad. About the end of the sixteenth century, it was reduced to an area of only twenty miles in circumference. The inhabitants erected lofty dikes for the purpose of saving their territories; but in the year 1634 a storm devastated the whole island, by which 1340 human beings, and 50,000 head of cattle, perished. Three very small islets are all that now remain to point out the place where once flourished the fertile island of Nordstrand.

It thus appears that there are causes in continual operation for the wearing down of the elevated parts of the earth's crust, and taking the component particles into lower levels. The effects of these causes may be easily traced in the aqueous rocks, many of which are simply deposits of sediment carried by water from high into low places, and subsequently hardened, probably by heat from below and pressure from superincumbent materials. Were such causes not in some way counteracted, dry land could not long exist; all would be taken down and buried in the sea—our planet being reduced to a plain spherical mass. We find the counteraction in certain forces incessantly tending to elevation of the superficial rocky crust.

Elevating Causes.—As degrading forces are chiefly owing to water, so those of an elevating character are chiefly owing to fire. They are therefore sometimes comprehended under the term *Igneous Agency*.

The manifestations of igneous agency at present observable may be considered under three heads—namely, *volcanoes*, *earthquakes*, and *gradually-elevating forces*. These phenomena may be viewed as the effects of subterranean heat, operating under different circumstances. A volcano may be described as an opening in the earth's surface, bearing the general appearance of a vent of subterranean fire, and through which smoke, cinders, and ashes are almost continually issuing, but which sometimes discharges great fragments of rock, and vast quantities of melted rocky matter, or *lava*. The general effect is a throwing up of earthy material, in a conical form, from a low to a high level, as represented in the following view of Mount Ætna.

* It has been calculated that water running with a force of 3 inches per second will tear up fine clay, 6 inches will lift fine sand, 8 inches sand as coarse as linseed, and 12 inches fine gravel; while it requires a velocity of 24 inches per second to roll along rounded pebbles an inch in diameter, and 36 inches per second to sweep forward angular stones of the size of a hen's egg.



Geographers at present reckon about 200 volcanic vents in activity throughout the earth. The greater number of the whole are in a line along the west coast of South and North America. There are many in the islands of the Pacific and Indian Oceans, and in the central regions of Asia. In Europe, there are only three in great activity—Ætna in Sicily, Vesuvius in Italy, and Hecla in Iceland. But a vast number of hills throughout France, Britain, and other countries, bear the appearance of having once been active volcanoes. As volcanic action often takes place in the bed of the sea (submarine volcanoes), and as there are probably many on land not yet described by geographers, the number of such vents throughout the earth must be considerably more than two hundred.

Of the power of volcanoes to throw up large quantities of solid matter, we have many examples. During an eruption of Ætna, a space around the mountain, 150 miles in circumference, was covered with a layer of sand and ashes, generally about twelve feet thick. In the first century, the cities of Herculaneum and Pompeii were buried beneath such a layer of matter by Vesuvius. In 1660, the philosopher Kircher, after accurately examining Ætna, and the ground adjoining its base, calculated that the whole matter thrown out by it at its various active periods, would form a mass twenty times as large as the mountain itself, which is 10,870 feet high, and thirty miles in diameter at the base. From this mountain, in 1775, there issued a stream of lava a mile and a half in breadth, twelve miles long, and 200 feet thick. At an earlier period, there was a stream which covered eighty-four square miles. In 1538, a large hill, since named Monte Nuovo, was thrown up in the neighbourhood of Naples in one night; and in 1759, in a district of Mexico previously covered by smiling plantations, a sudden outburst of volcanic action, which lasted several months, terminated in leaving six hills, varying from 300 to 1600 feet in height, above the old plain.

Of the effect of submarine volcanoes, some interesting observations have been made in recent times. In June 1811, an island was thrown up by volcanic agency, near St Michael's, in the Azores. Columns of cinders rose 700 or 800 feet above the surface of the sea, with a noise resembling that of distant artillery. In the course of a few days, the island was a mile in circumference, and about 300 feet in height, having a crater in the centre full of hot water. Some time afterwards it disappeared. In July 1831, a similar island was thrown up, under precisely similar circumstances, in latitude 37° 11′ north, and longitude 12° 44′ east, off the coast of Sicily. It consisted of stones, mud, and cinders, and was of circular form, about a mile and a half in circumference, with a crater of hot water in the centre, 400 yards in diameter. This island, named Sciacca, or Graham's Island, existed so long above the sea as to allow of many persons landing upon it. The Bay of Santorin, in the Greek Archipelago, which is about six miles long and four broad, contained, a few years ago, three volcanic isles, the first of which rose about the year 200, the second in 1650, and the third in 1709. In a part of the bay, where the water is generally several hundred feet deep, a shoal has for several years been gradually rising: about 1816, there were fifteen fathoms water upon it; in 1830, there were only three or four; the later accounts reduced it to two and a-half. This rising mass was ascertained to be of solid rock, about half a mile in length, by one-third of a mile in breadth; the water deepening suddenly all round it.

Many islands which have long been inhabited by man, bear all the appearance of having risen, in like manner, from the bosom of the deep. The islands of St Helena and Ascension, the Azores, the West India islands, Iceland, and many of the islands in the Pacific, are evidently the produce of volcanic action. "Owhyhee," says M. de la Beche, "is a magnificent example of such an island: the whole mass, estimated as exposing a surface of 4000 square miles, is composed of lava, or other volcanic matter, which rises in the peaks of Mouna Roa and Mouna Kaa, to the height of between 15,000 and 16,000 feet above the level of the sea."

The causes of earthquakes have not as yet been satisfactorily explained, but they are now generally allowed to be connected with volcanic agency. They occur less frequently, and generally with less tremendous effect, in Europe, than in some other parts of the world—those parts where volcanic agency is most active, being also the parts where earthquakes are most frequent and most dreadful. Though their effect is sometimes to cause a sinking of the ground, they may, upon the whole, be considered as among elevating causes. It is conceived that they are produced by gases confined in the molten interior of the earth, similar to those which find vent by volcanoes. Such gases, prevented by local circumstances from escaping, may, it is thought, thus shake the solid ground over a large tract, and even cause it to rise to a certain extent above its former level. The most striking proof which has been adduced in support of this doctrine, is the effect of the earthquake which took place in Chili in 1822. This is part of that continent in which volcanoes are most numerous and active. On the occasion referred to, a shock was felt along the coast for more than 1000 miles. The land for 100 miles along the coast, and backwards to the line of the Andes, was raised above its former level. At the shore, and for some distance along the bottom of the sea, the rise was three or four feet; so that rocks formerly submerged, and covered with shellfish, were now exposed above the sea. Old beaches, similar to that now raised, have also been observed in parallel lines along the coasts of Chili and Peru, ranging, according to Mr Darwin and M. Von Tschudi, from twenty to 120 feet above the ocean.

It has since been observed that old beaches, similar to those in Chili, exist in the neighbourhood of many seas. Along the Firth of Forth, in Scotland, there is one very conspicuous about forty feet above the present level of the sea, and which generally appears as a kind of bank a few hundred yards back from the present shore. In the Firths of Clyde and Cromarty, and indeed in every place along the British coasts favourable for their preservation, similar beaches, from twenty to several hundred feet above the present sea level, can be traced. They may always be detected by their terrace-like level, and by the presence of rounded pebbles, gravel, sand, and in some instances sea-shells, such as usually compose beaches at the present day. In some places, old beaches have been conspicuous enough to become objects of popular wonder. In the vale of Glenroy, in Inverness-shire, as also in some neighbouring vales connected with Glenroy, there are three terraces along the sides of hills, at the successive heights of 972, 1065, and 1165 feet, which the ignorant people of the district firmly believe to have been roads formed by the hero Fingal for hunting, but which are now shown pretty clearly to have been the shores of quiet estuaries or arms of the sea, similar to many which still exist in the Scottish Highlands. Among the Alps, in Spain, France, Norway, in North and South America, and indeed in almost every region which has undergone a narrow inspection, there are vales marked in exactly the same way as Glenroy.

The existence of a force which *gradually elevates* the land in many places out of the water, was discovered by Mr Lyell. His chief observations were made upon the shores of the Gulf of Bothnia, which he ascertained to have risen several feet in the course of the last century, and a few inches even since 1820.

Besides the greater elevating causes arising from subterranean fires, there are some lesser ones of less mysterious origin. The sands deposited on beaches are sometimes blown by winds in upon the land, covering the vegetable soil throughout a large space, and in some instances forming hills of considerable height and magnitude. Some parts of the coast of Holland are thus fenced with ranges of sand-hills, the whole mass of which has been blown back from the sea. On some parts of the French coast, large tracts, once smiling with cultivation, are thus buried under a sterile layer of sand, which is continually advancing, notwithstanding every effort of man. On the coast of Moray, in the north of Scotland, a tract once forming the barony of Culbleen, has been transformed into a sandy tract since the fifteenth century.

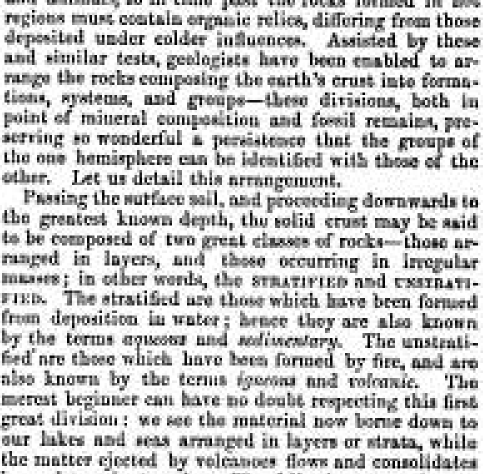
In various parts of the world, new land is elaborated by the efforts of coral insects. The works of these creatures are seen upon a vast scale in the Pacific, where whole ranges of islands are formed by them. On the coast of New Holland, there is a coral reef which stretches out to a thousand miles in length. The insects do not commence their laborious operations at a great depth below water; from sixty to 100 feet is considered the utmost extent to which the coral extends downwards. Many of these islands are of a circular or oval shape; hence the opinion that corals build upon the rims and in the centers of submarine volcanoes. The outer wall of the building emerges first above the waves, enclosing a pool of tranquil water. The seeds of vegetables are either brought there by sea-birds, or wafted by the ocean, and the islands soon become clothed with a mantle of green. The substance of which these islands and reefs are composed is lime, which the insects secrete from the sea-water, and cement together with a glutinous matter contained in their bodies. Mr Lyell, while surveying the Isthmus of Panama, detached a quantity of these animals, and placed them on some rocks in a shallow pool of water. On returning to remove them a few days afterwards, he found they had secreted stony matter, and had firmly attached themselves to the bottom. To such *organic* agencies of elevation as the coral animalcule, may be added the growth of shell-beds, the formation of peat, and other accumulating vital forces which contribute to the solid material of the earth's crust.

If we consider the operation of the elevating causes, we can be at no loss to understand how we should now see, as composing dry land, and sometimes in very lofty situations, strata which were once at the bottoms of seas; neither will it be surprising, if the irregular nature of volcanic forces is considered, that the strata so elevated rarely are found in their originally level position, but in all degrees of inclination—sometimes quite on edge, and even in certain rare instances folded backwards, so as to be upside down.

CLASSIFICATION OF ROCKS.

Subjected from the earliest periods to these conflicting forces, the crust of the earth must have undergone frequent and extensive modifications—modifications not merely as regards distribution of land and water, or of relative elevation and depression, but changes as to the composition and arrangement of the rocky material. The material of the first-formed rocks must have gone to compose those that followed, and so on in succession, to the present age. The series of rocks formed during any one era must present certain differences characteristic of that era, whether it was one of comparative quiet or of volcanic disturbance, and whether it was distinguished for exuberance or comparative destitution of vegetable and animal life. Again, just as at present fresh-water deposits differ from marine, so must rocks formed in lakes and estuaries differ from those deposited in the ocean; and as different climates are peopled by different kinds of plants and animals, so in time past the rocks formed in hot regions must contain organic relics, differing from those deposited under colder influences. Assisted by these and similar tests, geologists have been enabled to arrange the rocks composing the earth's crust into formations, systems, and groups—these divisions, both in point of mineral composition and fossil remains, preserving so wonderful a persistence that the groups of the one hemisphere can be identified with those of the other. Let us detail this arrangement.

Passing the surface soil, and proceeding downwards to the greatest known depth, the solid crust may be said to be composed of two great classes of rocks—those arranged in layers, and those occurring in irregular masses; in other words, the STRATIFIED and UNSTRATIFIED. The stratified are those which have been formed from deposition in water; hence they are also known by the terms *aqueous* and *sedimentary*. The unstratified are those which have been formed by fire, and are also known by the terms *igneous* and *volcanic*. The merest beginner can have no doubt respecting this first great division: we see the material now borne down to our lakes and seas arranged in layers or strata, while the matter ejected by volcanoes flows and consolidates in no determinate order. The following engraving represents the appearance which the stratified and unstratified rocks present in a section of the earth's crust.



Unstratified. Stratified.

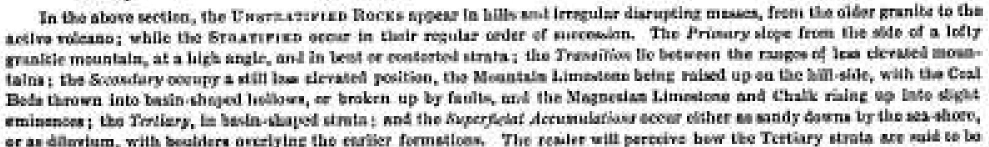
Reverting to the stratified division, the geologist finds them consisting of various materials, variously consolidated and crystallised, variously impregnated with metallic substances, and characterised by different remains of plants and animals. Here he finds sand and gravel, there clay and boulders; in one place chalk, in another coal; here marble, there roofing-slate; and so on in vast variety. He observes, besides, a certain order of superposition, notwithstanding that the igneous rocks have often disturbed the regularity of the stratified, and broken them up into inclined, contorted, and confused positions. On these grounds, the stratified rocks have been arranged into formations, systems, series, and groups. Thus the term *formation* is applied to designate strata which seemed to have been formed under nearly similar circumstances. A formation may consist of several *systems*—that is, strata having nearly the same mineral and fossil character; and there may be several *groups* in a system, such as a sandstone or limestone group. All these groups consist of *strata* which, according to their thickness or external appearance, are designated *beds*, *seams*, *layers*, *schists*, or *slates*. Bearing these terms in mind, the reader will be prepared to understand the following tabular arrangement of stratified rocks as they occur in the British islands:—*

* At this stage the student should direct his attention simply to the names and order of the formations, systems, and groups—returning to the details of the TABLE as a study after he has perused the descriptive portion of the treatise.

SUPERFICIAL.		SOIL—decomposed vegetable and animal matter, with earthy admixtures.
		ALLUVIUM—deposits of sand, gravel, and clay, formed by the ordinary action of water.
		DILUVIUM—deposits of gravel and clay with boulders, formed by unusual operations of water.
TERTIARY.		CRAG—calcareous conglomerate of marine shells and gravel; beds of marl.
		FRESH-WATER, OR ESTUARY BEDS—consisting of marls, imperfect limestones, and clays.
		MARINE BEDS—consisting of blue and plastic clays, thin beds of sand, lignite, &c.
SECONDARY FORMATION.	*Chalk System.*	CHALK—soft and white, with layers of flint; chalk, hard, and without flints.
		GAULT, or beds of bluish marly clays, with green sand.
		GREEN-SAND—beds of green ferruginous sands, with chert nodules.
	Oolitic System.	WEALDEN GROUP—beds of clay, argillaceous limestones, and sands.
		OOLITE—beds of oolite limestone, calcareous grits, sands, and clays, all calcareous.
		LIAS GROUP—bluish clays, alum shales, marls, and limestones, all finely stratified.
	New Red Sandstone System.	SALIFEROUS MARLS—variegated shales and shell limestone, with bands of sandstone.
		RED SANDSTONE GROUP—fine-grained, sometimes conglomerate.
		MAGNESIAN LIMESTONE—thick-bedded limestones and calcareous conglomerates.
	Carboniferous System.	COAL MEASURES—alternating beds of coal, shale, ironstone, and sandstone.
		MOUNTAIN LIMESTONE—thick-bedded grayish limestones and shales.
		CALCIFEROUS SANDSTONES—white, thick-bedded sandstones, and calcareous shales.
	Old Red Sandstone System.	YELLOW SANDSTONES, with beds of mottled shales and marls.
		RED SANDSTONES—sometimes fine-grained, sometimes quartzose and conglomerate.
		GRAY OR RUSTY-COLOURED SANDSTONES—micaceous, and often in flags or thin bedded.
TRANSITION.	*Silurian System.*	UPPER SILURIAN rocks—gray and bluish limestones, with coloured micaceous shales.
		LOWER SILURIAN rocks—impure shelly limestone, mottled sandstones, dark calcareous flags.
	Grauwacke System.	HARD ARGILLACEOUS rocks—thick-bedded sandstones, slaty sandstones and limestones.
		FINE AND COARSE-GRAINED slaty rocks—gray micaceous slates.
PRIMARY.	*Clay-Slate System.*	CLAY-SLATE—finely laminated; dark, liver, and purplish-coloured.
		HORNBLENDE AND CHIASTOLITE SLATES—finely laminated.
	Mica Schist System.	CHLORITE SLATES—greenish-coloured slates, with mica, mica-schist, talc schist, crystalline limestone, and quartz rock.
	Gneiss System.	GNEISS ROCKS—intermingled with irregular beds of quartz rock, crystalline limestone, and mica schist.

It must not be supposed, however, that the stratified rocks always occur in any portion of the earth's crust in full and complete succession, as represented above: all that is meant is, that such would be their order if every group and formation were present. But whatever number of groups may be present, they never happen out of their regular order of superposition—that is, clay-slate never occurs above coal, nor coal above chalk. Thus at London, tertiary strata occupy the surface; in Durham, magnesian limestone; in Fife, the coal measures; and in Perthshire, the old red sandstone and clay-slate: so that it would be fruitless to dig for chalk in Durham, for magnesian limestone in Fife, or for coal in Perthshire. It would not be absurd, however, to dig for coal in Durham, because that mineral underlies the magnesian limestone; or for old red sandstone in Fife, because that formation might be naturally expected to occur under the coal strata of that county, in the regular order of succession.

The unstratified or igneous rocks occur in no regular succession, but appear amidst the stratified without order or arrangement, heaving them out of their original horizontal positions, breaking through them in volcanic masses, and sometimes overrunning them after the manner of liquid lava. From these circumstances, they are in general better known by their mineral composition than by their order of occurrence. Still, it may be convenient to divide them into three great classes—*granitic*, *trappean*, and *volcanic*; granitic being the basis of all known rocks, and occurring along with the primary and transition strata; the trappean, of a darker and less crystalline structure than the granitic, and occurring along with the secondary and tertiary rocks; and the volcanic, still less crystalline and compact, and of comparatively recent origin, or still in process of formation. This division of the igneous unstratified rocks subserves many useful purposes in geology, at the same time that it is a distinction warranted by the nature, aggregation, and aspect of their component minerals. The *granitic*, so named from their distinctly granular and crystalline texture, comprise granite, syenite, serpentine, porphyritic, and other varieties of granite. The *trappean* (Swedish, "trappa," a stair) are so called from the step-like or terraced sides of the hills formed by these rocks, which include basalt, greenstone, clinkstone, trachyte, amygdaloid, &c. The *volcanic*, as the name implies, are those products discharged by recent or active volcanoes, such as lava, scoriæ, pumice, and tufa. As associated in the crust of the earth, the unstratified and stratified rocks would present something like the annexed section:—



Tertiary. | *Secondary.* | *Transition.* | *Primary.*

In the above section, the UNSTRATIFIED ROCKS appear in hills and irregular disrupting masses, from the older granite to the active volcano; while the STRATIFIED occur in their regular order of succession. The *Primary* slope from the side of a lofty granitic mountain, at a high angle, and in bent or contorted strata; the *Transition* lie between the ranges of less elevated mountains; the *Secondary* occupy a still less elevated position, the Mountain Limestone being raised up on the hill-side, with the Coal Beds thrown into basin-shaped hollows, or broken up by faults, and the Magnesian Limestone and Chalk rising up into slight eminences; the *Tertiary*, in basin-shaped strata; and the *Superficial Accumulations* occur either as sandy downs by the sea-shore, or as diluvium, with boulders overlying the earlier formations. The reader will perceive how the Tertiary strata are said to be above the Coal Measures, though they do not overlie them; and how the Coal Beds are above the Transition Rocks, though removed from each other by a wide extent of country.

ROCK FORMATIONS AND ORGANIC REMAINS.

PRIMARY.

Granite.—Geologists have been accustomed to describe this as the lowest and oldest of all rocks; and certainly no other rock has ever been found beneath it, except in peculiar circumstances afterwards to be described. If the mass of the earth, therefore, were to be judged of from the thin superficial crust with which we are acquainted, and were we not aware of its inconsistency with the mean density of the globe, as ascertained by astronomy, granite might appear to constitute the bulk of our planet—a vast nucleus on which all the stratified rocks rested. Geologists are now disposed, under a sense of their limited knowledge, to speak of granite, not as the lowest and oldest of all rocks, but as the lowest as yet discovered, and as one which, though in most of its forms old, is yet sometimes found of recent development. Granite, in fact, often appears as an igneous rock, which has been thrown up in a state of fusion through superincumbent strata of all kinds, penetrating into their chinks, and spreading over them on the surface. Even tertiary rocks are found broken up and covered by it—a proof that it has been formed since the deposition of those rocks, which is one of the most recent events in geological chronology. These are the peculiar circumstances in which it may be said that other rocks sometimes lie beneath granite.

Granite, then, may be described as generally forming a basis or bed for all the other rocks—as rising in some places from its unmeasured depths into chains of lofty hills—and as in other places penetrating in veins through superincumbent rocks, and partially covering them. It composes a considerable portion of the mountain ranges of Cornwall, Cumberland, Wicklow in Ireland, and the Scottish Highlands. The Alps, the Pyrenees, the Dofrefelds, the Abyssinian and other ranges in Africa, and the Andes in South America, are all more or less composed of rocks partaking of a granitic character.

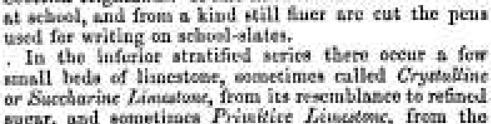
Three substances usually enter into the composition of granite; namely, (1) *quartz* or silex, a whitish glassy substance, composed of oxygen in union with one of the metallic base, silicium; (2) *felspar*, also a crystalline substance, but usually opaque and coloured pink or yellow, composed of siliceous and clayey matter, with a small mixture of lime and potash; (3) *mica*, a silvery glittering substance, which divides readily into thin leaves or flakes, and consisting principally of flint and clay, with a little magnesia and oxide of iron. In some granites, instead of mica, we find *hornblende*, a dark crystalline substance, composed of alumina, silex or flint, and magnesia, with a considerable portion of the black oxide of iron. Such granites are called *Syenite*, from their abundance at Syene in Egypt. Other varieties are—*Serpentine*, in which there are dark spots like those on the skin of the snake (hence the name), and *Porphyry* (from its reddish colour), of which the distinguishing peculiarity is its containing little angular pieces of felspar enclosed in the mass. Any igneous rock containing such fragments, distinct from the common mass, is said to be *porphyritic*.

Granite may then be regarded as a true igneous rock,* associated principally with the primary and transition formations, but occasionally exhibiting itself in outbursts and elevations among the strata of later eras. It presents numerous varieties; but these, either in the field or in cabinet specimens, are readily distinguishable from trappean and volcanic compounds.

Inferior Stratified Series.—Above the granite, in its ordinary position, lies the inferior stratified series, consisting mainly of two kinds of rock—gneiss and mica-slate—with alternating strata of hornblende rock, quartz rock, eurite, talcose slates, chlorite slates, and argillaceous slates; of all of which it may be said that they follow no very determinate order. The lowest of these rocks are of the same materials as granite, in a very slightly modified form, and they are nearly as crystalline in their texture. Geologists also find in many places that the granite *passes* into them—a term expressing a blending of the characters of rocks at the line of their junction. These two facts have led to the supposition, that the inferior stratified rocks were formed from the materials of the granite, disintegrated by mechanical or chemical means, and washed into the beds of vast seas, where, on their deposition, they were reached by the high temperature of the interior, and thereby reconsolidated in a crystalline form. To account for the rocks composed exclusively of one of the materials of the granite, we may suppose some chemical separation of those materials.

The most prevalent rock of the series is *gneiss*, a compound, like granite, of quartz, felspar, mica, and hornblende, and so highly crystalline as to be sometimes scarcely distinguishable from granite. A great portion of the Highlands of Scotland is composed of strata of gneiss, of vast thickness. *Mica-slate* or *mica-schist*, the next most prevalent rock of the series, is composed of mica and quartz. It is the surface rock of many extensive tracts of country. *Quartz rock*, which we may suppose to have been formed by a chemical separation of that component of granite, is also a prevalent rock. Humboldt takes notice of a mass of it in South America, more than 9500 feet in thickness. The round white pebbles, or "candy" stones, so often found on sea-beaches, and in the beds of rivers, are pieces of quartz rock. *Eurite*, of which felspar is the main ingredient, and *hornblende rock*, the chief element of which is signified by its name, may also be accounted for by a chemical origin.

Clay-slate is the geological term for the well-known stone with which houses are roofed. It is, as its name imports, composed mainly of clay—a substance too liberally diffused amongst the ingredients of granite, to admit of any wonder as to its being found in a nearly distinct state in this rock. Mica-slate and clay-slate are *fissile* in their structure—that is, capable of being split into very thin plates: hence the utility of slate as a material for covering houses. But a curious diversity exists in this respect between mica-slate and roofing slate. In the former, the *cleavage*, or direction in which it splits, is in the same line as the stratification; but in roofing slate, the cleavage is always more or less transverse. What makes the latter circumstance the more remarkable—when strata of roofing slate are found, as often happens, contorted or wavy, the direction of the cleavage is in one straight line through them all, indicating that the influence which produced the cleavage in that rock took effect after the whole had been laid down, and after, by some subsequent accident of pressure, they had been forced into a wavy direction.



Section Exhibiting Lines of Cleavage in Clay-Slate.

Probably this phenomenon owes its origin to electric or magnetic agency. Clay-slates are found in great abundance in Cornwall, Wales, Cumberland, and the Scottish Highlands. A fine kind makes the slates used at school, and from a kind still finer are cut the pens used for writing on school-slates.

In the inferior stratified series there occur a few small beds of limestone, sometimes called *Crystalline* or *Saccharine Limestone*, from its resemblance to refined sugar, and sometimes *Primitive Limestone*, from the period of its occurrence in the series. In Greece and Italy this rock has been subservient to the development of national talents, the highest that have ever been known of their class, for it is the marble from which the works of the Greek and Italian sculptors have been formed. In the geological history of our globe, its first appearance in the ascending series of rocks is an event of no small consequence, for limestone strata form a large proportion of the superior formations, and the manner in which they have been formed has engaged much attention. Limestone is the *carbonate of lime*; that is, a combination of the earth lime (itself a union of the metal calcium and oxygen) with carbonic acid (this being, again, a union of oxygen with the elementary substance carbon). Carbon is the largest element in the composition of vegetable and animal substances, and this its first appearance in the structure of rocks is of course a point of much interest, more especially as it is generally concluded that many of the superior limestone strata have been entirely formed

* To avoid all theory as to the origin of the Granitic Group, some geologists employ the term *hypogene rocks* (Gr. *hypo*, under; and *ginomai*): that is, nether or under-formed rocks.

of animal remains. We are thus tempted to surmise that the formation of the limestone beds of the inferior stratified series, marks some early and obscure stage of organic existence on the surface of our planet. No distinct remains of plants or animals have, indeed, been found in the series; and it is customary to point to the next upper series, in which both do occur, as the dawn of organic life. Yet many geologists are of opinion that the inferior stratified rocks might have contained such remains, though the heat under which the rocks seem to have been formed may have obliterated every trace of such substances. The inferior stratified series constitutes in most regions the great depository of the metals—gold, silver, tin, copper, &c.—which occur in irregularly-intersecting veins, composed of ore-stone differing in composition from that of the containing strata. For opinions as to the origin and character of veins, we must refer to the sheet—"METALS AND METALLURGY."

TRANSITION.

Grauwacke and Silurian.—All the rocks hitherto described are of crystalline texture, and, apparently, chemical phenomena have attended their formation. In the group we have now arrived at, traces of mechanical origin and deposition become apparent; but still a few strata resembling the preceding occur throughout the lower parts of this series, as if the circumstances under which the earlier rocks were formed had not entirely ceased. Hence the term *transition*, as implying a passing from one state of things to another.

The rocks forming the lower part of this group, and which are sometimes separately classed as the *Lowest Fossiliferous Group*, are an alternation of beds of chlorite, talcose, and other slates, resembling those of the inferior stratified series, with beds of clayey and sandy rock, of apparently mechanical origin, and thin beds of limestone in which a few fossils are found. It thus appears that the cessation of the chemical origin of rocks, and the commencement of organic life, are events nearly connected; and it has thence been surmised that the temperature of the earth's surface was now for the first time suitable to the production and maintenance of organic things. At the same time, the alternation of the rocks teaches us the instructive fact that the change was not direct or uniform, but that for some time the two conditions of the surface superseded each other. This is conformable with a general observation, which has been made by Sir H. de la Beche—namely, that however sudden changes may have taken place in particular situations, a general change of circumstances attending rock formations is usually seen to have been more or less gradual. The few fossils found in this part of the series—the Grauwacke proper—are, as far as ascertained, the same, or nearly so, as those of the superincumbent Silurian.

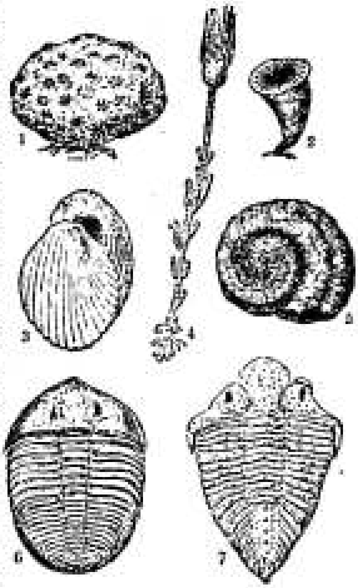
The Silurian group—so called from its being very clearly developed in that district of country between England and Wales which was inhabited by the ancient *Silures*—consists of arenaceous and slaty rocks, of evidently mechanical origin, intermixed with numerous beds of limestone and calcareous shales. The general composition of the series indicates its having been formed, like the grauwacke, of a fine *detritus* (matter washed from other rocks), and its having been deposited slowly; although, as in the case of the grauwacke, the arenaceous beds occasionally pass into coarse conglomerates. Indeed, until a recent period, this system was considered as a portion of the grauwacke group, and as marking its passage into the gray micaceous beds of the Old Red Sandstone. Merely looking at cabinet specimens, it would be impossible to distinguish between many of the grauwacke and silurian rocks; but taking them in the mass, they are readily distinguishable. In the first place, their sedimentary character is very marked; they present more rapid alternations from one kind of strata to another; they have undergone fewer changes by heat; and are generally looser and more earthy in their texture. The limestones are less crystalline than those of the early grauwackes; the arenaceous beds are also less siliceous, and more closely resemble ordinary sandstones; while the abundance of organic remains justifies their arrangement into a separate system.

The grauwacke forms the immediate surface in many large districts in Scotland, England, France, Germany, and North America, showing that, at the time of its formation, "some general causes were in operation over a large portion of the northern hemisphere, and that the result was the production of a thick and extensive deposit, enveloping animals of similar organic structure over a considerable surface." The igneous rocks associated with the transition series are chiefly granitic; effusions of trap making their appearance only among the later strata. Perhaps the most extensive and gigantic efforts of volcanic power were exhibited at the close of this period; and there is abundant proof that all the principal mountain-chains in the world were then upheaved. The Grampian and Welsh ranges, the Pyrenees, Hartz mountains, Dofrafelds, Uralian, Himaleh, Atlas range, Mountains of the Moon, and other African ridges, the Andes, and Alleghanies—all seemed to have received their present elevation at the close of the transition period.

Fossils of the Grauwacke and Silurian.—The fossils of the grauwacke and silurian (a few of which extend to the clayey and sandy slates immediately below) are of both plants and animals. Amongst the plants are algæ, or sea-weeds, showing that seas like the present now existed. Some land plants are also found, but of the simpler structures—as *filices*, or ferns; *equisetaceæ*, a class of plants of the character of the mare's-tail of our common marshes; and *lycopodiaceæ*, a class of the character of our club mosses. All of these land plants are *monocotyledons;* that is, produced from seeds of a single lobe, and therefore *endogenous*, that is, growing from within—timber plants being, on the contrary, the produce of two-lobed seeds, and growing by exterior layers. The *Flora* of this era thus appears of a very simple kind, indicating, generally, low-lying and marshy habitats.

The animals are also, in general, of a humble and simple kind. There is abundance of those creatures (*polypi*) resembling plants, which fix themselves on the bottom of the sea by stalks, and send forth branch-like arms for the purpose of catching prey, which they convey into an internal sac, and digest. At present, these creatures abound in the bottoms of tropical seas, where they live by devouring minute impurities which have escaped other marine tribes, and thus perform a service analogous to that of earth-worms and other land tribes, the business of which is to clear off all decaying animal and vegetable matter. But the class of animals found in greatest numbers in the grauwacke series of rocks are *shellfish*, possibly because the remains of these creatures are peculiarly well calculated for preservation. All over the earth, wherever grauwacke and silurian rocks are found, shellfish are found imbedded in vast quantities, proving that shellfish were universal at the time when that class of rocks were formed. Among the radiata or rayed animals, the *crinoid* or *encrinite* family occur for the first time, these differing from other corals in the self-dependent nature of their structure, their fixed articulated stalk, and floating stomach, furnished with movable rays for the seizure and retention of their food. As we ascend in the silurian group, the shellfish become more numerous and distinct in form; *spirifera*, *terebratulæ*, and *productæ*, are everywhere abundant; and *chambered* shells, like the existing nautilus, begin to people the waters. It must be remarked, however, that the encrinites and chambered shells of this early period are not so numerous, so gigantic, or so elaborate in their forms as those of the Secondary strata: it is in the mountain limestone group that the encrinites attain their meridian, and in the lias and oolite that the *ammonites* and *nautili* are most fully developed.

Of the crustacea of this era, the most interesting and abundant type is the *trilobite* (three-lobed), of which several genera and many species have been described, and to which scarcely any existing creature bears an analogy. The trilobite (see fig.) was a true crustacean, covered with shelly plates, terminating variously behind in a flexible extremity, and furnished with a head-piece composed of larger plates, and fitted with eyes of a very complicated structure. It is supposed by some to have made its way through the water by means of soft paddles, which have not been preserved; and by others, merely to have sculled itself forward by the aid of its flexible extremity. Of its various organs, the most interesting is the eye, of which several specimens have been obtained in a very perfect state. This organ, according to fossil anatomists, is formed of 400 spherical lenses in separate compartments, on the surface of a cornea projecting conically upwards, so that the animal, in its usual place at the bottom of waters, could see everything around. As there are two eyes, one of the sides of each would have been useless, as it could only look across to meet the vision of the other; but on the inner sides there are no lenses, that nothing may, in accordance with a principle observable throughout nature, be thrown away. It is found that in the serolis, a surviving kindred genus, the eyes are constructed on exactly the same principle, except that they are not so high, which seems a proper difference, as the back of the serolis is lower, and presents less obstruction to the creature's vision. It is also found, that in all the trilobites of the later rocks the eyes are the same. This little organ of a trivial little animal carries to living man the certain knowledge, that, millions of years before his race existed, the air he breathes, and the light by which he sees, were the same as at this hour; and that the sea must have been in general as pure as it is now. If the water had been constantly turbid or chaotic, a creature destined to live at the bottom of the sea would have had no use for such delicate visual organs.



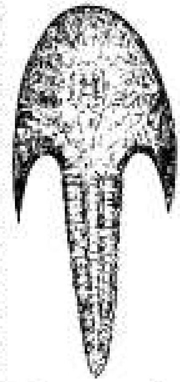
1. Astrea; 2. Turbinolia Fungites; 3. Leptena Lata; 4. Actinocrinites; 5. Euomphalus Rugosus; 6. Trilobite—Asaphus de Buchii; 7. Trilobite—Asaphus Tuberculatus.

A few bones and teeth of fishes have been found in the Silurian; but further exploration is necessary before we can pronounce decisively as to the abundance of vertebrated life at this period. The remains of this era, therefore, may be said to include specimens of all the four divisions of the animal kingdom—radiated, jointed, pulpy, and vertebrated animals; or radiata, articulata, mollusca, and vertebrata.

LOWER SECONDARY.

The Old Red Sandstone System, as indicated by the name, is chiefly arenaceous, presenting a succession of sandstones alternating with subordinate layers of sandy shale. The sandstones pass, in fineness, from close-grained fissile flags to thick beds of conglomerate, the latter being composed of pebbles from the size of a hazel-nut to that of a man's head. The whole system is tinged with the peroxide of iron, the colours ranging from a dark rusty gray to brick-red, and from a mottled purple and fawn shade to a cream-yellow. There are some calcareous beds in the system; but these are not regularly developed, and are all siliceous and concretionary in their composition and texture. Taken in the mass, the composition of this system is sufficiently indicated by the term *old red sandstone*—the epithet "old" being applied to distinguish it from another series of red sandstones which occurs above the coal measures, and is usually designated the *new red sandstone*.

The organic remains of the system, if not so numerous as those of the grauwacke beneath, or the carboniferous measures above, are at least equally interesting, on account of their peculiarities and adaptation to the conditions under which they were destined to exist. The remains of plants are few and indistinct, but are apparently allied to those found in the true silurian rocks. Taken as a whole, the old red sandstone system is particularly barren of vegetable remains, and seems to evince a condition of the earth which did not permit of the growth of plants unless in detached and limited areas; these plants being by no means high in the scale of vegetable organisation. Its animal remains are more abundant and distinct, but present little variety—the prevailing types being marine fishes of simple but curious structure. These *fossil fishes*, or *ichthyolites*, present the first distinct trace of the existence of the highest division of the animal kingdom—namely, *vertebrata*. It must be remarked, however, that the earliest genera are not of the most perfect structure, but form, as it were, a link between the humbler crustacea and fully-developed fishes, as represented in the accompanying figure of the *cephalaspis*, or buckler-head.



Carboniferous System.—This is a very extensive system, comprehending not only the coal measures proper, from which it takes its name, and which consists of alternating strata of coal, shales, sandstones, ironstones, &c. but embracing also the mountain limestone, which always underlies the coal group, and which, in turn, comprehends alternations of limestone, shales, sandstones, and imperfect coal beds.

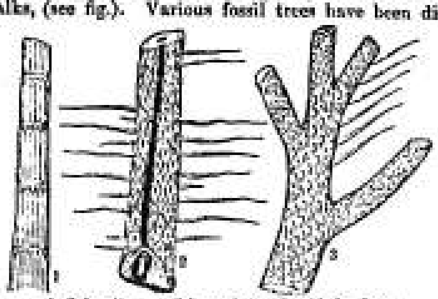
Mountain Limestone, so called from its being generally found flanking or crossing the trap hills which intervene between the old red sandstone and the coal measures, is an abundant rock. It is frequently traversed by beautiful veins of calcareous spar, and many valuable veins of lead-ore are associated with it in Britain and elsewhere. It is of various colours, but mostly gray, varying in intensity of shade. Its associated rocks are principally calcareous sandstones and shales, abounding in organic remains, corals, encrinites, &c. which point to a marine origin.

The superior group more particularly called *Carboniferous*, and variously termed the *Coal Measures*, is composed of beds of that mineral, often very numerous, alternating with beds of sandstone, shale, limestone, ironstone, and some other substances. As many as forty beds of coal exist in the neighbourhood of the town of Newcastle. The great utility of this mineral as a domestic fuel, and in the arts, gives it a high importance; and happy is the country in which it exists in any considerable quantity. In a merely geological point of view, it is equally important. This rock is entirely a mass of vegetable matter, which has accumulated in certain situations, and afterwards been covered over, pressed upon, and converted, by bituminous fermentation, into several varieties of coal.

Two hypotheses have been advanced respecting the circumstances under which coal was formed. According to one, the vegetable matter must have grown in dense forests and jungles for many years; then the land must have sunk, and become the basin of a lake or estuary, in which situation rivers would wash into it mud and sand, which would cover over the vegetable mass, and form superincumbent beds of shale and sandstone respectively. Then the ground would be once more elevated, or sufficiently shoaled up, to become again a scene of luxuriant vegetation. When the vegetation had again become accumulated, the land would be again sunk, and become once more the basin of a lake, in which case the beds of mud and sand might again be formed by rivers. And this alternating process is supposed to have taken place as often as there are beds of coal to be accounted for. The other hypothesis is, that, into lakes and estuaries, rivers coming from different quarters would bring the various matters forming the strata of the carboniferous group—a river from one direction bringing the mud which would form shale, another from another direction the vegetable matter which would form coal, and so on, each deposit perhaps taking place through the efficacy of some local circumstances, while the causes for the other deposits were temporarily suspended. Both theories are beset with difficulties; and perhaps the true solution is to be found in a combination of the two. Estuary and lake deposits, inundating rivers, a high temperature, a prolific Flora, and frequent elevations and subsidences of the land, seem to have been the conditions under which the coal measures were deposited.

Fossils of the Carboniferous Group.—In this group of rocks, upwards of 300 species of plants have been discovered, all of them now extinct. About two-thirds of them are ferns; the others consist of large *coniferæ* (allied to the pine), of gigantic *lycopodiaceæ*, of species allied to the *cactus* and *euphorbiaceæ*, and of palms. Most of these plants probably exist in the coal beds, forming, in fact, their sole composition; but the peculiar nature of this mineral renders it difficult to detect them by examination. Thin slices, however, have been examined by the microscope, and the vegetable structure has then been detected, where no external trace of it was visible. In cannel coal, a kind peculiarly compact, the vegetable structure is observed throughout the whole mass, while the fine coal retains it only in small patches, which appear, as it were, mechanically entangled. Splint and cannel coal often bear distinct impressions of plants. The plants are such as grow in hot moist situations; and it is therefore presumed that a climate of that nature existed at an early period where coal is now found, even in Melville's Island, which is within the polar circle.

Large fragments of trees are often found in the shale and sandstone beds of the carboniferous group—more frequently in the former than in the latter. As usual with fossil substances, they are converted into the material in which they are imbedded, but preserve all their original lineaments, except that they are generally changed from their original round to a flattened form, the result of the pressure they have sustained. In most instances, these fragments of trees appear to have been transported from a distance, and laid down horizontally in their present situation; but some have been found with their roots still planted in their native soil of mud, and the stems shooting upwards through several superior beds of various substances. Even in some coal beds, there are found stems of trees in their original vertical position—the roots being imbedded in shale beneath. In these instances, we must suppose the fossil to be on the spot where the living tree was planted, grew, and died. In the Bensham coal seam, in the Jarrow coal-field, a few years ago, there was found an upright tree of the kind called lepidodendron, thirteen and a half feet wide at the base, and thirty-nine feet high, the branches at the top being also entire: the lepidodendron is so called from the scaly appearance of its stem, the scales being the roots of the leaf stalks, (see fig.). Various fossil trees have been dis-



1. Calamites; 2. Stigmaria; 3. Lepidodendron.

covered in the sandstone beds of the carboniferous group at Craigleith and Granton, in the county of Edinburgh. One found in Craigleith quarry was twenty feet long, three feet in diameter, with scars where the branches had been torn off, and was ascertained, by microscopic inspection of slices of the trunk, to have been a conifera of the existing genus *Araucaria*.

The animal remains of the carboniferous group consist of zoophytes (corals, encrinites, &c.) in vast profusion, of shellfish, crustacea, and fishes. In the mountain limestone the crinoidea seem to have attained their meridian, for whole beds, many feet thick, and square miles in extent, are almost wholly composed of them; hence the not unfrequent term, *Encrinital Limestone*. Shellfish univalve, chambered, and bivalve, also abound; the trilobite and crustacea, allied to the modern *chiton*, are by no means uncommon; and fishes of a gigantic size and sauroid structure are scattered throughout the strata both of the mountain limestone and the coal measures.

New Red Sandstone System.—This series of strata, lying above the carboniferous system, comprehends rocks called the *red conglomerate*, formed of pieces of earlier rocks, some rough, some smoothed by rolling, all caked together; *magnesian limestone*, abounding in Germany and the north of England; *red or variegated sandstone*, a group of many varieties of colour, and principally of argillaceous and siliceous consistence; *muschelkalk*, a limestone varying in texture, but most frequently gray and compact—not found in Britain or France, but occurring in Germany and Poland; and *variegated marls*—beds of different colours, red, blue, and gray, composed of the remains of shellfish.

To these also belong beds or masses of *rock salt*, of which many exist in England, particularly in the county of Chester. Rock salt is a crystalline mass, forming irregular strata, sometimes of the thickness of several hundred feet. The substance is rarely pure, but generally contains some portion of argillaceous oxide of iron, which gives it a red colour. It is dug like coal and other minerals, and when dissolved and subjected to proper purification, is sold for domestic purposes.

Fossils of the New Red Sandstone Group.—The vegetable remains of this group belong to the same families as those of the coal strata, only they are found very sparingly and of diminished dimensions; but in the department of animal life, when we arrive at the muschelkalk, or shell limestone, we find a great difference, leading to a supposition that, at this era of geological chronology, circumstances had arisen changing the character of marine life over certain portions of Europe; that certain animals abounding previously, and for a great length of time, disappeared never to reappear, at least as far as we can judge from our knowledge of organic remains; and that certain new forms of a very remarkable kind were added.

The new creatures were of such a class as we might expect to be first added to the few specimens of fish which had hitherto existed: they were of the class of Reptiles—creatures whose organisation places them next in the scale of creation to fish, but yet below the higher class of animals which bring forth their young alive and nourish them by suck (mammalia). The earth was as yet only fit to be a partial habitation to creatures breathing its atmosphere and living upon its productions. The lands which existed were probably low and marshy, with a hot, moist atmosphere, so as to present an appropriate field of existence only for lizards, crocodiles, and creatures of similar character. It is also to be supposed that the land was at this period undergoing frequent changes and convulsions, so that only a class of creatures to which submersions and deluges were matters of indifference, could reside upon it without a greater waste of life than was part of the Great General Design. The reptiles, which first begin to appear in the muschelkalk, continued to flourish while a great succession of other rocks was forming: throughout the whole of the Secondary Formation, there were *few* other land animals.

UPPER SECONDARY.

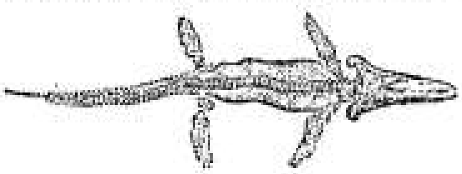
Oolitic System.—After the deposition of the new red sandstone, a further change was effected upon the general conditions of the globe, so as to produce not only an entirely different set of strata, but also different races of plants and animals. In most districts, the red sandstones and magnesian limestone were upheaved, to form new land, while portions of the former dry land were submerged beneath the ocean. By this process of elevation and depression the courses of previous rivers would be altered, former seas circumscribed and rendered more shallow, plants and animals subjected to a new distribution, and thus a different set of deposits would necessarily ensue. Instead of magnesian rocks, we have dark argillaceous and oolitic limestones; for variegated saliferous marls, we have blue pyritous clays; and instead of red and mottled sandstones, yellow calcareous grits. All this points to a new epoch in the terrestrial conditions of the world; and to the system of strata thus deposited geologists apply the term *oolitic* (Gr., *oon*, an egg, and *lithos*, a stone), from the resemblance which the texture of many of the beds bear to the roe or eggs of a fish. The system in England comprises three well-defined groups; namely, the Lias, the Oolite proper, and the Wealden clays—all of which are less or more developed in other parts of the eastern hemisphere.

The Lias, the lowest group in the system, is composed of dark argillaceous limestones, bluish clays, and shales. As indicated by the name (*lias*, corruption of *layers*), the limestones are finely stratified, and have evidently been deposited in tranquil waters. *The Oolite* is more varied in its composition, consisting of oolite limestones, calcareous conglomerates, yellowish sands, and clays, all more or less calcareous. The peculiar rounded grains which constitute the oolitic texture, consist either entirely of lime, or of an external coating of lime, collected round minute particles of sand, coral, shells, &c.; the grits are composed of sand, lime, fragments of shells and corals; and many of the clays present the same brecciated texture. *The Wealden group* (from the *wealds* or *wolds* of Kent and Sussex, where the deposit prevails) consists of beds of bluish clay, argillaceous limestones, impure oolites, and ferruginous sandstones. Fossil plants are abundant; and, as may be expected from this circumstance, local traces of coal are not unfrequent.

The organic remains of the Oolitic system are very numerous, and have long attracted the attention of geologists. They show a decided advance upon pre-existing races, inasmuch as insects, amphibious reptiles, and mammalia, make their appearance in the animal kingdom; while new tribes of vegetables, such as the cycadeæ, liliaceæ, &c. are added to the former Flora. The organisms of the lias, the oolite, and the lower members of the wealden, indicate the marine origin of these deposits; those of the upper weald an estuary character, from the comminglement of fresh water with marine species. With this distinction, the Fauna and Flora of this epoch may be thus summarily detailed:—*Plants*—seaweeds; a few equisetums; many ferns allied to those of the coal measures; cycadeæ, allied to the existing cycas revoluta and pine-apple; coniferæ, resembling the yew and pine; besides liliaceæ and other undescribed genera. *Animals*—zoophytes, more like existing species than those of the mountain limestone and silurian rocks; crinoidea, chiefly the pear-shaped encrinite pentacrinite; star-fishes, resembling the common ophiura and asterias; echinida (sea-urchins), of which the cidaris is one of the most beautiful and abundant; shellfish, both bivalves, univalves, and chambered; annulosa, like the common serpula and land-worm; crustacea, resembling the lobster tribe; insects like the beetle and dragon-fly; fishes, chiefly with enamelled scales; reptiles allied to the tortoise, to the crocodile, and gavial of existing rivers, but differing widely in their external forms and modes of existence; mammalia, two or three specimens of small marsupial animals allied to the opossums, and the somewhat doubtful remains of a monkey. In the upper or fresh-water wealden, there are no zoophytes or marine mollusca; but there are, according to Phillips, various land plants, fresh-water bivalves and univalves, some fishes, sauroid animals, and remains of turtles, both fresh-water and marine.

The reptiles of this early age were peculiar both in size and in structure. Some, which inhabited the seas, resembled lizards, but were of gigantic size; others, designed for land as well as sea, resembled the crocodiles which still exist in warm climates.

One of the most remarkable kinds (genera) has received the name of *Ichthyosaurus* (Fish Lizard), of which seven species or varieties have been discovered. The head is like that of the crocodile, composed of two long slender jaws, provided with a great number of teeth (in some cases 180), and eyes of great size (in one



Skeleton of the Ichthyosaurus.

instance, the cavity for the eye has been found to measure fourteen inches), while the nostril, instead of being near the snout, as in the crocodile, was near the anterior angle of the eye. The body was fish-like, arranged upon a long spinal column, which consisted of more than a hundred joints, and to which a series of slender ribs was attached, and terminating in a long and broad tail, which must have possessed great strength. The whole length of some specimens of the ichthyosaurus was about thirty feet. Instead of the feet, with which the lizard and crocodile are furnished, the ichthyosaurus had four paddles like those of the whale tribes, fitting it to move through the waters in the manner of those animals. It had also a construction of the sternum or breast-arch, and of the four paddles, similar to that found in the ornithorynchus, an aquatic quadruped of New Holland, and evidently designed, as in the case of that animal, to enable it to descend to the bottoms of waters in search of food. While the ichthyosaurus, then, is mainly allied to the lizard tribes, it combined in itself the additional characters of the fish, the whale, and the ornithorynchus.

The internal structure and the modes of living of the ichthyosaurus, have been in a most unexpected manner made clear by the discovery of the half-digested remains of animals found within them or in their neighbourhood. It appears that the creature possessed a large stomach, extending throughout nearly its whole body, and that it lived upon fish and other reptiles, including its own kind. It must have occasionally devoured creatures several feet in length. Masses of the refuse of the ichthyosaurus, petrified as hard as the finest marble, and well known to geologists under the name of *coprolites*, are found to be marked spirally, like the voidings of certain species of sharks and dog-fish, the intestinal gut of which winds greatly, in order that it may take up the least possible room. We thus obtain a distinct idea of the nature of a very important part of the bodily economy of this long extinct race of animals. The stomach occupied so large a space in their bodies, for the reception of large quantities of food, and it was at the same time so necessary that the speed of the animal in pursuit of prey should not be clogged by a very large or long body, that the smaller intestines had been, by a wise arrangement of nature, reduced nearly to the state of a flattened tube, coiled like a cork-screw around itself; "their bulk being thus diminished," says Buckland, "while the amount of absorbing surface remained nearly the same as if they had been circular."

The name *Plesiosaurus* is applied to another highly remarkable reptile of gigantic size, which inhabited the world before the days of mammalia. A particular species has been described as having a body and paddles which bore some resemblance to those of the ichthyosaurus, the former being more bulky, and the latter longer and more powerful. At the end of a long neck, like the body of a serpent, was a head resembling that of a lizard, but also partaking of the characters of the head of the crocodile and ichthyosaurus. The tail was short. The backbone of this creature, and the neck and tail continuing it, contained in all about ninety vertebral pieces, thirty-three of which composed the neck; and the vertebræ are found to be of a less fish-like structure than those of the ichthyosaurus, and not nearly so well calculated for rapid motion. The plesiosaurus probably lived chiefly on or near the surface of the water, breathing the air, and dabbling for prey like a duck or swan, but might also be able to descend to the bottom, and even to move, though awkwardly, upon land. One part of its organisation is peculiarly striking, as foreshadowing a structure of a more important kind: the paddles, which may be considered an advance or improvement upon the fins of fishes, are at the same time the type of the legs of quadrupeds and of the arms and limbs of man. The fore-paddle consists of scapula (shoulder-blade), humerus (shoulder), ulna (upper bone), and radius (lower bone), succeeded by the bones of the carpus and metacarpus, and the phalanges, equivalent to those which compose the palm and fingers of a human being.—(See ANATOMY, No. 13.) The hind paddle presents femur, tibia, and fibula, succeeded by the bones of the tarsus and metatarsus, and five toes. Thus "even our own bodies, and some of their most important organs, are brought into close and direct comparison with those of reptiles, which at first sight appear the most monstrous productions of creation; and in the very hands and fingers with which we write their history, we recognise the type of the paddles of the ichthyosaurus and plesiosaurus."

Of the crocodile family, found in abundance in this class of rocks, the *Iguanodon*, may be cited as a specimen. It was a huge animal, resembling the present iguana of South America, which chiefly lives upon plants and seeds. The smallest part of the thigh-bone of an iguanodon was found to be twenty-two inches in circumference, and much larger than that of any existing elephant. Species resembling the present gavial of the Ganges have also been found. It may fairly be inferred from the present habits of the gavial and other kinds of crocodiles, that at the time when the extinct species flourished, the world must have contained many low shores and savannahs, fitted for the residence of such creatures. Some parts of England are thus proved to have had at one time shores of lakes and estuaries resembling those of the Ganges, the Nile, and other waters in hot countries, and consequently a much higher temperature than at present.

But perhaps the greatest wonder of the reptile age was the creature called the *Pterodactyle*. Mainly a reptile of the lizard kind, its body possessed some of the characteristics of the mammalia: it had the wings of a bat, the neck of a bird, and a head furnished with long jaws, full of teeth, so that in this last part of its organisation it bore some resemblance to the crocodile. Eight species of the pterodactyle which have been found, vary from the size of a snipe to that of a cormorant. The eyes were of enormous size, apparently enabling it to fly by night. From the wings projected fingers, terminated by long hooks, like the curved claw on the thumb of the bat. These must have formed a powerful paw, wherewith the animal was enabled to creep or climb, or suspend itself from trees. It has been conjectured that the pterodactyle would chiefly live on flying insects, of which, it is important to notice, several varieties existed at the same time, their remains being found in the same rocks. And it is likely, from the size of the eyes, that it searched for prey by night as well as by day. But it has also been argued, from the great length and strength of the jaws, and the length of the neck, that the pterodactyle did not live solely upon flies, but likewise sought for fish in the manner of our own present sea-birds.

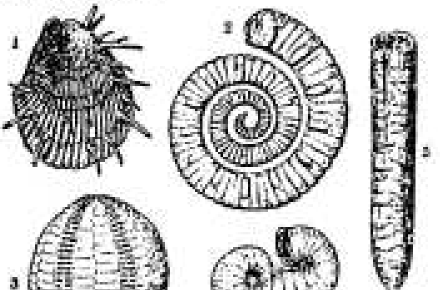
Tortoises also existed during this and the preceding age, as is proved by the marks of their feet (technically, *Sauroidichnites*) on beds of sandstone, and by their remains. But as yet few animals of a higher class had appeared upon earth—for the remains of certain creatures of the Opossum family, found in the oolite at Stonesfield, near Oxford, stand as yet so solitarily, that we can scarcely consider them as proving that mammalia were added to reptiles. With, then, flocks of pterodactyles flying in the air in pursuit of huge dragon-flies; gigantic crocodiles and tortoises crawling amidst the jungles of low, moist, and warm shores, and such monsters as the ichthyosaurus and plesiosaurus swarming on the surface of the sea, while its depths were peopled by infinite varieties of fish, shelled and vertebrated; we can form some faint idea of what sort of world it was while the strata between the coal and the chalk were in the course of being deposited.

Cretaceous or Chalk System.—Immediately overlying the wealden, and forming the upper portion of the secondary formation, occurs a set of calcareous, argillaceous, and arenaceous strata, distinguished in Europe as the Cretaceous System, from its containing the well-known mineral, *chalk* (Lat., *creta*). In this system, the arenaceous members are no longer sandstones, but loose unsolidified sands; the argillaceous beds are generally soft and marly clays; and the calcareous, instead of compact or crystalline limestones, present that soft earthy texture which prevails in chalk. All this attests a comparative recentness of formation, apart from great pressure, long-continued chemical action, or the indurating effects of heat. The strata occupy very limited spaces, and being decidedly of marine origin, point more to detached and inland seas as the areas of their deposit, than to the shores or bays of the ocean. Being thus, as it were, a local deposit, and of a thickness not exceeding 800 or 900 feet, the chalk has been more thoroughly explored than any of the older systems, and its fossils more rigidly compared with existing species. Upon investigation, it has been found that it embraces three well-marked groups; namely, the *Green-sand*, the *Gault*, and *Chalk*.

The *Green-sand*, which forms the lower division, is so named from its prevailing green colour, which it owes to a chloritous silicate of iron. In England, they are usually divided into the Lower and Upper green-sands, because of a bed of soft bluish marly clay which occurs about the middle of the group. The *Gault*, or *golt* (a local term), overlies the green-sand, and is not of great thickness, nor very regular in its occurrence. It is a bluish chalky clay, interstratified with layers of green-sand, and holds irregular balls of clay, ironstone, and iron pyrites. The *Chalk*, which forms the upper group of this system, is too well known to require description.

It consists chiefly of carbonate of lime, has an earthy texture, and is so soft as to yield to the nail. Though generally white, it sometimes passes into a dusky gray, or even red colour; and where it has come in contact with igneous rocks, it is indurated, and of a crystalline texture, like that of statuary marble. In England, the chalk strata average from 600 to 800 feet in thickness, and are usually divided into the lower and upper beds; the former being more compact, of a dusky white, varied with green grains, and containing few flints—the latter being a soft white calcareous mass, with chert nodules and regular layers of flints. Traces of stratification are scarcely distinguishable in the mass of the chalk, but are clearly evinced by the lines of flints and other nodular concretions. All the members detailed above do not occur in all chalk districts: for example, the green-sand is wanting in the north of England, chalk in the Carpathian deposits, gault in North America, while in South America the system is altogether imperfectly represented.

The organic remains found in the system are eminently marine. There are very few *plants*, and these chiefly of marine types, such as algæ, confervæ, and other sea-weeds. Rare fragments of ferns, cones of coniferous trees, cycadites, and dicotyledonous wood, have been detected in the green-sand; but, generally speaking, there is no formation so destitute of terrestrial organisms as the chalk. Among the *animal remains*, sponges, corals, star-fishes, annulosa, univalve, bivalve, and chambered mollusca, crustacea, fishes, and reptiles, are found in abundance; but, with one exception, mammalia are not known in the cretaceous rocks. The same races which appeared in the oolite appear also in the chalk, but of very different genera; so much so, that it has been observed that the cretaceous system contains genera never found in any rocks more ancient or more modern. The following are characteristic fossils:—



1. Plagiostoma spinosum; 2. Hamites intermedius; 3. Galerites albogalerus; 4. Scaphites striatus; 5. Belemnites mucronatus.

TERTIARY.

The Tertiary Formation comprises all the *regular strata* of limestone, marl, clay, sand, and gravel, which occur above the chalk. Before the labours of the celebrated Cuvier and M. Brogniart, these beds were regarded as mere superficial accumulations, not referrible to any definite period. Now, however, they are recognised as constituting a distinct formation—differing, on the one hand, from the cretaceous not only in its mineral composition, but in the higher order of organisms which it contains, and, on the other, from the superficial sands and clays, in being regularly stratified, and in imbedding the remains of animals distinct from existing races.* In general, the strata are loosely aggregated, are of no great thickness, and present appearances which indicate frequent alternations of marine and fresh-water agencies. Thus, marine remains are found in some beds, while others contain exclusively land animals and plants, and fresh-water shells. The whole suite being less consolidated than any of the secondary systems, and containing plants and animals approaching to existing forms, it presents a freshness of aspect which serves to distinguish it from older deposits; at the same time, the regularity of its deposition prevents it from being mistaken for any mere alluvial accumulation. In general, it occupies very limited and detached areas, as if it had been formed in shallow inland seas and estuaries, to which the waters of the ocean at times had access, and where, at other periods, fresh-water inundations prevailed. Another essential difference between the tertiary and the more ancient formations, consists in the fact, that the latter maintain a wonderful uniformity in their composition and character all over the globe; whereas the former present almost as many distinctions in composition as there are areas of deposit. For this reason it is impossible to give a description applicable to all tertiary strata; those of England and France, however, may be taken as types sufficiently characteristic.

The following is a descending section of the Paris basin, according to Cuvier and Brogniart:

5. Upper fresh-water group—marls, marly sands, shelly limestone, and siliceous or burr limestone.
4. Upper marine group—marls, sands and sandstones of a white or ochraceous colour, and loosely aggregated; thin layers of limestone.
3. Lower fresh-water—marls, gypsum (sulphate of lime), with bones of animals, and siliceous limestones.
2. Lower marine—consisting principally of a coarse sandy limestone (*calcaire grossier*), with calcareous marls and layers of greenish sand.
1. Plastic clay group—consisting of bluish plastic clays, with layers of sand, beds of lignite, and rolled pebbles. Supposed to be of estuary origin.

Although a very different succession takes place among the tertiaries of the south of England, yet there is sufficient resemblance in the position and aggregation of their strata, as well as in their organic remains, to establish the fact, that they belong to the same epoch as the rocks of the Paris basin. The annexed section shows the order of their occurrence to the south of London:—

4. Bagshot sands.
3. London clay—of a dull gray, or blue, or ochraceous colour; often full of green grains. Septaria and other ferruginous nodules occur in some parts. Numerous fossils.
2. Plastic clay and sands—sands of various colours, with occasional beds of lignite; also layers of sandy clay, with or without shells.
1. Sands—green and ferruginous, accompanied by flint pebbles, oyster shells, &c.

In other parts of England, the order of occurrence is somewhat different. It may be stated, however, in general terms, that the sands are most extensively developed: the clays chiefly in the southern basins; while at Oxford, Ramsholt, &c. the upper beds consist of a coarse conglomerate of corals, sand, pebbles, shells, &c. locally known as the "Crag," and so calcareous in some places as to be used as a limestone. As with the Paris and English deposits, so with other tertiary basins in Europe; those of southern France, Spain, Italy, Austria, Hungary, &c.—all showing an irregular succession of clays, sands, marls, lignite (wood-coal), and gypsum, which, when examined in relation to their positions, modes of aggregation, and fossils, are clearly referrible to the same period of formation.

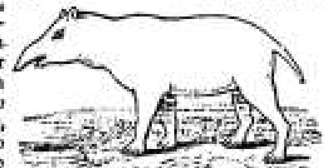
As to the extent of country occupied by tertiary deposits, there is yet no very accurate knowledge, inasmuch as many sands and clays, now regarded as the alluvium of existing valleys, may hereafter be referred to this system; and several areas of gravel, now looked upon as tertiary, be classed with more recent accumulations. As developed in Europe, the system spreads over wide areas, all remarkable for their conformation and connection with the outline of existing seas. Indeed, were the islands and continent of Europe to be submerged to the depth of 600 or 800 feet, the waters of the German, Baltic, English Channel, and Mediterranean seas, would cover most of the tertiary strata, showing that, with the exception of the general elevation which raised them into dry land, there has been comparatively little subterranean disturbance since the time they were deposited.

Igneous rocks are not found in connection with the tertiaries of England, though subterranean movements have thrown them into anticlinal ridges and basin-shaped hollows. In the south of Europe the case is otherwise, and the geologist finds in the igneous discharges of Auvergne, Switzerland, the Rhine, Hungary, and Italy, a link which connects the traps of the secondary period with the products of recent and active volcanoes.

The organic remains of the system constitute its most important and interesting feature. The fossils of earlier periods presented little analogy, often no resemblance, to existing plants and animals; here, however, the similitude is frequently so complete, that the naturalist can scarcely point out a distinction between them and living races. Geology thus unfolds a beautiful gradation of being from the corals, molluscs, and simple crustacea of the grauwacke—the enamelled fishes, encrinites, and cryptogamic plants of the lower secondary—the chambered shells, sauroid reptiles, and marsupial mammalia of the upper secondary—up to the true dicotyledonous trees, birds, and gigantic quadrupeds of the tertiary epoch. The student must not, however, suppose that the fossils of this era bring him up to the present point of organic nature, for thousands of species which then lived and flourished became in their turn extinct, and were succeeded by others, long before man was placed on the earth as the head of animated existence.

From their relative position, and from the organic remains contained in them, geologists have been enabled to distinguish, in the tertiary series of strata, four great eras of deposit. To the oldest of the tertiary eras, the term Eocene is applied; the second is called the Miocene period; the third, the Older Pliocene; and the fourth and latest, the Newer Pliocene; names founded on the respective proportions which their fossil shells bear to shells of existing species. In each of these periods is included a great fresh-water, as well as a marine deposit. Of the animals which flourished in each of these periods, we shall endeavour to give some account—premising in reference to the vegetable world, that the fresh-water beds have yielded cycadeæ, coniferæ, palms, willows, elms, and other families exhibiting the true dicotyledonous structure.

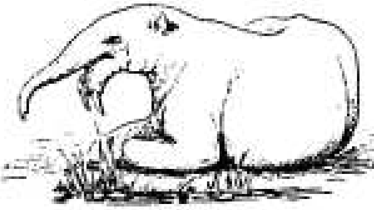
After the chalk formation, a period of considerable repose seems to have ensued, during which a large portion of the existing continents, and in especial the hollows and basins on their surface, appear to have been the site of vast lakes, rivers, and estuaries. From these was deposited the first great fresh-water formation of the Eocene period. While this deposit was going on, the globe was tenanted only by such quadrupeds as live beside rivers and lakes. Nearly fifty extinct species of mammalia, chiefly of this character, were discovered by Cuvier in the first Eocene fresh-water formation. The most of these belonged to the class Pachydermata (*thick-skinned* animals), of which the elephant, the rhinoceros, the hog, the tapir, and the horse, are remarkable existing examples. This class of animals, it may be observed, only includes such thick-skinned creatures as have no more prominent mark to distinguish them than their *skins*. The seal and river-horse, for example, are thick-skinned; but then they are *amphibious*, and that is a more prominent distinction. The extinct animals to which we now refer resemble the tapir more than any of the other Pachydermata. Among these extinct creatures, the most worthy of notice are the Palæotherium, the Anoplotherium, the Lophiodon, Anthracotherium, and one or two other families, including, some of them, not less than eleven or twelve distinct species. These mammiferous families had some general traits of resemblance, and the description of the great *Palæotherium* (ancient wild beast) may afford an idea of the main features of all. This animal was about four feet and a half in height to the wither, and somewhat squat and clumsy in its proportions. On each foot were three large toes, rounded, and unprovided with claws; the upper jaw was much longer than the under. The tapir, and partly also the hog, if large enough, would closely resemble the great palæotherium. "The palæotheria," says Buckland, "probably lived and died upon the margins of the then existing lakes and rivers, and their dead carcasses may have been drifted to the bottom in seasons of flood." The other mammiferous families of the first Eocene formation were all, like the palæotheria, herbivorous, and had, it is probable, similar habits.



Palæotherium.

The number of animals, aquatic and terrestrial, whose remains are found in the other deposits of the Eocene period, is immense. In some gypsum quarries of that era, scarcely a block can be opened which does not disclose some fragment of a fossil skeleton. The following list of the animals found in the gypsum quarries of Paris, will show sufficiently how very different from the gigantic reptiles of the secondary eras were the creatures that tenanted, and found fitting sustenance on, the earth during the Eocene period:—Besides various extinct pachydermatous families, there were found extinct species of the wolf and fox, of the racoon and genette, among the carnivorous tribes; of the opossum; of the dormouse and squirrel; nine or ten species of birds, of the buzzard, owl, quail, woodcock, sea-lark, curlew, and pelican families; fresh-water tortoises, crocodiles, and other creatures of the reptile class; and several species of fishes:—all of these animals, be it remembered, being *extinct species* of existing families, exclusive of the pachydermatous animals, and the fishes, which were extinct species of *extinct families*. The number of fossil shells found in the Eocene formations is estimated by Mr Lyell at 1238. As in the case of the terrestrial creptures, few of these shellfish are of recent or existing species, not more, at the utmost, than three and a half in every hundred. We do not, moreover, recognise in the strata now under consideration, these prodigious accumulations of *microscopic* shells, as they are called from their extreme minuteness, that distinguish the formations of the secondary or preceding ages. One small piece of rock, of the ages in question, has been found to contain above ten thousand chambered shells, though the whole weighed only an ounce and a half. In fact, great beds of secondary limestone seem to be almost wholly composed of microscopic shells. Such phenomena are not presented in the Eocene or subsequent tertiary deposits. The shells of these periods, as has been already observed, approximate more to the character of recent or existing species.

The second, or Miocene period, however, of the tertiary ages, brings us a step nearer to the existing condition of things. Whereas only three in the hundred of Eocene fossils were of recent species, of the Miocene shells we find eighteen in the hundred to have existing representatives. Along with the mammalia, also, of the Eocene period, we find that the Miocene deposits present us with the earliest forms of animals existing at the present time. In Dr Buckland's Bridgewater Treatise, a table is given, exhibiting the animals found at Darmstadt, in a bed of sand referrible to the Miocene period. In this list are mentioned two skeletons of the dinotherium, a large herbivorous animal; two large tapirs; calicotherium—two large tapir-like animals of this name; two rhinoceroses; hippotherium, an animal allied to the horse; three hogs; four large cats, some as large as a lion; the creature called the glutton; agnotherium, allied to the dog; and an animal allied to the bear. From this list the reader will perceive the gradual approach in the Miocene animals to existing species. The largest of the terrestrial mammalia yet discovered belongs to the period now under notice; it is the dinotherium, or gigantic tapir, already mentioned. No complete skeleton has yet been discovered; but from the bones found, Cuvier and others imagine the animal to have reached the extraordinary length of eighteen feet. The most remarkable peculiarities of its structure consist in two enormous tusks at the end of its lower jaw, and the shoulder-blade, which resembles that of a mole, and is calculated to have



Dinotherium.

given the power of digging, or other free movement, to the fore-foot. It is probable that this stupendous creature lived in fresh-water lakes, and had the half terrestrial half aquatic habits of the walrus or river-horse.

In the Miocene period, the seas became the habitation of numbers of marine mammalia, consisting of dolphins, whales, seals, walrus, and the lamantin, or manati. Few of these animals were of the same species as those which exist at present; but the differences were far from being great or remarkable. This circumstance, as well as the considerable number of fossil shells identical with existing ones, exhibits an approach in the character and tenantry of the Miocene seas to the present state of things in these respects. The discovery, also, of true terrestrial mammalia, as the rhinoceros and hog, in the Miocene formations, shows, that since the era of the gigantic reptiles, a large portion of the earth's surface had assumed the condition of dry land, fit for the support of the common herbivorous creatures. At the same time, the occurrence of such animals as the dinotherium proves, as Dr Buckland remarks, that many regions were still covered with great lakes and estuaries. It now remains to inquire into the nature and peculiarities of the animals characterising the Pliocene age, which, for convenience, has been arranged into two periods, the Older and Newer Pliocene, the latter of which immediately preceded the formation of the diluvial layer constituting the present superficial matter of the globe: whereas only eighteen in the hundred of the Miocene shells were of recent species; in the Older Pliocene from thirty-five to fifty, and in the Newer Pliocene not less than from ninety to ninety-five in the hundred, are identical with shells of existing species. This great change is accompanied by the disappearance of the Palæotherian family and others, which formed the most striking animal remains of the periods immediately preceding. In place of these extinct species of *extinct* Pachydermatous or thick-skinned families, we observe in the strata of the Pliocene periods a vast number of remains of *existing* Pachydermatous families, such as the elephant, the rhinoceros, and the hippopotamus, though these remains belong to varieties that are now extinct. The first traces also now appear of ruminant animals—of oxen, deer, camels, and other creatures of the same class. But though it is of importance to notice the existence of such remains in the Pliocene ages, in order to exhibit the progressive approach to the present state of things in the animal kingdom, it is in the huge and extraordinary creatures, now no longer to be seen on the face of the earth, that the interest of such an investigation as the present chiefly lies.

The enormous creature called the *Great Mastodon* belongs to the Pliocene era. Of all the fossil animals whose skeletons have been found *complete*, or nearly so, the mastodon is the largest. It is about one hundred and twenty years since its remains were first discovered in America, and vast quantities of them have been since found in the same region, buried chiefly in marshy grounds. One skeleton, nearly complete, was dug up on the banks of the Hudson in 1801, and it is from this that a correct knowledge of the animal has been principally derived. In height, the mastodon seems to have been about twelve feet, a stature which the Indian elephant occasionally attains. But the body of the mastodon was greatly elongated in comparison with the elephant's, and its limbs were thicker. The whole arrangement of the bony structure resembled that of the elephant, excepting in one point, which Cuvier regarded as of sufficient consequence to constitute the mastodon a different genus:—this was the cheek-teeth, which are divided, on their upper surface, into a number of rounded, obtuse prominences, arranged not like the elephant's, but like those of the wild boar and hippopotamus; whence it is concluded, that, like the latter animals, the mastodon must have lived on tender vegetables, roots, and aquatic plants, and could not have been carnivorous. The lower jaw of the skeleton found on the Hudson is two feet ten inches in length, and weighs *sixty-three pounds*. Like the elephant, the mastodon had two tusks, curving upwards, and formed of ivory; and in the opinion of Cuvier, it had also a trunk of the same kind with the former animal's. Altogether, making an allowance for several additional feet of length, it may be considered as varying but little from the larger specimens of the elephant. From the immense number of mastodon bones which have been dug up in various parts of the earth, and particularly in the new world, we must conclude that at no distant period of time the terrestrial surface was extensively peopled by these enormous creatures.

Another creature, belonging to the later Pliocene ages, if not indeed to the era of the diluvial formation, has been discovered in America, both north and south. This is the *Megatherium* (great wild beast), an animal more widely removed in character from any existing creature, than any of the other fossil remains that have been yet observed. The megatherium was discovered towards the end of the last century. A skeleton, almost entire, was found nearly at one hundred feet of depth, in excavations made on the banks of the river Luxan, several leagues to the south-west of Buenos Ayres. The megatherium was a tardigrade (slow-moving) animal, like the sloth, but of gigantic dimensions, and calculated to subsist on roots and succulents, and on the foliage and young shoots of trees, for the uprooting and overturning of which its structure seems to have been admirably adapted. Its habits and peculiarities are thus described by Dr Buckland. After stating, that with the head and shoulders of a sloth, it combined, in its legs and feet, an admixture of the characters of the ant-eater and the armadillo, and resembled them still more in being cased in a coat of armour, he continues—"Its haunches were more than five feet wide, and its body twelve feet long and eight feet high; its feet were a *yard in length*, and terminated by most gigantic claws; its tail was probably clad in armour, and much larger than the tail of any other beast among living or extinct terrestrial mammalia. Thus heavily constructed, and ponderously accoutred, it could neither run, nor leap, nor climb, nor burrow under the ground, and in all its movements must have been necessarily slow. But what need of rapid locomotion to an animal whose occupation of digging roots for food was almost stationary? And what need of speed for flight from foes to a creature whose giant carcass was encased in an impenetrable cuirass, and who, by a single pat of his paw, or lash of his tail, could in an instant have demolished the cougar or the crocodile? Secure within the panoply of his bony armour, where was the enemy that would dare encounter this behemoth of the Pampas (the South American region where it existed), or in what more powerful creature can we find the cause that has effected the extirpation of his race? His entire frame was an apparatus of colossal mechanism, adapted exactly to the work it had to do; strong and ponderous, in proportion as this work was heavy, and calculated to be the vehicle of life and enjoyment to a gigantic race of quadrupeds, which, though they have ceased to be counted among the living inhabitants of our planet, have, in their fossil bones, left behind them imperishable monuments of the consummate skill with which they were constructed."

Associated in the same set of deposits—that is, in detrital beds of somewhat later origin than the tertiaries of Europe—Mr Darwin has discovered in South America the remains of several gigantic quadrupeds besides those of the megatherium. Of these, the most remarkable are—the *Megalonyx*, nearly allied to the megatherium; the *Scelidotherium*, an animal as large as the rhinoceros, but partaking of the character of the Cape ant-eaters and armadillos; another great armadillo-like animal with a bony covering; the *Macrauchenia*, a huge beast, with a long neck like a camel; and the Toxodon, perhaps the strangest animal ever discovered. The macrauchenia is described as belonging to the same division of the pachydermata as the rhinoceros and tapir, but showing in the structure of its long neck a clear relation to the camel, or rather to the alpaca and llama. As to the toxodon, it equalled in size the elephant or megatherium; but the structure of its teeth proves indisputably that it was intimately related to the gnawers, the order which, at the present day, includes most of the smallest quadrupeds. In many details it is allied to the thick-skinned animals; and, judging from the position of its eyes, ears, and nostrils, it was probably aquatic, like the dugong and menatee, to which it is also allied. "How wonderfully," remarks the discoverer, "are the different orders, at the present time so well separated, blended together in different parts of the structure of the toxodon!"

SUPERFICIAL ACCUMULATIONS.

After the deposition of the tertiary strata, a great change took place in the relative distribution of land and ocean. Most parts of Europe, America, and the other continents were elevated above the waters; other regions seem to have been submerged, and an arrangement of physical conditions established not differing widely from those now existing. But these new conditions did not for an instant arrest the degrading and transporting power of water, the wasting effects of the atmosphere, the disturbing efforts of volcanoes, or the progressive developement of organic life: the same agents which had exerted themselves, from the beginning of time, in modifying the physical features of the world, continued their career, only differing in power and degree according to this new arrangement. Thus accumulations of sand, gravel, clay, vegetable and animal matter, took place above the previously deposited strata—every river, lake, sea-shore, shell-bed, coral-reef, and peat-moss, contributing its peculiar quota. The term Superficial Accumulations is applied to these loosely-aggregated masses of matter—whatever be their composition or mode of formation—to distinguish them from the tertiary sands and clays, in all of which *stratification* is distinct and undeniable. Other designations have been proposed; but most of them are objectionable, on the ground of involving theoretic opinions as to the time and origin of the deposits. The following synopsis exhibits both the nature of the accumulations, and the agencies concerned in their aggregation:—

Agencies.	*Nature of Accumulations.*
DETRITAL.	Erratic blocks or boulders; dark tenacious clays.
	Ossiferous gravels, sands, and pebbly clays.
	Ossiferous caves, fissures, and breccia.
MARINE.	Raised or ancient beaches; submarine forests.
	Marine silt, sand-drift, shingle beaches, &c.
	Submarine deposits and accumulations.
FLUVIATILE.	Terrace-deposits on valley sides, marking successive water-levels, and distinct from general oceanic levels.
	Valley deposits, consisting of river sand, gravel, silt, &c.
	Deltoid or estuary deposits, ancient and progressive.
LACUSTRINE.	Sites of ancient lakes now silted up with various debris.
	Marls—such as shell, clay, and calcareous marls.
	Lacustrine silt, and accumulations now in progress.
MINERAL AND CHEMICAL.	Calcareous—calc-tuff, sinter, travertine, stalactites, and stalagmites.
	Siliceous and aluminous deposits from springs, &c.
	Saline and sulphureous deposits from springs, from the sea, volcanoes, &c.
	Bituminous exudations, pitch lakes, &c.
ORGANIC.	Vegetable—peat-mosses, jungles, vegetable drift.
	Animal—shell-beds, coral-reefs, &c.
	Soils—primitive earths, with admixtures of organised matter.
VOLCANIC.	Earthquakes—elevations and depressions, caused by
	Volcanoes—elevations, disruptions, and other changes caused by
	Discharges and accumulations of lava, scoriæ, dust, &c.

The above synopsis comprises all masses of matter which produce any sensible modification of the earth's surface; other accumulations than these must be of a very local and limited description. All these masses are, moreover, of obvious formation, and are either still in progress of accumulation, or have been accumulated since the Tertiary era; that is, since our planet assumed its present superficial aspect, and relative distribution of land and sea, or nearly so. On this account they may be designated "Formations of the Current Era," none of them presenting much difficulty of solution, with the exception, perhaps, of the *Erratic Block* or *Boulder Group;* the others have been already noticed under the head of MODIFYING CAUSES.

The boulder formation, or diluvial drift, consists, as stated, of a thick mass of dark tenacious clay, which overlies extensive districts, intermingled with numerous boulders having a rounded and water-worn appearance. There is nothing like regularity of deposit in the mass, unless it may be said that it attains the greatest thickness and uniformity of composition on extensive plateaus like those of the coal measures, at the eastern extremity of certain valleys, and on the south-eastern flank of hills belonging to the secondary period. The clay is generally of a dark-blue colour, though in some localities it assumes a reddish hue. There are few lines of lamination in the mass, and no appearances of regular stratification, unless in some districts where there is a sort of natural division into "upper and lower clays"—the lower being dark and more compact, the upper lighter in the hue, and separated from the other by a thin reddish streak. Waiving these minutiæ, the whole may be described as a covering of compact dark clay, from 10 to 120 feet in thickness, full of boulders and rolled stones, from the size of an egg to many tons in weight; these blocks occupying the bottom, middle, or surface of the mass, without regard to gravity or any other law of arrangement. The boulders are principally of primitive rocks, the more friable strata of the secondary measures being less capable of resisting the drifting action to which the mass has evidently been subjected, and which in all cases appears to have passed in a direction from north-west to south-east.

To account for this deposit, many theories have been advanced; but the one chiefly worthy of notice is that which supposes that those portions of Europe now covered with erratic blocks were submerged after the deposition of the stratified formations; that this submergence was caused by some extraordinary revolution in the planetary relations of our earth; that it was accompanied by a change of climate, and other terrestrial conditions; that while in this state icebergs and avalanches formed around the earlier mountains which were still left above water; and that these icebergs, as they were loosened from the shore by the heat of summer, and floated southward by the currents of the ocean, dropped their burden of boulders and gravel precisely as Captain Scoresby found modern icebergs dropping their debris in the northern seas, and as the officers of the recent antarctic expedition observed similar phenomena in the Southern Polar Ocean. It is further supposed, that while icebergs distributed the erratic blocks and other debris in deep waters, avalanches and glaciers were forming moraines of gravel in the valleys of the then existing land analogous to what is observed in the alpine glens of Switzerland. Again, one cannot read Mr Simpson's account of the shores of the Polar Seas, and learn that the ice formed during winter over whole leagues of gravel, breaks up during summer, and is blown on the beach by winds, or piled up by the tides, where, melting, it leaves long flat-topped ridges, without perceiving a wonderful resemblance between these effects and the long singularly-shaped ridges of "diluvial" gravel. According to this theory, it is easy to account for the south-eastward direction of the drift, for the Polar Ocean still maintains its great southward current to the equatorial seas, modified, undoubtedly, in its course by the inequalities of the bottom over which it passes. The chief difficulty to be obviated, is the temporary diminution of temperature which the north of Europe and Asia must have then experienced.

The igneous rocks connected with these superficial accumulations are essentially the products of active existing volcanoes; the raised beaches and old water-levels so frequent along our shores, whether resulting from elevation of the land or subsidence of the ocean, seem to indicate a more general, tranquil, and gradual cause than any set of volcanic operations.

The remains found in the superficial accumulations, for we can scarcely regard them as fossils, are all of a comparatively recent character and construction. A few of the animals existing during the deposition of the lower beds are now extinct, others present variety, if not specific distinctions; while in the higher accumulations nothing occurs which partakes not of the character of the current era. The boulder clays and gravels are all but void of organic relics; and it is only after that truly glacial period is passed, that the remains of land and sea animals are to be discovered—in some districts abundantly, in others rarely, and over all, a distribution somewhat analogous to that now existing. One of the most curious, as well as the most gigantic animals found in these deposits, is the *Mammoth*, or *fossil elephant*. It was surmised, when numbers of mammoth bones were first discovered in Italy, and other southern countries of Europe, that they were the remains of elephants brought by the Romans and others from Asia and Africa; but the incalculable quantities of them ultimately detected in Russia, Siberia, and other districts, where elephants were never brought in the shape of Oriental tribute, as they were to Rome, showed that their presence was to be attributed to natural causes, and not to the casual agency of man. In truth, the beds of the Volga, Don, and other northern rivers, are filled with them; and this can be accounted for only on the hypothesis, either of an alteration in the habits of the elephant, or of a great change of climate in these parts, or of some immense moving force on the face of the earth, which has carried them thither. The instance in which part of the flesh was found along with the bones, will supply us with a general description of the mammoth. When the animal, on this occasion, was first seen through the mass of ice in which it lay, the soft parts were nearly entire. After the natives had fed their dogs for a long time with the mountainous bulk of flesh, Mr Adams of St Petersburg heard of it, and set out to see it. When he reached the spot, the skeleton was entire, with the exception of a fore-leg. The spine of the back, a shoulder-blade, the pelvis, and the rest of the extremities, were still united by ligaments and a portion of the skin. The other shoulder-blade was found at some distance. The head was covered with a dry skin. One of the ears, in high preservation, was furnished with a tuft of hair, and the pupil of the eye was still discernible. The brain was found in the skull, but in a dry state. The neck was furnished with a *long mane*, and the skin, generally, was covered with black hairs and a reddish sort of wool. Of the quantity of hair and bristles that had been on the body, some idea may be formed from the fact, that thirty pounds of them were gathered from the ground, where the dogs, in eating the flesh, had dropt them. The tusks were more than nine feet long, and the head, without the tusks, weighed more than four hundred pounds. Altogether, the skeleton of this mammoth was about the size of a large elephant's. Skeletons similar to this have been found in abundance in the islands of the Arctic Sea. They differ in several minute points of structure from the common elephant, and on this circumstance the most rational explanation of their being found in such cold climates is founded: this explanation is, that the mammoth elephant was of a species fitted to be a native of cold countries; and of this reasoning, the different structure, and the long thick hair, are held to be proofs. Whether this may be the case or not, it seems certain that the mammoth's existence must have been very recent, and must have approached closely to, if not encroached on, the era of man.

Of man himself no remains have been found, save in the most recent and superficial deposits—as alluvial mud, calcareous breccia, volcanic tufa, and the like—thus proving him to be one of the latest, if not the very latest, inhabitant of this globe.

SUMMARY.

The history of the earth thus presents a long series of mineral and vital gradations, as yet but imperfectly interpreted by geology. The stratified formations, from the gneiss to the existing surface, bear evidence of these gradations, both in their composition and mode of aggregation; so also do the unstratified rocks—the granitic, trappean, and volcanic compounds—by the order in which they succeed each other. On the other hand, organic being rises, as it were, from the simple zoophyte to man himself, appearing at successive eras, as new conditions permitted its development. As system gradually merges into system, so the Fauna and Flora of one period seem to live into that of another, there being always certain races which serve as links of connection between succeeding eras. This idea of gradation implies not only an incessant onward change among the rock materials of the earth, but also that certain races of plants and animals must be perpetually dropping out, as links from the great chain of animated nature. And such is the fact even with respect to the current era. The mammoth, mastodon, megatherium, and other huge pachydermata, which passed from the tertiary to the modern epoch, have long since become extinct, leaving their bones in the clays and gravels of our valleys. The elk, bear, wild boar, wolf, and beaver, are now extinct in Britain; and what takes place in limited regions, must also occur, though more slowly, in wider continents. The dodo of the Mauritius, the dinornis and apteryx of New Zealand, are now matters of history; and the same causes which led to their extinction seem hurrying onward to the obliteration of the beaver, ostrich, kangaroo, and other animals whose circumscribed range of existence is gradually being broken in upon by new conditions. Such facts as these, taken in connection with the numerous superficial changes produced by rivers, lakes, seas, peat-beds, coral-reefs, earthquakes, and volcanoes, have led to speculations as to the conditions which yet await our planet.

Respecting the future history of the globe, it were vain to offer any conjecture. Subjected as it is to the numerous modifying causes previously described, we know that vast changes are now in progress, and that the present aspect of nature is not the same as that it must assume a thousand years hence. But what may be the character and amount of these changes, what the new conditions brought about by them, or what the races of plants and animals adapted to these conditions, we have no means of determining. This only we are assured of, that whatever vicissitudes may affect the globe, they will be tempered in perfect accordance with the happiness of organised existence: that Supreme Intelligence which has maintained the past will continue to protect and superintend the future.

METEOROLOGY—THE WEATHER.

Meteorology is the science of the Weather, and treats of the phenomena which occur in the atmosphere, their causes and effects. Men in all ages of society have been led, by motives of necessity or comfort, to study the indications of the weather in the different appearances of the skies. The mariner, the shepherd, the husbandman, and the hunter, have the strongest motives to examine closely every varying appearance which may precede more important changes. The result of these observations forms a body of maxims, in which facts are often stated correctly, but mixed with erroneous deductions and superstitious notions, such as the credulity of ignorant people always renders them ready to adopt. Hence the disposition to refer the ordinary changes of the weather to the influence of the moon, and to the stars; and to look for signs of approaching convulsions, even in the moral world, in comets, meteors, and other unusual phenomena. The progress of science, which tends to separate the casual precursors from the real causes of events, refutes these false reasonings, dissipates the empty terrors to which they give rise, and aims, by more patient, long-continued, and wide-extended observations, to deduce the general rules by which the phenomena of the atmosphere appear to be regulated.

Meteorology, therefore, taken as a distinct branch of knowledge, rests on no idle conjectures or imaginary fears, but has its foundations in the ascertained truths of physical science. The phenomena to which it refers are accounted for by natural laws disclosed to us in the study of chemistry, electricity, the atmospheric properties, optics, acoustics, heat, and other departments of physics. Of all branches of learning, none perhaps is more serviceable in clearing the mind from superstition; and on that account alone, independently of all other considerations, we are anxious that meteorology, as a science, should be extensively understood among the classes whom we have the pleasure to address. That nothing may be left to doubt, we commence by a recapitulation of the leading facts connected with the extent, composition, density, and other mechanical properties of the atmosphere.

THE ATMOSPHERE.

The atmosphere is an invisible aëriform fluid, which wraps the whole earth round to an elevation of about forty-five miles above the highest mountains. This great ocean of air, as we may call it, is far from being of a uniform density throughout its mass. At and near the level of the sea it is most dense, in consequence of the pressure of the superincumbent strata. As we ascend mountains, or in any other way penetrate upwards, the air becomes gradually less dense; and so thin is it at the height of three miles, as, for instance, on the summit of Mont Blanc, one of the Alps, that breathing is there performed with some difficulty. Beyond this limited height, the density of the air continues to diminish in the duplicate ratio of the altitude; and at the elevation of about forty-five miles it is believed to terminate, or at least to become so attenuated, that its density is inappreciable. So dense are the lower in proportion to the higher regions, that one-half of the entire body of air is below a height of three miles, the other half being expanded into a volume of upwards of forty miles in altitude.

The atmosphere, like all liquid and aëriform fluids, pressing equally in every direction, must exert a certain pressure on all objects, the degree of pressure being of course in proportion to the height above the mean surface of the earth. The part at which the pressure is greatest is at the level of the sea, for there the atmosphere is highest. The pressure at that level is ordinarily computed to be about 15 lbs., or, more correctly, 14.6 lbs. avoirdupois on every square inch of surface. The surface of a man of ordinary stature is about 15 square feet, or 2160 square inches, whence the whole atmospheric pressure which his body sustains amounts to the enormous sum of 31,536 lbs.! This great pressure is not sensible, however, because it is balanced by the reaction of the elastic fluids in the interior of our bodies. Under the exhausted receiver of an air-pump animal life is soon destroyed: on the summit of a very high mountain not only is fatigue and difficulty of respiration experienced, but the pulse is accelerated; and it has happened that the blood has started from the eyes and ears, and other tender parts of the body, in consequence of the diminished pressure.

The extreme height of the atmosphere is not observable from the situation in which we are placed on the earth. Our eye, on being cast upwards, perceives only a vast expanded vault, tinted with a deep but delicate blue colour; and this in common language is called the heavens or the sky. The blueness so apparent to our sense of sight is the action of the rays of light upon the thin fluid of the upper atmosphere, and the brightness is in proportion to the absence of clouds and other watery vapours. In proportion as the spectator rises from the surface of the earth, and has less air above him, and that very rare, the blue tint gradually disappears; and if he could attain a height at which there is no air, say fifty miles above the level of the sea, the sky would appear dark or black. Travellers who have ascended to great heights on lofty mountains, describe the appearance of the sky from these elevated stations as dark, or of a blackish hue.

Notwithstanding its transparency, the air thus intercepts and reflects the sun's rays, multiplies and propagates them by an infinity of repercussions; and were it not for this property, objects would never be illuminated unless exposed to the direct light of the sun. It is also the recipient and retainer of the solar heat reflected from the earth; and were it not so constituted, the solar rays would be returned to space, and an excessive cold continually prevail. Chemically speaking, it is a gaseous admixture—every hundred parts of which are composed of 79 nitrogen, and 21 oxygen—with about one part in a thousand of carbonic acid. Besides these, which are the permanent constituents of the atmosphere, there is always a certain amount of aqueous vapour, amounting from 1 to 1·0 per cent.; and in certain localities traces of ammonia, sulphurous acid, muriatic acid, and other ingredients are to be occasionally detected. The atmosphere may therefore be regarded as the laboratory in which clouds, rain, snow, and other vapours are formed—the medium through which the light and heat of the sun are diffused and equalised—an element without which animal and vegetable life could not exist, for both incessantly inhale and exhale its elements; and an agent indispensable to those physical operations which constitute the progressive history of our planet.

The Barometer.—The pressure of fifteen pounds to the square inch at the level of the sea, is found by experiment to be equal to the weight of a column of mercury of thirty inches in height; and the fact of such being the case, has suggested the construction of an instrument to measure the atmospheric pressure at different points and in various circumstances. This instrument is called the *barometer*, a compound from two Greek words, signifying weight-measurer.

The barometer in common use consists of a narrow glass tube upwards of thirty inches in length, and bent upwards at its lower extremity, as represented in fig. 1. The mercury is introduced into the tube with great care, so that a perfect vacuum exists at the upper extremity. The surface of the mercury in the bent part is open to the action of the atmosphere, and buoys up a small plummet or float F, to which a thread is attached; the thread proceeds upwards to a small pulley G, over which it goes, and terminates in a small ball W. The friction of the thread on the pulley turns a small index H, which points to figures on the surrounding dial. Commonly, the whole apparatus, except the dial-plate, is concealed in an ornamental frame. Barometers of this description are adjusted in such a manner that the smallest rising or falling of the mercury from atmospheric action, affects the index on the dial, and consequently shows the degree of pressure.

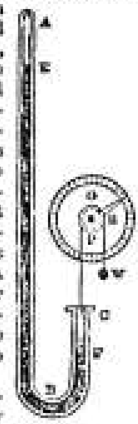


Fig. 1.

In common circumstances, the mercury ranges from twenty-nine to thirty inches. It seldom sinks so low as twenty-eight or rises to thirty-one. When it falls, an indication is given of diminished pressure; and as diminished pressure causes the air to expand, and consequently to be sensibly cooled, moisture is liable to be precipitated in the form of rain. Hence a fall in the mercury of the barometer is considered a prognostic of rain or wet weather, and a rise the reverse. The dial of the barometer is marked accordingly.

The usual rules, however, as to prognosticating the state of the weather from the action of the barometer, are in many cases very illusory; because much depends on the situation in which the instrument is placed. If situated near the sea's level, the pressure on the mercury will appear greater than if on a high ground, and, consequently, no general scale can apply to conditions so very dissimilar. In alluding to the vulgar errors entertained on this subject, Dr Lardner remarks—"It is observed that changes of weather are indicated, not by the actual height of the mercury, but by its change of height. One of the most general, though not absolutely invariable rules is, that where the mercury is very low, and therefore the atmosphere very light, high winds and storms may be expected. The following rules may generally be relied upon, at least to a certain extent:—1. Generally the rising of the mercury indicates the approach of fair weather; the falling of it shows the approach of foul weather. 2. In sultry weather the fall of the mercury indicates coming thunder; in winter the rise of the mercury indicates frost; in frost its fall indicates thaw, and its rise indicates snow. 3. Whatever change of weather suddenly follows, a change in the barometer may be expected to last but a short time. Thus, if fair weather follow immediately the rise of the mercury, there will be very little of it; and in the same way, if foul weather follow the fall of the mercury, it will last but a short time. 4. If fair weather continue for several days, during which the mercury constantly falls, a long continuance of foul weather will probably ensue; and again, if foul weather last for several days, while the mercury continually rises, a long succession of fair weather will probably succeed. 5. A fluctuating and unsettled state of the mercurial column indicates changeable weather. The domestic barometer would become a much more useful instrument, if, instead of the words usually engraved on the plate, a short list of the best established rules, such as the above, accompanied it, which might be either engraved on the plate or printed on a card. It would be right (concludes this writer) to express the rules only with that degree of probability which observation of past phenomena has justified. There is no rule respecting these effects which will hold good."

The Thermometer.—The atmosphere possesses the capacity of receiving and containing heat from the sun's rays or any other source of warmth, but this capacity is proportionate to the degree of density of the air, and accordingly varies in different situations. It is well known that the air is more warm on low than on high grounds, and this is a peculiarity in its condition arising from the difference of density at the two places. If we take a pound weight of air near the sea's level, and another pound weight at a spot a mile above the sea, we shall find that each pound contains precisely the same quantity of heat; but in the case of that taken near the sea, the air will feel warm, and in the case of the other, the air will feel cool. This seems a contradiction, yet it is a truth. A pound weight of air taken near the sea, is compact in substance, and goes into a comparatively small bulk; but that taken from a high part of the atmosphere is thin, and occupies a much larger space. This explains why the thin air on high grounds is seemingly colder than on low situations. Aloft, the air is as warm as it is below, but there is less of it; the particles are more widely asunder, and this produces the effect of a greater coldness. Properly speaking, the cold in high situations arises from the want of air, rather than from the air itself.

In the warmest regions of the globe, the air is cold at the tops of high mountains, merely because the air is there thin and incapable of forming a medium for the retention of the sun's rays. In every country there is a point of altitude at which water freezes on all occasions, whether summer or winter. In Europe, this point—called by some the snow line, or point of eternal snow—is from five to six thousand feet above the level of the sea; in the hot regions of Africa and America, it is fourteen thousand feet high. At these points of altitude respectively, snow lies constantly unmelted on the mountain sides and summits. In the warm regions of Hindostan, the atmosphere is as cool and pleasant at a certain height on the Himalaya Mountains as it is in the northern part of Europe. The plains of Mexico, under a burning sun, would not be endurable by man, if they were not at such an elevation as to possess an atmosphere so rare as to be incapable of being heated to excess.

Although the heat of the atmosphere thus depends on the density of the fluid, it is proper to state that it is likewise influenced by other circumstances. Certain bodies have the power of heating the atmosphere in a greater degree than would otherwise be the case. For example, in valleys the heat is thrown off from the sides of adjacent hills, from forests of trees, or other objects; and in these situations the air is hotter than if there were no such radiation. If the spot be sheltered from the cooling effect of winds, there is another cause of increase to the temperature.

Fig. 2.

The degrees of heat and cold in the atmosphere are called its temperature; and for finding this correctly, with reference to a standard, an instrument has been invented, called the *thermometer* a word signifying heat-measurer. It is a glass tube with a bulb at the bottom, into which mercury or quicksilver is put, with a scale of figures along the tube to mark the rising of the quicksilver. This instrument differs from the barometer, inasmuch as the quicksilver is sealed up close from the air. The atmospheric heat, however, affects the metallic fluid in the bulb, and, according to its warmth, causes it to expand and rise in the tube. The degree of temperature is indicated by the figures to which it ascends.

Our common thermometer (Fahrenheit), of which a representation is given in fig. 2, has a gradation from zero, near the bulb, to 212, the degree of heat of boiling water. In the scale of figures, 32 is marked as the freezing-point—that is to say, when the mercury is at the height of 32, *water* freezes; and the more it is below that point, the more intense is the frost: 55 is reckoned moderate heat, and 76 summer heat, in Great Britain: 98 is the heat of the blood in the average of living men.

Different nations adopt different graduations in the scale of thermometers, which is a fertile source of error and confusion in estimating and comparing the statements of temperature made by scientific men in different countries. Wherever the English language prevails, the graduation of a person called Fahrenheit is generally preferred. By the Germans, Reaumur's is used; and the French now adopt what they term a centigrade thermometer. In the French centigrade thermometer, 0 is the freezing-point, and 100 the boiling-point; in Reaumur's thermometer, 0 is the freezing-point, and 80 the boiling-point. Each degree of Reaumur is equal to two and one-fourth of Fahrenheit. It was at one time imagined that the greatest cold could make the fluid in the thermometer fall only 32 degrees below the freezing-point, the place to which it then fell being *zero*, and therefore the notation has been commenced by Fahrenheit at that place. But much greater degrees of cold exist at different parts of our globe in winter, and may be produced artificially, so that the fluid in the stem of the thermometer often descends below that point, and is then said to be at so many degrees below zero.

Water, as above mentioned, boils at 212 degrees, but this is only under the common pressure of the atmosphere near the sea's level. By removing a portion of the pressure either by an air-pump or by ascending a height, the vaporific or boiling point will be reached correspondingly sooner. On this account, we might ascertain with tolerable accuracy the height of mountains, by noticing at what degree of heat by the thermometer water boiled. A writer in the *Encyclopædia Britannica* has given the following instructions on this subject:—

"Boil pure water in an open vessel at the bottom of the elevation, and observe on the thermometer the point at which it boils. Boil it again at the top of the mountain, and observe with the thermometer the point at which it now boils; the difference of temperature, multiplied by 530 feet, will give a close approximation to the height of the upper above the lower station. This will give an approximation; but if greater accuracy be required, it will further be necessary to correct for the difference of the temperature of the air at the two stations, in the following manner:—Add the temperatures of the air at the stations, and subtract sixty-four from their sum; multiply the remainder by one-thousandth part of the height found, and this will be the correction to be added to the height formerly found. The result thus found will still require a slight correction for the figure of the earth and latitude of the place; but this does not amount to more in our latitude than an addition of about two feet in a thousand, which forms a second correction.

To illustrate the mode of deducing heights from the boiling-point, as we have given it, we take the following example:—Water boils on the top of Ben Nevis at 203·8 degrees, while at the side of the Caledonian Canal it boils at 212 degrees, the temperature being 30 degrees on the summit of the mountain, and 35 degrees below. In order to determine the height,

4358, true measured height—the difference being less than 1 foot.

This method, however, is seldom susceptible of so high a degree of accuracy, even with the most carefully conducted experiments."

The Hygrometer.—One of the principal meteorological phenomena of the atmosphere is its capacity for receiving and holding moisture. Evaporation, to a lesser or greater extent, is in constant exercise over the whole earth. The ocean, lakes, rivers, fields, are ever yielding up water to the atmosphere, and plants and animals are also at all times giving forth exhalations. The atmosphere is thus a great receptacle for the moisture of the earth, and its capacity in this respect is increased by an increase of temperature. In a hot day, much more evaporation is produced than in one which is cold, but it is not on that account more perceptible by the senses. The more warm and free the air, so is the moisture less observable in its mass; and it is only when the atmosphere sinks to a certain pitch of cold, that we begin to see the suspended moisture in the form of mists and clouds. Thus, in a hot day, we do not see the breath issuing from our mouth, it being conducted away in an ethereal state, but in a cold damp day in winter, we see it proceeding in puffs at every expiration.

The state of the atmosphere as respects its moistness, is called its *hygrometric condition*, from the hygrometer, an instrument for ascertaining the relative degree of moisture in the air. There are various kinds of hygrometers, depending on the principle of the shrinking and expanding of bodies in relation to the degree of humidity with which they are affected. Fibrous vegetable substances, such as ropes, contract by imbibing moisture, while, on the contrary, hairs and catgut (strings of violins), contract by drought. Hair has been found to be the most delicate in hygrometrical motions. The celebrated Saussure, a Swiss philosopher, accomplished the construction of a hygrometer from a single long hair, previously cleaned in a soda ley. Various philosophical toys, as ornaments for mantel-pieces, have also been constructed to indicate the dryness or moistness of the atmosphere, all on the similar principle of contraction and expansion of a hair, piece of catgut, or part of the beard of the wild-oat. One of the most useful instruments of this class is a small object resembling a watch in external appearance, designed to prove the dampness or dryness of beds: a moveable hand on the dial-plate points out very speedily the hygrometrical condition of the bedclothes on which the instrument is laid.

Hygrometers of the kind just mentioned, however ingenious, fail as instruments of science or comparison, chiefly from the circumstance of their liability to lose their contractile and expansive energy, as well as the difficulty of making many of them possessing similar powers. To supply the required instrument of comparison, Professor Daniel contrived a very elegant hygrometer, which is now universally in use. It consists of a glass tube, bent nearly in the form of ⫍, supported on a stand, with a ball at each extremity, and containing only some ether. Within one of the depending limbs a thermometer is placed. The instrument operates on a little ether being dropped on one of the balls; evaporation immediately takes place, heat is abstracted, and the ball containing the thermometer is so cooled, that a dew perceptibly gathers on its surface. The degree of temperature at which the dew is seen to collect, marks the exact hygrometric condition of the atmosphere. The principle is precisely that on which a bottle of cold liquor, on being brought into a warm apartment, collects dew on its surface. If no dew appears on a bottle in such circumstances, the atmosphere of the room is certainly very dry.

CLOUDS.

The capacity of the atmosphere for moisture, even in the most favourable circumstances, is limited. The air cannot be loaded with water, in any form, beyond a certain point. Meteorologists mention, that if saturated with vapour even to its utmost extent, the whole would not form more than from six to seven inches of rain; in other words, not more than six or seven inches of water can be maintained in solution throughout the forty-five miles of atmosphere above, at any one time. The capacity for retaining moisture is greatest in the lower strata of the atmosphere, or where it is most dense and warm. At great elevations, such as eight or ten miles, the air is too thin to hold water in solution; and in all ordinary circumstances, the vapours of the earth do not ascend above four or five miles from its surface at the sea's level. Above those heights, whatever be the state of the weather beneath, all is clear and comparatively dry. In very few cases do clouds rise above the height of three miles; the field of their evolutions in temperate climes is most frequently not above a mile or a mile and a-half high.

Clouds, it will be perceived, are in reality dependent on temperature, and temperature is often dependent on winds. In a warm and dry summer day, evaporation proceeds with great activity, and, in a manner invisible to the eye, the moisture rises to the higher regions of the air. If the sun be powerful, the moisture may thus ascend several miles, and be dispersed like a gas, leaving no cloud to indicate its existence. All, therefore, appears clear, serene, and beautiful. Currents of cold air may now be supposed to intrude on the scene—the vapour is condensed—and clouds consequently make their appearance. A similar occurrence will take place by the weakening of the sun's rays, and withdrawal of heat at the approach of night, when clouds, as is well known, are always most numerous.

Clouds are commonly formed by the ascending of the invisible vapour into the cold regions of the air, where they take shapes conformable to the degree of temperature and action of varying currents. These currents, and other circumstances affecting them, are so constantly changing, that seldom for a single minute do they remain in one form, but shift into all sorts of postures, rise, fleet away to a distance, congregate, sink, disperse, and vanish. While the aggregation of clouds is caused by their coming in contact with cold currents of air, their evanishing is attributable to their being acted on by currents or strata of air warmer than those in which they have previously been sustained. The dispersal and evanishment of clouds may occasionally be seen to advantage in the neighbourhood of ranges of hills terminating abruptly. The clouds resting on the hill-tops are seen to begin to move towards the precipitous declivity, in consequence of the springing up of a breeze in that direction; and when they arrive at the precipice, they seem to tumble over and vanish in the fall. Dr Arnott speaks of the beauty of this phenomenon at Table Mountain, at the Cape of Good Hope; and we have observed it occurring at the termination of the range of Pentland Hills, near Edinburgh. The explanation of the phenomenon is simple: the cloud, on rolling from the summit of the hill, falls into an atmosphere of a higher temperature, and its particles being diminished into the gaseous form, disappear. When, on the contrary, a cloud is seen to ascend a hill, it enters a region of cold, and being condensed, it is precipitated as a shower of rain.

Luke Howard, in his Essay on Clouds, distributes them into four essentially different formations. These formations are—1. *Cirrus*, consisting of thready fibres diverging in all directions, or curled up at one end; 2. *Cumulus*, or roundish bank of cloud, increasing from a horizontal base upwards; 3. *Stratus*, layers vastly extended, connected, and horizontal; 4. *Nimbus*, the heavy black cloud dissolving in rain. The intermediate stages between these formations are designated by the compounds *cirro-cumulus*, *cirro-stratus*, *cumulo-stratus*, and *cirro-cumulo-stratus*.

By the same meteorologist, the clouds are generally assigned to three atmospherical regions—the upper, the middle, and the lower one, to which a fourth, the lowest, may be added. In the upper region, the atmosphere is in such a state, that it can receive and sustain only light and thin vapours; and to this district belongs the *cirrus*, a representation of which is given in fig. 3. Of all the various forms of cloud, it has the least density, but the greatest height and variety of shape and direction. It is the first indication of serene and settled weather, and first shows itself in a few fibres, spreading through the atmosphere. These fibres by degrees in-

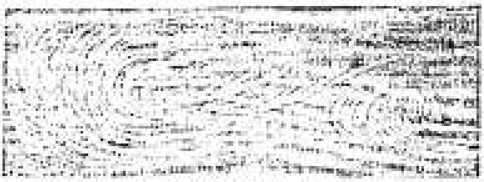

Fig. 3.—The Cirrus.

crease in length, and new fibres attach themselves to the sides. The duration of the cirrus is uncertain—from a few minutes to several hours. It lasts longer, if it appears alone and at a great height; a shorter time, if it forms in the neighbourhood of other clouds. From its usually curling appearance, the cirrus is called in England the *mare's-tail* cloud.

The *cirro-stratus* exists in a high region of the air, and is often the cirrus in an altered shape. It is gene-

Fig. 4.—Various forms of Cirro-stratus.

rally in the form of long horizontal streaks, which are ever shifting their figure and position. Sometimes it is a long row of slanting streaks, and at other times an apparently drawn out and translucent cumulus. In the latter form, when shone upon, at the close of day, it is not unlike a long feathery streak of fire.

The *cirro-cumulus*, of which a representation is given in fig. 5, consists of a collection of small white clouds,

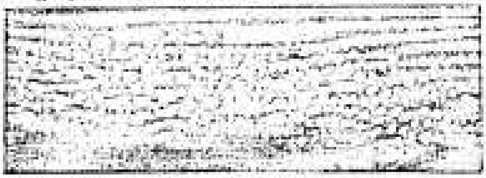

Fig. 5.—Cirro-cumulus.

of a roundish form, which give to the sky the appearance called dappled, and are in summer considered a prognostic of settled weather, or at least of an increase of temperature. Occasionally, the cirro-cumulus may be observed to change into the cirro-stratus.

The *cumulus* is a cloud of a much more massive character. It is vapour in the most compact form, and usually moves with the stream of air nearest to the earth. This region can receive much humidity, but not in perfect solution. The humidity becomes collected, and shows itself in masses rising conically, and resting on a region of air capable of giving it support. The annexed

Fig. 6.—Various forms of Cumulus.

engraving, fig. 6, represents the more usual forms of cumulus, whether in separate or congregated masses. The appearance, increase, and evanishing of cumulus, in fine weather, are often periodical, and correspondent to the degree of heat. Generally, it forms a few hours after sunrise, attains its highest degree in the hottest hours of the afternoon, and decreases and vanishes at sunset. Great masses of cumulus, during high winds, in the quarter of the heavens towards which the wind blows, indicate approaching calm and rain. If the cumulus does not disappear, but rises, a thunder-storm is to be expected during the night. If the upper region, with its drying power, predominates, the upper parts of the cumulus becomes cirrus. But if the lower region predominates (into which the densest vapours are attracted and dissolved into drops), the basis of the cumulus sinks, and the cloud becomes stratus, which is of moderate density, and its lower surface rests generally upon the earth or the water.

The *stratus* is the proper evening cloud, and is in reality the vapour which creeps along the ground or mounts into the lowest region of the air at sunset, after a fine summer day. All mists and fogs are of this species of cloud, which in its lightest state does not wet leaves or any objects with which it comes in contact. In calm evenings, the stratus may be seen ascending from the valleys to the higher grounds, and there, as

Fig. 7.—The Stratus.

shown in fig. 7, it extends itself in masses like a fleecy mantle. It generally arrives at its point of greatest density about midnight, or between that time and daylight, and disappears at sunrise by the gradual elevation of temperature in the atmosphere. Sometimes it remains quiet, and accumulates in layers, till the atmosphere is incapable of sustaining its weight, when it assumes the condition of the heavy and dark *nimbus*, and falls in a shower of rain.

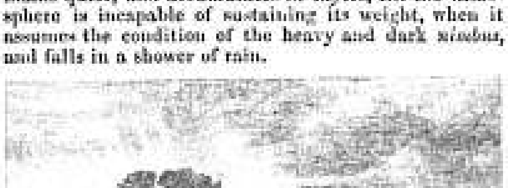

Fig. 8.—The Nimbus.

The various circumstances which concur to precipitate moisture in the atmosphere into the visible form of clouds, are summed up as follows by Mr Graham Hutchinson, in his Treatise on Meteorological Phenomena (Glasgow, 1835):—"1. When a diminution of the atmospheric temperature, unaccompanied by atmospheric rarefaction or transportation, takes place. 2. When a diminution of the atmospheric temperature, arising from atmospheric rarefaction, takes place. 3. When a diminution of the atmospheric temperature, arising from the transportation of air from a warm to a cold climate by the agency of winds, takes place. 4. When an intermixture, and consequent reduction to a mean temperature, of different portions of air, of previously different temperatures, takes place. If any one, or any combination of these circumstances happens to occur, when the atmosphere is previously saturated with humidity; or supposing the atmosphere previously somewhat under-saturated, if they take place to such an extent as to produce over-saturation, a precipitation of moisture into the visible form of cloud or mist is the necessary consequence."

Clouds of the cumulus form are frequently seen to rest or hover over the tops of mountains, and it has therefore been supposed that hills attract clouds. Undoubtedly, from electric causes, clouds are occasionally attracted by mountain-tops, where they discharge their contents in a thunder-storm; but in common circumstances, attraction is not the cause of cumulus on hills. The ordinary cause is a low temperature of the atmosphere at these altitudes—a temperature lower than that of the region of air at the same height away from the hills. The mode of cloud-formation on mountain ranges seems to be this: the warmer air of the valleys or of the sea, loaded with invisible particles of moisture, is blown in the direction of the hills, and being compelled to ascend, the particles become visible when they attain the summit. But the wind does not rest there: the particles are blown away beyond, and perhaps vanish in a warmer region of air, but new particles are constantly coming up to supply their place; and thus a shifting appearance is given to the masses of clouds which we observe hovering on the tops of the hills. "Mountains of themselves," observes Mr Hutchinson, "that is to say, without wind, can form no clouds; and winds of themselves, that is to say, without the aid of atmospheric rarefaction which accompanies their exaltation while passing over mountains, are, in this respect, equally inefficient. In short, mountains in all climates may be regarded as passive instruments in the formation of clouds only during windy weather. And whenever their height is such that the temperature of the lower atmospheric strata, while surmounting them, becomes so much reduced as to cause over-saturation, the formation of clouds must take place. Hence, the higher the mountains, the more certain they are, during windy weather, to cause the formation of clouds; and the nearer the hygrometric condition of the aërial strata, before beginning to ascend the mountains, is to the point of saturation, the less height will suffice for that purpose. Accidental coldness on the tops of mountains sometimes adds to their efficacy in causing the formation of clouds. Such may be occasioned by snow-falls during the cold season remaining unmelted, or only partially melted (as frequently happens on the northern exposure of mountains in the northern hemisphere), till long after the returning heat of spring and summer has rendered the falling of snow, at corresponding altitudes, extremely improbable.

Haze—Mist—Fog.—Mists or fogs, as has been noticed above, are a variety of clouds, and are scientifically described by the term *stratus*. A haze is that species of vapour in which the watery particles are only partially or imperfectly condensed, so as to produce an indefinite obscuration, which generally may be observed in the evening, when the temperature of the air becomes diminished by the decline of the sun towards the horizon. When viewed from a distance, the surface of the earth always appears enveloped in a haze of greater or lesser density; and although, when sailing on an open expanse of ocean, the atmosphere may appear very clear, yet, on being viewed from a high mountain, the water will appear obscured by a haze, which will be found to extend many feet above its surface. When the watery vapour in the surrounding air becomes more condensed, with a defined outline in the form of a cloud, either resting on the surface of the earth, or a few feet above it, then it is termed a mist; and when the whole atmosphere around appears equally obscured, then we give it the name of a fog, which, however, is not to be confounded with that moist and obscured state of the air which often accompanies our easterly and westerly winds.

Mists, as well as fogs, consist of thin vesicles of water containing air. How these vesicles are formed, is not well understood; but the general opinion is, that mists and fogs arise from air of unequal temperatures, holding moisture in solution, mingling together. Accordingly, the mixture of the evening sea-breeze with the air above the land often produces dense mists; for the air above the sea is warmer than that above the land, and when they intermix, a condensation of aqueous vapour into mist or fog takes place. Besides this, the contraction of the air, from its becoming colder after sunset, often produces a condensation of the watery particles floating in it. In addition to which, there can be no doubt that a certain quantity of vapour rises up, or evaporates, from the earth itself, which we may suppose to have been within a short period moistened by rain, and this, having become elevated to some distance above the ground, in like manner becomes condensed. During the night, therefore, the air above the surface of the earth is thus generally rendered hazy, and light mists are observed hanging in gauzy folds along the sides and around the summits of hills and mountains; hence Lord Byron, in noticing the approach of morning, gives us this beautiful passage:—

> "Night wanes; the vapours round the mountains curl'd
> Melt into morn, and light awakes the world."

Fogs are often, especially in large towns, remarkably dense; indeed, so much so as to occasion serious accidents from their interference with distinct vision. This frequently happens in London, and in other large cities, and arises from smoke, vapours, dust, &c., being stagnated in the thick fog. On certain calm winter days it may be observed, that the smoke, on leaving the chimneys, descends towards the ground, and downward currents often set through flues at the bottom of which there is no fire. Fogs seldom rise high in the atmosphere; hence Dr Darwin, in giving an account of one which overspread a tract of ground through which he had occasion to ride, states, that on every rising of the ground he was quite above its level, though in descending again it was so thick that he could scarcely see a yard beyond his horse's head. In the northern regions, fogs are extremely dense, owing, doubtless, to the difference between the temperature of the air which sweeps over the immense tracts of ice extending through those desolate regions, and that of the air which passes over the warmer surface of the ocean. It is one of the greatest annoyances which the whalers and navigators in those dangerous seas have to encounter.

Colour of the Clouds, &c.—Clouds being composed of pure watery particles, cannot intrinsically possess the colour of any foreign body; nevertheless, by the peculiar action of the rays of light on different parts of their mass, they frequently assume a variety of tints, particularly red and orange, at and shortly after sunset. The sun and moon likewise, when shining through a dense vapoury medium, assume a deep red tinge. Superstition would ascribe these phenomena to supernatural causes; but, in truth, all is but a simple effect of the refrangibility of the rays of light. The white rays are decomposed in shining through the globules of vapour, and they shine as if coming from a prismatic spectrum. In the article OPTICS, it will be explained that each of the seven rays of which the white light is composed has a different degree of refrangibility, and it is on this account that a variety of colours exist in nature. "Had it been otherwise—had the objects of the material world," says Sir David Brewster, "been illuminated with white light, all the particles of which possessed the same degree of refrangibility, and were equally acted upon by the bodies on which they fall, all nature would have shone with a leaden hue, and all the combinations of external objects, and all the features of the human countenance, would have exhibited no other variety than that which they possess in a pencil sketch or china-ink drawing. But he who has exhibited such matchless skill in the organisation of material bodies, and such exquisite taste in the forms upon which they are modelled, has superadded that ethereal beauty which enhances their more permanent qualities, and presented them to us in the ever-varying colours of the spectrum."*

In cold climates the sky has generally a dull blue or grey tinge, even in fine weather, a circumstance arising from the prevalence of moisture in the air, which forms a kind of gauze, through which our eye is unable to penetrate. In more warm and genial climes, such as that of Italy, the colour of the sky is a bright blue, and in hot weather slightly purplish. This brilliance arises from the comparative absence of vapoury particles; yet that vapour does exist in the clearest azure sky is indisputable, for it is by refraction of light that the colour appears. If moisture were entirely absent, there would be no refrangibility, and consequently no blue colour. The sky, as formerly mentioned, would be black. The reason assigned for the prevalence of a blue colour in the sky is, that the blue rays are reflected more copiously than any of the others.

* Life of Sir Isaac Newton, p. 78.

DEW.

Dew is a result of an alteration of temperature after sunset. No sooner does the sun begin to decline towards the horizon, than its rays fall more slantingly on the earth, whereby their intensity is diminished, and a change of temperature immediately ensues; for the air soon feels chilly and damp, and the grass beneath our footsteps becomes moistened with a genial and refreshing dew.

It has been elsewhere explained, that all bodies receive a certain quantity of heat, which in particular circumstances they again emit; in doing which they necessarily become colder than they previously were, unless they receive in exchange another quantity of heat sufficient to compensate for the loss they have sustained. In this case, their temperature will remain stationary; but if they part with more than returns to them, their temperature necessarily must fall. When, then, the object so cooled is encompassed by a warm and moist medium, it condenses, by its cold contact, vapour on its surface, and thereby becomes moistened. Hence the origin of dew; for no sooner does the sun sink towards the horizon, than the blades of grass which clothe the surface of the earth give out the heat which they have been receiving during the day; the consequence of which is, that their temperature falls so much below that of the surrounding air, that they condense on their surfaces part of the moisture which immediately surrounds them. The temperature of the body, as indicated by the thermometer, at which this deposition takes place, is called the "dew point," which, for the formation of dew, must always be below the temperature of the surrounding atmosphere: indeed, the quantity of dew formed will always be in proportion to the coldness of the grass and to the quantity of moisture suspended in the air. Besides this, after the sun has set, the moisture which the earth has imbibed during the day, and which still rests below the grassy surface, rises up or evaporates—in doing which, it rises up through or between the blades of grass, the cold contact of which gradually condenses it. Dew, therefore, on calm and clear nights, is more abundant shortly after rain than during a long season of dry weather. During westerly or southerly winds, which are generally impregnated with moisture, it is also formed more copiously than during easterly and northerly winds. Besides the quantity of moisture existing in the air, the greater or lesser copiousness of the dew formed, depends, as we have premised, on the coldness of the objects on which it is about to be condensed. If the night be calm and clear, the grassy blades emit their heat freely, and it is dispersed through the atmosphere without any equivalent return, whereby the temperature of the grass soon sinks sufficiently low to condense the surrounding vapour; but if, instead of this, the night be cloudy, then the clouds reflect, like mirrors, the rays of heat back again to the grassy blades, and prevent this diminution, so that less dew is then deposited. If, in addition to the sky being overcast with clouds, the weather be windy, no dew will be formed; for the temperature of the grass is then prevented sinking by the agitation of the air, by which a warmer current is continually brought to succeed the colder current by which it is surrounded. Hence, if, during the night, the weather, from having been calm and serene, become windy and cloudy, not only will dew cease to form, but that which has been already deposited will disappear, or diminish considerably. Every kind of covering or shelter which extends above any object, will interrupt the radiation or escape of its heat; for which reason gardeners, to prevent plants being chilled, cover them over, on the approach of evening, with a layer of straw or matting.

For reasons similar to those now advanced, the grass which is situated beneath the boughs of large and spreading trees, becomes only sparingly moistened with dew; for the shelter above interrupts the progress of radiation from the substances underneath, and so preserves their temperature. Accordingly, it is an established axiom, that whatever diminishes the view of the sky, as seen from the exposed body, will occasion the quantity of dew to be less than would have been deposited if the exposure to the sky had been complete. Dew is formed, therefore, more sparingly and irregularly in cities than in the country, where the most open grassy plains are always the most abundantly bedewed. In this country it begins to appear in shady places as soon as the heat of the atmosphere has declined; but though the grass on clear still evenings often becomes moist several hours before sunset, dew is seldom present in such quantities as to exhibit visible drops until the sun reaches the horizon; nor does it become copious until some time after sunset. It continues to form also in shaded places some time after sunrise; and it is remarkable, that more dew forms a little before, and in shaded places a little after sunrise, than at any other period. It has also been observed, that more dew is formed between midnight and sunrise than between sunset and midnight—a circumstance which is owing to the cold of the atmosphere being greater in the latter than in the former part of the night. As the quantity of dew deposited thus depends so much on the degree of coldness which the body about to be bedewed attains, its quantity must be materially modified by the greater or the lesser facility with which substances part with their heat. Grass, being a filamentous substance, parts more readily with its heat than garden mould or gravel; wherefore dew is more plentifully deposited on meadow grounds than on ploughed lands. Thus, cultivated soils are refreshed with abundance of dew, while barren rocks and sandy deserts do not receive this congenial moisture. Indeed, every shrub and herb, every leaf and blade of grass, possesses, according to its kind, a different power of radiation, so that each condenses as much dew as is necessary for its own individual and peculiar exigencies. Thus, not even a single dew-drop seems to have been formed by the rude hand of chance, but is adjusted by the balance of infinite wisdom to accomplish a definite and benevolent purpose.

THE WINDS.

A change in the temperature, a diminution of the vapour, or any other cause that may occasion a portion of the surrounding atmosphere to contract or expand, will give rise to the aërial currents denominated winds, which, indeed, bear a strong analogy to the currents which occur in the ocean. When the air by which we are surrounded becomes heated, it expands, and grows specifically lighter, in consequence of which it mounts upwards; and the colder and denser air which surrounds the mass thus rarefied, rushes in to supply its place. When the door of a heated apartment is thrown open, a current of air is thereby immediately produced; the warm air from the apartment passing out, and the cold air from the passage rushing in. So, also, in those buildings where the manufacture of glass is carried on, the heat of the furnace in the centre being intense, a violent current of air may be observed to force its way in through the doors or crevices on the opposite sides of the house. On applying these principles to account for the origin of the wind, we find that, when the rays from the sun, by their reflection from the earth's surface, have heated or rarefied a portion of the surrounding air, the air so rarefied ascends into the higher regions of the atmosphere, and the colder air by which it was surrounded moves forward in a sensible current to fill the vacuity. When, also, a condensation of vapour in the atmosphere suddenly takes place, giving rise to clouds which speedily dissolve in rain, the temperature of the surrounding air is sensibly altered, and the colder rushing in upon the warmer, gives rise to a sudden gust of wind. For this reason, a cold heavy shower passing overhead, with a hasty fall of snow or hail, is often attended with a violent and sudden gust of wind, such as sailors call "a squall," which ceases when the cloud disappears, but is renewed when another cloud, sweeping along in the same direction, brings with it a fresh blast.

The general nature of the winds in this and in other countries depends very much on the character of the region whence they may have swept; and, accordingly, it is necessary to remember that the globe is divided into *five* zones or belts—the torrid, which is exposed to the direct rays of the sun; the two temperate zones, which, meeting the rays of the sun obliquely, enjoy a moderate degree of heat; and the two frigid zones, which, deprived of the heat of the sun for a great part of the year, and during the other part receiving his rays still more obliquely, are regions of ice and snow which, it would appear, are destined ever to remain uninhabitable solitudes. Generally, in the British islands, a westerly wind is moist, because it comes from the Atlantic, where a great quantity of vapours arise. When mingled with that of the south, which comes from the torrid zone, it is rendered particularly warm. The east wind is the driest, because it comes from the continent of Asia, where there are few seas. The north wind, however, is the coldest, because it sweeps from the immense tracts of ice and snow in the frigid zone. The north-easterly winds, therefore, being so dry and cold, are in this country proverbially the most chilly and bitter.

While the south-west is the most predominant wind in Europe, the north-east winds in spring may be regarded as periodical in the climate of Britain; it is to be remembered, however, that the succession of the seasons of the year, with their characteristic changes of temperature, depend principally on the relative position of the earth to the sun. The more vertically or directly the sun's rays reach the surface of the earth, descending in a more concentrated manner, the greater is the degree of heat which they produce; but the more obliquely they fall, being thereby more scattered, and consequently falling with less power, the smaller is the degree of heat they impart. Accordingly, in the winter season, the sun's rays reach the surface of the globe in our latitude more obliquely than they do in the summer season; consequently, that season is characterised by the coldness which then prevails; therefore, the winds, powerful as their agency certainly is, exercise only a subsidiary influence in modifying the temperature of the seasons. Besides this, the physical aspect of a country, its mountains and table lands, its chains of hills and its valleys, its rocky elevations and its level plains, its protected or exposed coasts, all influence very materially the direction of the wind, which must, as it sweeps along, coincide with the elevations and depressions of the country over which it passes. Hence it has been shown by physicians, that the climate in certain districts of England, owing to the protection of surrounding elevations, rivals in salubrity, even in the most trying seasons, many of the most favourite and fashionable resorts for invalids in the south of France.

Besides the division of the winds founded on their direction from the cardinal points—as into north, north-east; south, south-east; west, south-west; east, &c.—they are divided by meteorologists into four classes, namely, regular, irregular, periodical, and hot winds; the causes of which, with the phenomena by which they are attended, will now be considered.

Regular Winds—Trade-Winds.—In order that we may distinctly understand the cause and nature of the trade-winds, it is necessary to bear in mind that the earth, in the centre of its circumference, at an equal distance from the poles, is divided by a line called the equator into two hemispheres—the northern and southern. Across the equator, cutting it obliquely, there passes another great circle called the ecliptic, which describes the path the sun traverses. It extends 23½ degrees north and 23½ degrees south of the equator, which is the utmost limit the sun traverses; for, when arrived at either of these boundaries, he again seems to return towards the equator. It must be very evident that the region of the earth included within a circle drawn 23½ degrees north and 23½ south of the equator—which will comprehend the greatest portion of Africa, a considerable part of Asia and America, and many large, fertile, and populous islands in the East and West Indies—will receive constantly the solar rays in a direction so little oblique, that the most intolerable heat might there be anticipated. It was therefore called the torrid zone; and the limits at which the sun stops, and appears to retrace his course, have received the name of tropics, or circles of return. This being premised, and it being also remembered that the earth revolves daily, "her silent course advancing," round the sun from west to east, the cause of the trade-winds will be readily understood. The rays of the sun, in its apparent motion from east to west, obviously rarefy, by the heat they impart, the air beneath, and the air so rarefied rises into the higher regions of the atmosphere. While this takes place, the colder air from the adjoining temperate zones rushes in to supply its place. But it is from the polar regions, north and south, that these colder currents originally come; and did the earth remain at rest, such would be their obvious direction. Instead of this, however, north of the equator the direction of the trade-winds is from the north-east; south of the equator, from the south-east; the cause of which is thus explained:—The velocity with which the earth revolves is inconsiderable, if appreciable, at the poles, but increases as we advance, and is at its maximum at the equator; the winds, in sweeping from the poles, do not acquire a corresponding velocity with the motion of the earth, as they advance towards the equator; therefore, moving more slowly than the earth, they are left behind, striking bodies with the excess of the earth's velocity; so that, to the observer who imagines himself at rest, the air appears to move in a direction contrary to the rotation of the earth, namely, from east to west. While the trade-wind thus blows upon the surface of the earth, there is no doubt that an opposite current, probably that of the rarefied air which has ascended, flows in the contrary direction, at a great elevation in the atmosphere.

The external limits of the trade-winds are 30 degrees north and 30 degrees south of the equator; but each limit diminishes as the sun advances to the opposite tropic. The larger the expanse of ocean over which they sweep, the more steadily do they blow; accordingly, they are more steady in the Pacific than in the Atlantic, and in the South than in the North Atlantic Ocean. Within the region of the constant trade-winds, rain seldom occurs, but it falls abundantly in the adjoining latitudes. The reason is, that rain is produced by the sudden mixture of air of different temperatures charged with moisture; but the constant circulation and intermixture of the air from the upper strata of the atmosphere, or ground current, maintains so equal a temperature in these latitudes, as not to occasion the condensation of vapour which is necessary for the production of rain. Besides which, it is plausibly enough alleged by Daniel, that the aqueous vapour constantly flows off in the current of the equatorial wind into the adjoining temperate zones. Within the limits of the trade-winds, contrary to what might have been anticipated from the latitude, the atmosphere is peculiarly cool and refreshing.

The agency of the winds in clearing the atmosphere from noxious effluvia, and keeping it from stagnating, is so apparent, that it scarcely requires to be noticed. In the case of the regular winds to and from the equator, an interchange of atmosphere is effected, beneficial to both torrid and temperate zones. On this interesting point in natural science, the following observations are made by Leibig in his work on Organic Chemistry (1840):—"The proper, constant, and inexhaustible sources of oxygen gas are the tropics and warm climates, where a sky seldom clouded permits the glowing rays of the sun to shine upon an immeasurably luxuriant vegetation. The temperate and cold zones, where artificial warmth must replace deficient heat of the sun, produce, on the contrary, carbonic acid in superabundance, which is expended in the nutrition of the tropical plants. The same stream of air which moves by the revolution of the earth from the equator to the poles, brings to us, in its passage from the equator, the oxygen generated there, and carries away the carbonic acid formed during our winter. The experiments of De Saussure have proved that the upper strata of the air contain more carbonic acid than the lower, which are in contact with plants; and that the quantity is greater by night than by day, when it undergoes decomposition. Plants thus improve the air, by the removal of carbonic acid, and by the renewal of oxygen, which is immediately applied to the use of man and animals. The horizontal currents of the atmosphere bring with them as much as they carry away; and the interchange of air between the upper and lower strata, which their difference of temperature causes, is extremely trifling when compared with the horizontal movements of the winds. Vegetable culture heightens the healthy state of a country, and a previously healthy country would be rendered quite uninhabitable by the cessation of all cultivation." How grand the theory in these passages respecting the influence of winds on vegetation! Those streams of air, which superstition would ascribe to demons, are among the most beneficent means arranged to preserve atmospheric salubrity, and afford materials for man's subsistence.

The Monsoon.—In India, a very remarkable periodical or half-yearly wind prevails, which is called the Monsoon, from a Malay word *mousin*, which signifies season. It blows one-half the year from the south-west to the north-east, and the other half from north-east to south-west. The former is accompanied by rain and tempest, and constitutes in India the "rainy season;" the latter, although in this respect admitting of some modifications, constitutes the "dry season" of the year. The south-west monsoon, in the southern parts of India, commences about the beginning of June; but in proceeding northwards, it does not commence until later. It is ushered in by vast masses of clouds, which arise from the Indian Ocean; and as they advance towards the north-east, gather and thicken as they approach the land. In a few days afterwards, the sky assumes a more troubled aspect towards the evening, and it is in the night that the monsoon generally sets in. It begins with violent blasts of wind, which are succeeded by floods of rain, during which the lightning flashes without intermission; at first illuminating the sky, showing the clouds near the horizon; then discovering the distant hills, and leaving them again shrouded in darkness; then, in an instant, reappearing in vivid and successive flashes, which exhibit even the nearest objects in all the clearness and distinctness of noonday light. The thunder, in the mean time, continues in loud peals, and when it ceases, the rain pours in heavy torrents. This lasts for several days; the sky then clears, the air becomes soft and pure, the rivers are full and tranquil, and the whole face of the earth, as if by enchantment, appears clothed with thick and luxuriant verdure. The rain, after this, falls at intervals for about a month; then it increases in violence, and attains its height in the month of July, when it descends thickly and heavily *en masse* from the heavens. Then this monsoon, in August, somewhat diminishes; in September it abates, or is entirely suspended until the end of the month, when it again re-appears; and departs, as it came, amidst thunder and lightning, and all the turmoil of tempest.

Such is the south-west monsoon, as it appears in the greater part of India; but it is liable to considerable variations, caused by the influence of the sea and the mountainous regions along which it may sweep. Near the sea, the rain falls more plentifully; because, from the more abundant evaporation, the air is there more charged with moisture. The mountains also affect its course, by interrupting and diverting the progress of the winds and the clouds they bear. Thus, the wind which brings the rain to the north-eastern part of the Indian continent, originally blows from the south-west over the Bay of Bengal, until it reaches the Himalaya Mountains, and those which join them from the south; these check its current, and compel it to follow their range towards the north-west; but when it has continued so far towards the north-west as to meet that chain of mountains called the Hindoo Coosh, then it is by them turned off towards the west, and sweeps along until interrupted by the range of the Solimaun, which prevents its proceeding farther in that direction, or compels it to part with the clouds with which it was laden. If the reader will for a moment trace on the map the course here described, he will at once perceive the influence these mountains must have in modifying the direction and general character of the monsoon.

Hitherto we have principally noticed the south-west monsoon, which constitutes the "rainy season" in India; to this succeeds the north-east monsoon, which, with the exception of the eastern side of the Coromandel coast—to which it brings the periodical rains that begin about the middle of October, and end generally in the middle of December—is attended with dry weather throughout the peninsula. After setting in, during the month of September, with considerable variations in its commencement, the north-east monsoon establishes a milder though not less absolute dominion, which lasts until the end of February or the beginning of March. From that period to the month of June, the winds are irregular, and the heat very great all over the peninsula. In respect to the cause of the monsoons, they are, on the authority of the celebrated philosopher Halley, to be explained on the same principle as the trade-winds; the action of the sun's rays inducing a rarefaction of the air, and consequent rushing in of a colder current from the sea and land; and the physical aspect of the country, its elevations or plains, modifying the reflection and influence of the solar rays: which causes, taken conjointly, sufficiently account for the periodical recurrence and local peculiarities of the monsoons.

Sea and Land Breezes.—The sea and land breezes, occurring in warm climates, may also be classified under the head of periodical winds; they occur in the following manner:—During the day, the wind blows for a certain number of hours from the sea to the land; but when evening arrives, it changes its direction, and blows as many hours from the land to the sea. In this country the sea-breeze sets in about seven or eight in the morning, and is strongest at noon, but continues very sensible until three o'clock, when the surface of the sea will be observed to exhibit ripples of a deep blue colour. After this, at six in the evening, the land-breeze commences. The sea now assumes a greenish hue; and this breeze continues until eight the next morning. The cause of this alternation may be readily explained. During the day, the air over the surface of the earth is more heated by the rays of the sun than that over the surface of the sea; because the earth, from its greater density, comparative state of rest, and numerous elevations, reflects the sun's rays sooner, and with more power than they are reflected from the sea, which, from its state of constant motion and transparency, imbibes the warmth very intimately, though more slowly. Accordingly, when the sun, having arisen above the horizon, has, by the reflection of its rays, thus imparted a sufficient degree of warmth to rarefy the body of air over the land, the air so rarefied ascends into the higher regions of the atmosphere, while that over the surface of the sea, being scarcely at all rarefied, rushes in to supply its place. Hence, a sea-breeze, or current of air from the sea to the land, at this time prevails; but when the sun again begins to sink below the horizon, the body of air over the surface of the land becomes rapidly cold, and the earth itself, by radiation, parts very quickly with the warmth it had absorbed. Then the land air, being below the temperature of the sea air, rushes in to supply its place, and thus during the night, a land-breeze, or a current of air from the land to the sea, is produced. When the sea-breeze first sets in, it commences very near the shore, and gradually extends itself farther out at sea, and, as the day advances, becomes more or less hot. Hence, the sails of ships have been observed quite becalmed six or eight miles out at sea, while at the same time a fresh sea-breeze has been blowing upon the shore. The cause of this is obvious: for it is natural to suppose that the mass of air nearest the land will be the first to rush in, for the purpose of supplying the place of the air which is rarefied immediately above it. On this account the effect of the sea-breeze is said not to be perceptible at a distance of more than five or six leagues from the shore, and for the most part becomes fainter in proportion to its distance from land. The distance, on the other hand, to which the land-breeze extends in blowing across the sea, depends on the more or less exposed aspect of the coast from which it proceeds.

Hot Winds—the Simoom.—Hot winds of a very dreadful character occur in Arabia, Egypt, Syria, and adjacent countries, the moving air having acquired a prodigious degree of heat and aridity in passing over the hot desert continents. One of the most appalling of these winds has been called by the Arabs the *simoom*, from a word meaning poison; and it is also known by the name of the *kamsin*, which signifies fifty days. When the simoom begins to blow in Arabia, the atmosphere assumes an alarming aspect. The sky, at other times so clear, becomes dark and heavy; the sun loses his splendour, and appears of a violet colour. The air is not cloudy, but thick from the subtle dust with which it is loaded. Sometimes the sky appears yellow, from the refraction of light on the minute pieces of quartz which are floating in the air. Sometimes it has a peculiar and frightful blue colour; which variety of this wind comes from those districts where the soil is composed of a great deal of blue-coloured marl and limestone. At first, the wind is light and rapid, and not remarkably hot; its temperature, however, soon increases, until it ranges at upwards of 123 degrees Fahrenheit. The danger, however, is most imminent when it blows in sudden squalls, as then the rapidity of the wind increases the heat to such a degree as to be altogether intolerable. "When this wind occurs," says Volney, "all animated bodies discover it by the change it produces in them. The lungs, which a too rarefied air no longer expands, are contracted and become painful. Respiration is short and difficult, the skin parched and dry, and the body consumed by an internal heat. In vain is recourse had to large draughts of water; nothing can restore respiration: in vain is coolness sought for; all bodies in which it is usual to find it deceive the hand that touches them. Marble, iron, water—notwithstanding the sun no longer appears—are hot. The streets are deserted, and the dead silence of night reigns every where. The inhabitants of towns and villages shut themselves up in their houses, and those of the desert in their tents, or in wells dug in the earth, where they wait the termination of this destructive heat." All travellers bear testimony to the destructive effects of this wind; and it is stated that camels are so conscious of their danger from its influence, that they instinctively bury their nostrils in the sand, and keep them there until the squall is over.

The Sirocco—the Solano.—The sirocco is the name given to the hot wind which occasionally blows in Sicily, and which is supposed to derive its origin from the excessively heated deserts of Africa. The solano is a term applied to a modification of this wind which is met with in Spain and Portugal. The heat of the sirocco wind is described to be excessive. Brydone observes, that, when he experienced its first blast, he felt as if his face had been exposed to the burning steam from the mouth of an oven. When this wind occurs, the inhabitants of every town close their doors and windows against the admission of the external air, and sprinkle their apartments with water. Not a person ventures into the open air. It lasts from six or seven to thirty-six or forty hours. During this period the air is thick and heavy, and the sun does not appear. The thermometer, from 70 or 72 degrees, suddenly rises to 110 or 112 degrees, or even higher. When this sirocco wind, which always blows from the south, shifts, the north wind, which is called the *tramontane*, succeeds, and the country is again relieved from this distressing visitation.

Besides these winds, which are in some degree local, there are the *harmattan*, a cold dry wind, which is frequent in Africa and other eastern countries; the *bize*, a cold frosty wind, which descends from snow-covered mountains like the Alps; and *whirlwinds*, or *tornados*, which are common to all countries, but most destructive in warm regions.

Velocity of the Wind.—The velocity of the wind is from an imperceptible movement to 100 miles in an hour. When it moves at the rate of 1 mile per hour, it is said to be hardly perceptible; at 2 or 3 miles, just perceptible; at 10 to 15 miles, pleasant or brisk; at 20 miles, bracing; at 20 to 25 miles, very brisk; at 30 to 35 miles, high; at 35 to 45 miles, very high; at 50 miles, storm or tempest; at 60 miles, great storm; at 80 miles, hurricane; at 100 miles, hurricane, tearing up trees, and throwing down houses, &c.

The Anemometer.—Many years ago, an instrument called the *anemometer* was contrived, for the purpose of measuring the force of the wind; and latterly an apparatus with the same name has been invented, to measure not only the force, but to indicate the direction of the wind at every minute of the day. From an exterior vane, a connexion is established to a pointed index in the form of a pencil, which, according as the vane moves, travels on a sheet of paper spread on a table in a room beneath, and marks the paper in certain waving lines as it proceeds. The pencil being influenced by the movements of a clock, and the paper being ruled into divisions for every hour of the day, a most effectual record is produced. Anemometers of this kind are now established at all the principal observatories.

RAIN.

It has been explained in the preceding paragraphs, that the waters of the earth yield up a certain quantity of moisture into the air, which, being condensed, assumes the form of clouds of greater or lesser density and magnitude, floating at a variable distance above us in the regions of the atmosphere. It has also been shown that clouds consist of an assemblage of small vesicles, or globules of moisture, which, on being affected by a diminution of temperature, lose their suspensory property, and gathering into larger globules, they drop to the ground in the form of water drops or a shower of rain. The fall of rain, therefore, is the result of so simple and obvious a cause as to require no lengthened explanation; and the only circumstances demanding our attention are the lesser or greater size of the drops, the closer or more distant arrangement of the showers, and the quantity which falls in reference to peculiar localities and different regions of the globe.

Within the tropics, and also in Great Britain when the air has been charged with electricity, as often happens during the dry summer or autumnal months, the rain-drops are very large; but during the wet and chilly season which attends the fall of the year, they are often very small, and, as it is technically termed, *drizzling*. It is a remarkable fact, and worthy of our notice, that drops of rain have always been found larger in the lower regions of the atmosphere. Thus, Dr Walker observed, in going down a high mountain, that the drops gradually increased in size as he descended. At a little way below the summit of the mountain, the precipitation appeared only a gentle mist; but this gradually became denser as he descended, until, on reaching the valley, it increased to a heavy rain. In the year 1776, Dr Heberdeen proved this curious fact. He placed one instrument for measuring the quantity of rain which falls, called the *rain-gauge*, on the square part of the roof of Westminster Abbey; another on the top of a neighbouring house considerably lower than the first; and another on the ground in the adjoining garden. The rain collected on each was as follows:—Top of Westminster Abbey, 12 inches; top of the house, 18 inches; and on the ground, 22 inches: so that much more rain was collected in the lower than in the upper rain-gauge. It has been observed, that this difference may in some measure be owing to the action of the wind, which might drift the rain from the higher and more exposed vessel; but let the greatest pains be taken to avoid this difficulty—which may be done by placing all the vessels in positions equally exposed to the wind—still the fact will hold good, that the quantity of rain increases as we descend in the atmosphere.

It has been conjectured that the increased size of the drops, as we descend mountains into valleys, depends on their uniting together as they fall. But the truth seems to be, that the increased quantity of moisture precipitated is owing to the continued evaporation going on at the earth's surface. When the sun has withdrawn his rays, or is overcast by a dense cloud in the higher regions of the heavens, and when the air is loaded with excess of vapour, should an additional quantity arise from the earth's surface, it must be obstructed in its ascent, and, meeting with a colder current, be condensed, and converted into rain. In traversing a mountainous country during a storm, we have had occasion to observe this fact; for often the rain by which we have been wet through has seemed not so much to descend from above, as to be formed immediately around us. The garments about the knees of the pedestrian will, under such circumstances, be wet through, while his shoulders remain comparatively dry. Hence, marshy and maritime situations which emit much vapour are observed to be remarkably rainy. Mountainous regions are generally visited also with much rain, in consequence of the condensation of clouds on the summits of the hills. When the hills are in the neighbourhood of the ocean, their tendency to excite rain is greatly increased; and in proportion as we leave hills so situated, and pass into inland and more level districts, the less rain will be found to fall.

Winds, however, exert the chief influence over the atmospheric condition which produces rain. Thus, if winds blow from instead of to a hilly country, the clouds will be carried elsewhere, and be precipitated in lower regions at a distance. But if these low-lying regions be warm, the clouds will be radiated, and their particles, in a refined state, will be carried onwards by the winds, till they come over a cold high-lying country, where they will drop in heavy showers. In this manner the vapours from the Mediterranean are carried over Egypt, and do not collapse into rain till intercepted by the higher regions of Abyssinia. In consequence of certain winds blowing within the tropics, most countries near the equator have their *rainy seasons*—periods during which much greater quantities of rain fall than we are accustomed to in temperate climes. The rains in India, which are often so desolating in their effects, as already noticed, generally occur during the shifting of the monsoons, and also during what is termed the south-west monsoon.

In that part of Peru called Valles, which lies on the north and south side of Lima, and is bounded on the east by the Andes, and on the west by the Pacific Ocean, it never rains at all; but during winter, the earth is covered with a fog so thick and dense, as to intercept the rays of the sun. These fogs supply sufficient moisture to render the most arid and barren soil fertile, and to convert the disagreeable dust in the streets of

Lima into mud. The reason why it never rains in this country, is, that the wind always blows from the south, that is, from a colder to a warmer region of the world.

Speculations on the chance falling of rain in such countries as Britain are exceedingly hazardous, in consequence of the variability of the winds, and the conditions of the atmosphere at points far beyond our knowledge. With respect to the likelihood of rain, we can attain only a few general principles, all beyond which is doubt and difficulty. For example, if the weather be steady and dry, the winds, if not distracted by any foreign circumstance, will continue blowing and carrying away the evaporated moisture to distant regions, thus averting rain; but if, in the meanwhile, the temperature suddenly falls, or the winds shift, clouds immediately make their appearance, and showers of rain are the consequence. Yet there are exceptions to these general rules, as we will immediately mention.

In all countries, particular winds are noted for being accompanied either by wet or by dry weather: thus, the south and the south-west winds bring much moisture into Britain, while those from the north and north-east are cold, dry, and penetrating; hence the old proverb—

> "When the wind's in the south,
> It's in the rain's mouth."

Not only does this arise from the immense surface of ocean over which these winds sweep south of the equator, the evaporation from which must be prodigious, but from these southerly winds being of a higher temperature, whereby they hold a greater quantity of vapour in suspension or solution, the condensation of which must be proportionally greater on arriving in this colder climate. Accordingly, it has been observed that the wind will turn from the north to south quietly and without rain, but, on returning from the south to the north, will blow hard and bring much rain. Again, if it begin to rain from the south, with a high wind, for two or three hours, and the wind falls, but the rain continues, it is likely to rain for twelve hours or more, and does usually rain until a strong north wind clears the air. For the same reason, winds from the west and south-west are considered to bring with them wet weather; hence the old saying—

> "A rainbow in the morning is the shepherd's warning;
> But a rainbow at night is the shepherd's delight."

In the morning, the sun rising in the east shines directly upon the rain falling in the west, and thereby warning the watchful shepherd of the approach of wet weather with this humid wind; but at night, when the sun sinks in the west, its rays fall on the rain in the east, and the shepherd then sees the storm departing; hence this is one of the many popular sayings founded on observation of nature.

Men of science have made very careful inquiries to ascertain the quantity of rain which falls in certain places during a given time, and the instrument devised for that purpose is the *rain-gauge*. Its construction is very simple, consisting merely of a graduated tube, surmounted by a funnel-shaped vessel for receiving the rain; the quantity entering the tube (whose area bears a known ratio to that of the receiving vessel) indicating the amount of fall in that particular locality. The annual quantity of rain is greatest in tropical countries, and diminishes as we approach the poles; a circumstance explicable by the greater evaporative qualities of the atmosphere in warm than in cold countries. The following table illustrates the progressive diminution of rain as we reach higher latitudes:—

	North Latitude.	Inches of Rain.
Uleaborg,	65 degrees, 30 minutes.	13·5
Petersburg,	59 — 56 —	17·5
Edinburgh,	55 — 58 —	24·5
London,	51 — 31 —	22·2
Paris,	48 — 50 —	19·9
Rome,	41 — 54 —	30·0
Calcutta,	22 — 23 —	81·0
Vera Cruz,	19 — 5 —	62·0
Bombay,	18 — 57 —	80·0

The mean quantity falling annually in England is reckoned to be 32 inches, or, according to Dalton, 31·3; but this is unequally distributed. At Keswick, in Cumberland, the depth, on an average of seven years, was found to be 67 inches; and at Plymouth, in Devonshire, 45 inches. In the western parts of Scotland, the depth is from 30 to 35 inches, which is from 6 to 10 inches more than that on the east coast.

Although the quantity of rain which falls in tropical countries is usually greater than what is precipitated in colder regions, it is dispersed over less time, and chiefly falls in heavy showers during a limited season of the year. In our temperate climates, therefore, we have more rainy and drizzling days throughout the year than are experienced in warm countries; and it is this which gives the character of moistness and personal discomfort to our climate.

The seasons of the year, while they contribute, by their variety, to our pleasure and happiness, are characterised by such weather as is best adapted to the necessities of the vegetable and animal creation; wherefore the proportions of rain vary in different months of the year. In summer we have not so many rainy days as in winter; but the showers are then heavier, the streams of rain closer together, and the quantity which falls is greater than during any other season. Dr Dalton has ascertained that the first six months of the year may be regarded as dry, and the last six as wet months. Another ingenious author has inferred, from long observation, that in spring it rains oftener in the evening than in the morning, but that towards the end of summer, oftener in the morning than in the evening, and storms at this time are apt to occur a little after sunrise.

The reason that in winter less rain falls, though we have more rainy days than in summer, is, that the temperature of the air is less variable in winter, and the condensation of moisture not so forcible; therefore, the rain continues falling in small drizzling drops, which, accompanied or followed by chilly north-east winds, gives rise to colds and coughs, and many distressing maladies. It is also to be observed, that, while a clouded and damp atmosphere favours the increase of vegetable foliage, it is not so favourable to its fructification. In such seasons, while the blades of grass grow broader, the nutritious principle which they should contain is not well developed; so that animals feeding on this poorer grass are obliged to take a larger portion to satisfy their appetites. Cattle and sheep which feed on such pasturage, may be observed to be almost continually eating; whereas, in moderately dry seasons, when the occasional rains have been heavier, every blade of grass grows more healthily, its nutritious principle is better evolved, and less sufficing, the same animals may be seen lying down and ruminating in the shade. In the progression of the seasons, rain falls at all times during the twenty-four hours; but it has been ascertained that much less falls by day than by night.

Rain has occasionally been known to fall of a peculiar colour or substance; but this, like other atmospheric phenomena, admits of an explanation on natural grounds. In the year 1810, a shower of red rain fell in Hungary. It lasted a quarter of an hour, and the water was like blood. This was ascertained to be owing to the rain-water being loaded with the red pollen of certain kinds of trees from a neighbouring forest. Red rain, however, is more frequently caused by an incorporation with the atmosphere of a minute fungous vegetation or of animalcules, both too small to be seen by the naked eye. *Viscid* or a kind of *glutinous rain* has likewise fallen. In the Transactions of the Royal Society of London, an account is given of a shower of viscid rain which happened in Ireland. On examination, it was found to be owing to the presence of extraneous matter, partly vegetable and partly animal. In 1828, a substance was shown to the French Academy, which fell in the plains of Persia. It was edible, and afforded nourishment to cattle and many other animals. This nutritious matter was found to be a vegetable production—the *Lichen* *esculentis* of botanists—which had been transported thither by the wind.

We are not, in these various instances, to forget the powerful agency of the wind, which often has been proved to carry, to a prodigious distance, sand and dust, and the ashes and scoriæ which have been thrown up during the eruption of volcanoes. Whirlwinds and waterspouts are often powerful agents of transport, and we are not altogether to discredit the marvellous "showers of fishes," &c. which are sometimes reported.

Signs of Rain.—We conclude our observations on rain by enumerating a few of those prognostications of approaching rain, which, admitting of explanation, are most interesting. When the moon is of a pure silvery colour, good weather is indicated; but when it has a brown or chestnut-coloured tint, rain may be expected. This is owing to the effect of the vapour in the atmosphere in refracting the moon's light. For the same reason, when stars are surrounded by coloured halos, the approach of rain is indicated.

When mountain ranges or distant objects appear nearer to us than usual—when sounds are heard more clearly from a distance—when the odour of plants is more than usually powerful, rain may be prognosticated. The first of these signs arises from the effect of an excess of moisture in reflecting and refracting the rays of light—the two last from sounds as well as odours being conveyed better through a damp than through a dry air. The low flight of swallows indicates approaching rain. The cause of this is, that they pursue flies, which delight in warm air; and these flies, escaping from the excess of moisture above, descend nearer to the surface of the earth, and are there pursued by these birds.

Ducks, geese, and other water-fowls, before the approach of rain, may be seen to throw water with their bills over their backs, and dive frequently; the cause of which is, that, although so much in the water, they do not like being wet to the skin; to avoid which, when warned by the peculiar sensation preceding rain, they close their plumage together, by throwing a sudden weight of water on their bodies, in the direction of the growth of their feathers.*

Before the fall of rain, cattle may sometimes be observed stretching out their necks, and snuffing in the air with distended nostrils, which, doubtless, is occasioned by the odours of plants being more powerful than usual, when the air is saturated with an excess of moisture.

Man in strong and robust health does not feel his constitution affected by that change in the state of the atmosphere which precedes rain; but persons who are in delicate health are often much affected. Pain of the head, toothache, irritability of temper, pains in old sores which have healed, the aching of corns, and excessive nervousness, are all, in certain habits of body, signs of approaching wet weather.

Dogs closely confined in a room become drowsy and stupid before rain; the same, in a less degree, is observed of cats; horses neigh much; cattle low; the fallow-deer becomes restless; and many other animals, from the uneasiness they feel owing to the altered condition, prognosticate the approach of rain. Insects, being very sensible of every change in the state of the atmosphere, are good weather-guides; hence, fine weather may be predicted when many spiders' webs are seen in the open air; also when bees are found far beyond their hives. On the contrary, when spiders remain hidden, and bees do not range abroad as usual, rain may be expected. Many flowers and plants are excellent prognosticators of the weather. When the flower of the chickweed expands freely, and remains open, no rain will fall for many hours; but when it closes, showery weather or continued rain may be expected. The trefoil, the convolvulus, and many other plants, contract their leaves before the approach of rain, or during dull cloudy weather.

* Luke Howard's Climate of London, notes to vol. I.

FROST—SNOW.

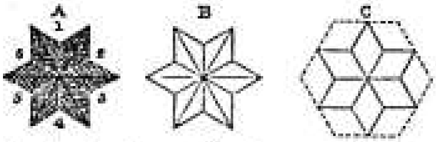
When the temperature of the atmosphere falls to a certain degree of cold (indicated by 32 degrees in our thermometers), which it does principally from the weakness of the sun's rays in winter, the phenomenon of frost or freezing ensues. Freezing is a process of congelation, or, properly, crystallisation, produced by the withdrawal or absence of heat, and by which water assumes the form of ice.

When the temperature of the atmosphere arrives at that low pitch which effects freezing, the watery particles which are upheld in the clouds are frozen in their descent, and coalescing, reach the earth in the form of flakes of snow; and these accumulating on the ground, constitute the appropriate characteristic of the winter season. An intensely cold current of air, mixing with the vapour suspended in a warmer current, occasions, as in the case of hail, this precipitation. Snow, however, is formed in the lower regions of the atmosphere, or might, if commencing in a small nucleus, in higher regions, be converted in its descent into hail. That snow is formed in this manner, there can be no doubt; for a very cold stream of air, admitted into a room in which the contained air is warmer, and loaded with watery particles, will occasion its formation. In the huts of the people in the desolate arctic regions, snow is often so formed; they stop the chinks, yet still the walls are often covered with a thick icy crust; and whenever a cold current from the external air is admitted, snowy flakes are precipitated. Dr Robertson states, that, in a crowded assembly-room at St Petersburg, a stream of cold air was accidentally admitted into the room by a gentleman breaking a pane of glass, on which the vapour in the air was immediately congealed, and fell in the form of snow-flakes. In Siberia, Pallas, Chappe, and others, have seen it formed under similar circumstances; and by the narrative of the Dutchmen who wintered in Nova Zembla, we are informed that a shower of snow fell, from the vapour of expiration, every time there was any communication with the external air. The peculiarities of snow consist in its extreme lightness, and also in its being purely white. Its lightness is occasioned by the excess of its surface exceeding so much in comparison the matter it contains, and its whiteness is owing to the minute particles into which it is divided; hence, when ice is pounded, it is equally white. When snow, however, accumulates in large quantities, its weight becomes very considerable. Snow occurs in all regions of the globe at a certain height above the level of the sea, but falls more abundantly on plains as we proceed from the equator to the poles. In the arctic regions, snow falls nine days out of ten during the months of April, May, and June, and often a depth of two or three inches is deposited in an hour. In these regions, the thickest precipitations are observed to precede the occurrence of storms.

The forms of snow-flakes present an almost endless variety; they are often very regular and beautiful, and reflect with exceeding splendour the rays of the sun. When they are very large, they are said to indicate the approach of thunder. After a copious fall of snow, when the temperature is too low to produce any moisture, its level surface may often be seen sprinkled with thin delicate plates of ice, which refract the light in colours as varied and brilliant as drops of dew. At such times, on the borders of lakes, and on the leaves of trees, groups of feathery icy crystals may be seen, remarkable for the most exquisite delicacy.

Dr Daniel Clarke, in his *Travels in Russia*, mentions that, while at St Petersburg, he observed flakes of snow falling in regular and beautiful forms. "The season," he says, "began to change before we left Petersburg. The cold became daily less intense; and the inhabitants were busied in moving from the Neva large blocks of ice into their cellars. A most interesting and remarkable phenomenon took place the day before our departure; the thermometer of Celsius stood at that time only 5 degrees below the freezing-point, and there was no wind. Snow, in the most regular and beautiful crystals, fell gently on our clothes and on the sledge, as we were driving in the streets. All of them possessed exactly the same figure and the same dimension. Every particle consisted of a wheel or star, with six equal rays, bounded by circumferences of equal diameters: they had all of them the same number of rays branching from a common centre. The size of each of these little stars was equal to the circle presented by dividing a pen into two equal parts. This appearance continued during three hours; in which time no other snow fell, and there was sufficient leisure to examine them with the strictest attention, and to make the representation given in the first figure.

A B C



As water, in its crystallisation, seems to consist of radii diverging from a common centre, by the usual appearances on the surface of ice it might be possible to obtain the theory, and to ascertain the laws, from which this stellar structure results. An equiangular and equilateral plane hexagon is divisible into three equal and similar rhombs: and if the engraved figure A be attentively observed, it will appear that each linear ray of the star is a diagonal (see fig. B) joining the acute angles of a rhomb, whose sides are the loci of the extreme points of the lines of ramification from these diagonals. The rhomb may therefore be the primitive form of water crystallised. This seems the more manifest, because, if equal and similar rhombs be applied between all the rays of the star A, in the spaces 1, 2, 3, 4, 5, and 6, an equilateral and equiangular hexagon will be the result, as represented by the dotted line in fig. C." The same star-like shape of snow-flakes has been seen in Britain. According to a notice in an Edinburgh newspaper, the phenomenon occurred in Lanarkshire in the winter of 1838.

Snow is occasionally seen of a brown colour, which arises from its being impregnated with earthy substances, brought from the mountains by those streams of water which are derived from the thawing of ice or snow. Much oftener has snow been observed of a red colour, which appears generally to have arisen from its intermixture with some vegetable substance. Captain Scoresby informs us, that, in the arctic regions, the redness of the snow may occasionally be attributed to the droppings of the little auk (*Alca alle*), which feeds on shrimps, and congregates in immense numbers.

Snow, which in Britain falls generally most copiously during the months of December, January, and February, seldom occurs so early as October, and is generally, after remaining some time on the ground, dissipated by an increase of temperature, arising from the direct action of the sun's rays or the fall of rain. Occasionally, however, it disappears without any apparent thaw, or so much dissipates as to leave deep furrows on the snowy plain. This arises from the snow itself being evaporated, which will occur even below the freezing-point. "On the night of the 10th of February," says Luke Howard, "I exposed 100 grains of light snow, spread on a dish (which had previously the temperature of the air) of six inches in diameter. In the first hour after dark it lost five grains; in the third it acquired a grain, the wind having changed, and the temperature, which had been falling from 25°, inclining to rise again. In the course of the night the loss was about 60 grains." This very ingenious author adds, that this evaporation from snow probably supplies the water for the formation of those thin mists which appear during intense frost. The air then becomes partially loaded with particles of ice, or of water at so low a temperature as to be ready to become solid the moment they find support. Hence, too, may arise the hoar-frost, which is found to accumulate on the windward side of the twigs and branches of shrubs and trees. Snow seldom remains long, in temperate latitudes, on plains or in valleys, but on the tops of high mountains it occasionally appears throughout the year. The cause of its continuance on these exalted spots, is the thinness of the atmospheric air, which is incapable of holding sufficient heat from the sun's rays to melt the general mass.

Sleet is only a modification of snow. When aqueous globules freeze in the higher regions of the atmosphere, they aggregate together, and form flakes of snow; and when these have partly thawed, and have again become frozen, they constitute sleet, which is thus caused by the variable temperature of the atmosphere. Sleet falls at all seasons, and sometimes changes into rain and sometimes into snow. It occasionally falls, indeed, very heavily, gathering and freezing additional moisture in its descent.

Hail is described by meteorologists as frozen drops of rain, the freezing having taken place while the smaller vesicles of water were assuming the heavier properties of the rain-drop. A cold current of air, blowing suddenly in the direction of a rain-cloud, is understood to be the immediate cause of most hail-showers. Hailstones vary much in shape; they are generally oval or round, but sometimes thin, flat, irregularly globular, angular, pyramidal, occasionally irregular, having a central point whence proceed numerous icy spiculæ, like rays in all directions; and, also, although more rarely, they have appeared as six-sided prisms. Hailstones vary in size from that of a small seed to that of a boy's marble, the smaller generally falling in the more northerly climates, the larger in the south of Europe. In different parts of France and Britain, very large hailstones have occasionally fallen, and done serious damage.

It is calculated that a single drop of water, the diameter of which is only the one-thousandth of an inch, will, in descending through the air, acquire a velocity of nine or ten feet every second; wherefore it is less surprising that hailstones of such magnitude and weight should occasionally prove destructive, not only to delicate plants but even to animals. The large size of hailstones is attributed to an accumulation during the progress of their descent. It is probable that the largest commences its formation with a small nucleus, which receives continual accessions from vapoury particles which it freezes and attaches to itself as it proceeds. Accordingly, hailstones are found to be smaller on the tops of mountains than in the neighbouring plains or valleys; because, not falling so far, they do not augment their size by the addition of successive layers of congealed watery vapour.

Hoar-frost, which appears like a beautiful powdery crystallisation on trees and herbage, is only frozen dew. The conversion of dew into hoar-frost is another wise arrangement in nature, by which plants are protected from the severity of a freezing cold atmosphere.

THUNDER AND LIGHTNING—STORMS.

Independently of the storms of regular occurrence in warm climates, such as monsoons and simooms, there occur sudden and violent atmospheric agitations, both at sea and land, the causes of which are various, though generally depending on rapid transitions of temperature and electrical influence. Two kinds of storms, in particular, are dependent on electrical action in the atmosphere and clouds—the common thunder-storms of temperate climates, and those of a very violent nature occurring in the form of hurricanes in tropical regions.

Thunder-Storms.—Storms of thunder and lightning are simply a case of electrical discharges from one cloud to another, and are a means adopted by nature to restore electrical equilibrium in the atmosphere, and at the same time clear the air from unwholesome vapours or properties. The explanation of thunder-storms given by Professor Thomson, in his Outlines of the Science of Heat and Electricity, being the best we have seen, we shall lay it before the reader:—"Air and all gases are non-conductors; but vapour and clouds, which are composed of it, are conductors. Clouds consist of a kind of bladders of vapour, charged each with the same kind of electricity. It is this electric charge which prevents the vesicles from uniting together, and falling down in the form of rain. Even the vesicular form which the vapour assumes is probably owing to the particles being charged with electricity. The mutual repulsion of the electric particles may be considered as sufficient (since they are prevented from leaving the vesicle by the action of the surrounding air and of the surrounding vesicles) to give the vapour the vesicular form. In what way these clouds come to be charged with electricity, it is not easy to say. But, as electricity is evolved during the act of evaporation, the probability is, that clouds are always charged with electricity, and that they owe their existence, or at least their form, to that fluid. It is very probable that when two currents of dry air are moving different ways, the friction of the two surfaces may evolve electricity. Should these currents be of different temperatures, a portion of the vapour which they always contain will be deposited; the electricity evolved will be taken up by that vapour, and will cause it to assume the vesicular state, constituting a cloud. Thus we can see, in general, how clouds come to be formed, and how they contain electricity. This electricity may be either vitreous or resinous, according to circumstances. And it is conceivable that, by long-continued opposite currents of air, the charge accumulated in a cloud may be considerable. Now, when two clouds, charged, the one with vitreous and the other with resinous electricity, happen to approach within a certain distance, the thickness of the coating of electricity increases on the two sides of the clouds which are nearest each other. This accumulation of thickness soon becomes so great as to overcome the pressure of the atmosphere, and a discharge takes place, which occasions the flash of lightning.

The noise accompanying the discharge constitutes the thunder-clap, the long continuance of which partly depends on the reverberations from neighbouring objects. It is, therefore, loudest and largest, and most tremendous in hilly countries. These electrical discharges obviously dissipate the electricity; the cloud condenses into water, and occasions the sudden and heavy rain which always terminates a thunder-storm. The previous motions of the clouds, which act like electrometers, indicate the electrical state of different parts of the atmosphere. Thunder, then, only takes place when the different strata of air are in different electrical states. The clouds interposed between these strata are also electrical, and owe their vesicular nature to that electricity. They are also conductors. Hence they interpose themselves between strata in different states, and arrange themselves in such a manner as to occasion the mutual discharge of the strata in opposite states. The equilibrium is restored; the clouds, deprived of their electricity, collapse into rain; and the thunder terminates. In thunder-storms, the discharges usually take place between two strata of air, very seldom between the air and the earth. But that they are sometimes also between clouds and the earth cannot be doubted. These discharges sometimes take place without any noise. In that case, the flashes are very bright; but they are single flashes, passing visibly from one cloud to another, and confined usually to a single quarter of the heavens. When they are accompanied by the noise which we call *thunder*, a number of simultaneous flashes of different colours, and constituting an interrupted zigzag line, may generally be observed stretching to an extent of several miles. These seem to be occasioned by a number of successive or almost simultaneous discharges from one cloud to another, these intermediate clouds serving as intermediate conductors, or stepping-stones, for the electrical fluid. It is these simultaneous discharges which occasion the rattling noise which we call *thunder*. Though they are all made at the same time, yet, as their distances are different, they only reach our ear in succession, and thus occasion the lengthened rumbling noise, so different from the snap which accompanies the discharge of a Leyden jar.

If the electricity were confined to the clouds, a single discharge, or a single flash of lightning, would restore the equilibrium. The cloud would collapse, and discharge itself in rain, and the serenity of the heavens would be restored; but this is seldom the case. I have witnessed the most vivid discharges of lightning from one cloud to another, which enlightened the whole horizon, continue for several hours, and amounting to a very considerable number, not fewer certainly than fifty, and terminating at last in a violent thunder-storm. We see that these discharges, though the quantity of electricity must have been immense, did not restore the equilibrium. It is obvious from this, that not only the clouds, but the strata of air themselves, must have been strongly charged with electricity. The clouds, being conductors, served the purpose of discharging the electricity with which they were loaded, when they came within the striking distance. But the electric stratum of air with which the cloud was in contact, being a non-conductor, would not lose its electricity by the discharge of the cloud. It would immediately supply the cloud with which it was in contact with a new charge. And this repeated charging and discharging process would continue to go on till the different strata of excited air were brought to their natural state."

After these explanations, it is only necessary to say, that however awful the noise which thunder usually makes, it is in no shape dangerous. The real danger is from the lightning, which has a tendency to strike high pinnacles of buildings or spires of churches; but if these high places be furnished with metal rods to conduct the lightning to the ground, no injury is likely to occur. Lightning, either silent or accompanied by thunder, is of much rarer occurrence in the British islands than on the continent of Europe.

Law of Storms.—Considerable attention has been bestowed by various men of science on what are supposed to be the regulating principles of storms; for it cannot be doubted that, however irregular their occurrence and apparent action, they are subject to certain fixed laws, and these it is important to discover. As yet, the law of storms has assumed no very distinct or generally recognised form, almost every student of atmospheric phenomena having his own theory on the subject. The question upon which the chief difference exists, is, whether storms blow in direct lines or in circles. The probability is that storms of wind are greatly influenced by the configuration of the localities over which they blow, as well as by the opposition they may meet with in their course: for example, a violent gale of wind, coming in direct force against a lofty mountain, will probably be transformed into a whirlwind; and a similar result will follow the opposing contact of two fierce winds.

At a meeting of the British Association at Newcastle in 1838, Lieut.-Colonel Reid, of the Royal Engineers, laid before that body his views respecting the laws of storms, which have met with general acceptation. From extensive observation on foreign stations and at sea, he was of opinion, with Mr Redfield and Colonel Capper, two persons who had previously investigated the subject, that hurricanes are great whirlwinds, and that these whirlwinds were progressive. "The general phenomena of these storms," he observed, "will be understood, if the storm, as a great whirlwind, be represented by a circle whose centre is made to progress along a curve, or part of a curve, which is in most cases of a form approaching the parabolic, the circles expanding as they advance from the point at which the storm begins to be felt—the rotatory motion, in the northern hemisphere, being in the contrary direction to that in which the hands of a watch go round; while, in the southern hemisphere, the rotation is in the same direction as that in which the hands of a watch revolve. He pointed out how his views were illustrated by the disastrous storm of 1809, experienced by the East India fleet, under the convoy of the *Culloden* line-of-battle ship, and the *Terpsichore* frigate, and four British men-of-war, which left the Cape of Good Hope about the same time, intending to cruise about the Mauritius. Some of these vessels scudded and ran in the storm for days; some, by lying to, got almost immediately out of it; while others, by taking a wrong direction, went into the heart of it, foundered, and were never heard of more; others, by sailing right across the calm space, met the same storm in different parts of its progress, and the wind blowing in opposite directions, and considered and spoke of it as two storms which they encountered; while others, by cruising about within the bend of the curve, but beyond the circle of the great whirl, escaped the storm altogether, which had been for days raging on all sides of them. This led him to draw the very important practical conclusion as to how a ship should act when she encountered a gale, so as to escape from it. By watching the mode of veering of the wind, the portion of a storm into which a ship is falling may be ascertained: if the ship be then so manœuvred as that the wind shall veer aft instead of ahead, and the vessel is made to come up instead of being allowed to break off, she will run out of the storm altogether; but if the contrary course be taken, either through chance or ignorance, she goes right into the whirl, and runs a great risk of being suddenly taken aback, but most assuredly will meet the opposite wind in passing out through the whirl. To accomplish her object, he showed, by a diagram, that it was necessary the ship should be laid on opposite tacks, on opposite sides of a storm, as may be understood by drawing a number of concentric circles to represent the whirl of the hurricane, and then different lines across these, to represent the course of ships entering into or going through the storm."

Mr Espy, an American gentleman, who laid a number of facts on the subject before the British Association in 1840, arrives at the same conclusion as Redfield, Capper, and Reid; but adds, that the whirlwinds blow progressively towards a common centre. This blowing inwards to a centre, Mr Espy conceives to be the consequence of the sudden and powerful ascent of a column of air at that centre, from the atmosphere being there more heated than elsewhere.

If any careful observer of atmospheric phenomena on the ocean, possess facts which tend to throw any light on this exceedingly important branch of science, it is his duty to make them known for the general benefit of mankind.

UNUSUAL METEORIC PHENOMENA.

Among the meteoric phenomena which are of less frequent occurrence than those already noticed, may be included rainbows, figures in the air, luminous meteors, ignis fatui, the aurora borealis, halos, parhelia, and aërolites. As may be seen by referring to the article OPTICS, No. 19, the cause of rainbows is simply the refraction of light through the drops of a shower of rain (or, as may be frequently seen, through the spray of a cataract).

With respect to the appearance of figures in the air, such as representations of landscapes, men, and animals, ships at sea, and so on, it is likewise shown in the article OPTICS, that they are a natural consequence of peculiar refractive powers of the atmosphere at the time of the occurrence. The Mirage of the desert, the Fata Morgana of the Venetians, the Brocken of the Hartz Mountains in Germany, and the armies seen in the air, according to Scottish superstition, all belong to this class of meteoric phenomena.

Luminous Meteors.—These are of various kinds. One of the most familiar is the Will o' the wisp, or *ignis fatuus* (the fire of fools), which appears at night on marshy grounds or places of sepulture. The appearance is that of a small flickering light, struggling in an irregular manner at the height of one or two feet from the ground, and sometimes standing for a few moments over a particular spot. When approached or pursued, the lights are agitated by the motion of the air, and seem to elude investigation. The cause of this species of meteor is well known to men of science; the light being nothing more than phosphureted hydrogen gas, arising from decomposing substances in the ground, spontaneously ignited. The meteors commonly called *falling stars*, which shoot from the upper region of the atmosphere, are ascribed to a similar origin: they are masses of matter inflated with phosphureted hydrogen gas, which, being spontaneously ignited, shoot in a downward direction to the earth. The greatest height whence they come is not above two or three miles, and seldom so much. Electricity, it may be supposed, is also concerned in this class of meteors.

Aurora Borealis.—In extreme northern and southern latitudes, and generally in the coldest season of the year, the sky appears luminous with streams of soft light, called the aurora borealis or the northern lights. This beautiful phenomenon is comparatively seldom seen as far south as the centre of England, but is frequently observed in Scotland, where it is popularly known by the name of *streamers*. In the latter country it appears a little after sunset, and uniformly arises in the north, inclining generally a little to the west; and it occurs more frequently about the time of the equinoxes than at any other season of the year. Its manner of arising, and the general characters it assumes, vary extremely; indeed, so much so as almost to preclude any accurate description. Sometimes, an hour or two after dark, it seems to illumine the northern region of the sky with no more than a gentle and subdued twilight, which gives a soft relief to the surrounding darkness. Sometimes detached masses of light suddenly appear in different parts of the sky, from which silvery and tremulous beams shoot with dazzling and evanescent splendour. Not unfrequently, indeed, from one single spot of light the beams vividly and rapidly extend. Sometimes the phenomenon is first discernible in delicate streaks or threads of light, which enlarge and shift with inconceivable rapidity, until a tremulous arch is formed, which completely spans the azure vault. Very often one general or principal arch is observed, with smaller ones at unequal distances, which frequently move laterally towards each other, and suddenly unite into one broad and brilliant mass. Often, from the horizon, in the north, one limb or segment of the arch streams up into the heavens, and sometimes several of these arise at distances from each other. The varying splendour of the coruscations, and the rapid and playful movements which they display, as they sweep across the heavens, excite alike the wonder and admiration of the spectator.

The height of the aurora has been variously computed to be from 100 to 700 miles above the surface of the earth, and consequently far beyond the sphere of our atmosphere. All the conjectures hazarded with respect to the nature and cause of the aurora have been unsatisfactory: the most feasible conclusion is, that the phenomenon is a demonstration of electric fluid in its passage from the polar to the equatorial regions. Well-digested facts are still required to form an exact and satisfactory theory on the subject.

Halos—Parhelia.—In the colder regions of the globe, and sometimes in temperate climes during cold weather, what are called halos and parhelia, or mock-suns and mock-moons, are sometimes seen. A halo usually consists of two concentric circles of coloured or refracted light, such as that of a rainbow, the one forming an angle of about 23½ degrees, the other an angle of about 47 degrees, with the sun or moon. In different parts of these circles, and chiefly in opposite points at a similar altitude with the sun, bright spots of unrefracted light are seen, which have received the names of mock-suns or mock-moons, according as the light is received from the sun or from the moon during the appearance of the halo. From these bright spots diverging horns of light are occasionally observable. It is generally agreed that a halo is produced by the sun or moon's light being refracted by frozen vapour in the atmosphere. The cause of the parhelia, or bright sun-like spot, is more difficult of definition. Some suppose it to be caused by the frozen vapour being arranged in such a manner at particular points, as allows the light of the sun or moon to be transmitted in a concentrated, instead of a refracted form.

Aërolites.—These are fiery meteors, which, in various forms and sizes, are seen to shoot from the heavens, and, falling to the earth, are found to consist of certain kinds of stones. The chronicles of almost every age and country record the fall of these bodies, which sometimes arrive on the surface of our planet individually, and at other times in what must be called a stream or shower. The celebrated Gassendi informs us that, on the 29th November 1637, about ten o'clock A.M., while the sky was perfectly serene and transparent, he saw a flaming stone, apparently about four feet diameter, fall on Mount Vaision in Provence. This stone was encircled with a zone of various colours, like a rainbow, and accompanied in its fall with a noise resembling the discharge of artillery. It was of a dark metallic colour, extremely hard, and 59 lbs. in weight. In June 1668, two stones, one of which weighed 300, and the other 200 lbs., fell near Verona. The event took place during the night, and when the weather was perfectly serene and mild. They appeared to be all on fire, descending in a sloping direction, and with a tremendous noise. The phenomenon was witnessed by a great number of people, who, when the sounds had ceased, and their courage was sufficiently re-established, ventured to approach these celestial deposits, and found that they had formed a ditch; such had been the force with which they had descended. One of the largest meteoric stones which have ever fallen is now exhibited in a room in the British Museum; it is several feet in diameter, of great weight, shaped like a spheroid, and brown in exterior appearance.

All meteoric stones that have been examined present a similar structure and appearance. The chemical analysis of one which fell in France in 1810 may be taken as a sample of the whole:—Silica, 36·4; alumina, 3·6; lime, 4·2; magnesia, 13·6; iron, 25·0; nickel, 6; manganese, 0·6; sulphur, 5; chrome, 1·5: total, 90·7. The velocity with which the stones are shot through the atmosphere renders them red hot, and some time elapses after their fall before they cool and can be handled.

With respect to the origin of aërolites, there are four theories, each having its supporters. According to Laplace, Poisson, Dr Hutton, and others, they are stones projected from volcanoes in the moon; it being demonstrated that an initial velocity of 6000 feet per second would be sufficient to drive them beyond the moon's attraction, and to bring them within the greater attraction of the earth. Another set of philosophers allege they are projected from volcanoes on the earth, which is exceedingly improbable. Playfair and others say it is not unlikely that the stones are formed in the atmosphere by an aggregation of particles of matter, the result of gaseous vapours; this chemical theory is also very unsatisfactory. The fourth and most probable theory is, that the stones are *asteroids*, or diminutive planets, drawn to the earth's surface when our globe, in its annual revolution, arrives at points near which these bodies are performing a circuit round the sun. A series of remarkable phenomena, of recent occurrence, serve to support this theory. On the morning of the 12th, 13th, or 14th of November every year since 1833, there have occurred, at different parts of both Europe and America, showers of meteoric bodies of a most brilliant appearance; and it has thence been conjectured that the earth, in its revolution round the sun, had fallen in with these bodies in the same, or nearly the same, part of its orbit. If such be the true hypothesis, it follows that these meteors are travellers in space, performing circuits like the planets, and have most likely been projected from the sun in the same manner as the earth and other planetary bodies are believed to have been hurled from that luminary. Showers of fiery meteors, sometimes only gaseous, and at other times solid, are, however, found to occur annually in August, December, and other periods of the year. In September 1841, a shower of many millions of meteoric stones, the greater number of which were not larger than small hailstones, occurred in Hungary, their chief ingredients being oxydate of iron, oxide of iron, and oxyhydrate of iron, with flint, lime, clay, and clay earth.

THE WEATHER.

From the preceding account of the various phenomena of the atmosphere, it must be evident that prognostications respecting the weather must be extremely uncertain, if not, for the most part, quite illusory. According to an ancient prejudice, it has been supposed that the moon, on entering its different quarters, exercises an influence over the weather; but this is ascertained by men of science to be without foundation in reality. The moon affects the tides of the ocean, but in no other known manner has it any influence over the ordinary phenomena of our planet.

It has been seen that winds are the grand disturbers of the weather, and that to them we may proximately ascribe the occurrence of clear skies, fogs, clouds, rain, &c. As the winds originate from circumstances frequently far beyond our horizon, and cannot consequently be foreseen, every prognostic of either fine or bad weather is liable to complete derangement. The chance floating of icebergs from the northern polar regions to a temperate latitude in the Atlantic, has been known to shed such a cold over Britain, as to destroy the best hopes of summer. To utter prophecies of the coming weather, in a country exposed to such contingencies, appears ridiculous. It has long been a favourite belief with certain classes of persons that the weather goes in cycles—that after a limited number of years, the same succession of weather in the different seasons of the year recurs, and is repeated periodically. A period or cycle of nine, eighteen, thirty-six, and fifty-four years has been variously fixed upon. In Scotland, nineteen years has been more generally believed to form a cycle, and on that account leases of farms are commonly made out for that period, in order to give the agriculturist the benefit of an entire round of weather. To suit and support these theories, which rest on no solid foundation, almanacs have been put forth, pretending to foretell the weather of the coming year; but, unless when favoured by accidental resemblances between the weather and the prediction, all such oracular prophecies have been disproved by facts.

As far as the records of meteorological phenomena for a long series of years warrant a conclusion, the following principles respecting the weather may be considered settled:—1. The weather of each year stands by itself; 2. The weather differs annually, and is different in different places according to circumstances; 3. The weather in the interior of continents is so regular in its seasonal variations, that these may be foretold with considerable certainty; 4. The weather of the British islands is so irregular, from unforeseen causes, that predictions as to its condition are only warrantable in very general terms at any season of the year; 5. That agricultural improvements, such as draining of lakes and morasses, the cutting down of forests, &c. improves climate, and tends to equalise temperature; and, 6. That the asperities of cold in our winters, and extreme heats of our summers, have been modified in some degree by these causes. Altogether, it may be said of our climate, that though in some respects uncomfortable, it is improved in its salubrious properties; and, by allowing out-of-door exercise and employment for a greater number of days throughout the year than that of most other countries, is highly conducive to health, mental energy, and social advancement.

PHYSICAL GEOGRAPHY.

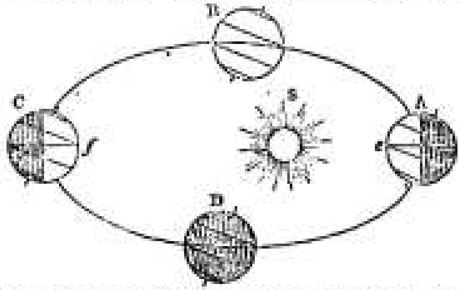
GEOGRAPHY—from *gê*, the earth; and *grapho*, I write—in its simple and literal signification, is that science which describes the superficial appearance and conditions of our globe. It naturally divides itself into two great branches—1. *Physical Geography*, which treats of the earth as a superficies composed of land and water; considers the position, extent, altitude, and general character of the former; and the position, extent, depth, currents, and other motions of the latter. In short, all that relates to the distribution of land and water, variations of surface, temperature and climate, and distribution of plants and animals as dependent thereon, are the legitimate objects of this species of geography. 2. *Political Geography*, which refers merely to the division of the earth's surface by man into territories, empires, kingdoms, and states; treats of their boundaries, the history of their occupation, their produce, commerce, population, laws, religion, and other topics which constitute the fundamental features of human polity. The latter of these branches will form the subject of several subsequent treatises; to an exposition of the former—dwelling more on principles than on mere descriptive details—we intend to devote the present number. Before doing so, however, it will be necessary to advert to the cosmical relations and constitution of our planet as determined by astronomy, geology, chemistry, and meteorology.

GENERAL CONSTITUTION OF THE GLOBE.

Astronomy informs us that the earth we inhabit is one of a number of *planets* which revolve round the sun as a common centre, constituting what is usually denominated the SOLAR SYSTEM. These planets are situated at different distances from the central orb, and differ also in their magnitudes, their densities, and in their periods of revolution. They are nearly spherical in form, are opaque, have no light of their own, but merely reflect that of the sun; and all move from west to east in nearly circular orbits. Several of them serve, in turn, as centres for other bodies of revolution, which are known by the name of *satellites*—as the moon, for example, which is the satellite or attendant of the earth. Besides the planets and their satellites, there is a third and numerous class of bodies belonging to the solar system, namely, *comets*, which revolve round the sun in regular periods, but in orbits so elliptical, that in parts of their course they approach nearer to the great orb than any of the planets, and in others recede so far into the regions of space, as to be entirely beyond the reach of our most powerful telescopes. The *stars* belong to other systems of revolution, and have, so far as has yet been determined, no perceptible effect upon the conditions of our globe, though undoubtedly bearing, like everything in nature, a universal harmonious relationship.

The earth, as an individual planet, is situated at the distance of 95,173,000 miles from the sun; has a mean diameter of 7912 miles; performs a revolution round the sun in 365 days 5 hours 48 minutes and 49 seconds, which constitute the space of time called a year; rotates on its own axis once in 23 hours 56 minutes and 4 seconds—that is, in one day; and in these movements is attended by the moon, which is distant 237,000 miles, is 2160 miles in diameter, and which completes her revolution in 27 days 8 hours, or in one lunar month. We have spoken here of the mean diameter of the earth, because, upon accurate measurement, it has been found to be not a perfect sphere, but an *oblate spheroid*, whose greater diameter is 7925·648, and whose lesser is only 7899·170 miles. This gives a difference of 26·478 miles between the two diameters, or a flattening at each pole of about 13¼ miles—a result that may be artificially illustrated by twirling with rapidity a ball of any yielding material, such as putty, round a spit thrust through it as an axis, when a bulging at the outer circumference will take place, causing the ball to lose its original spherical form. This bulging takes place through what is called the law of centrifugal force, and from what we know of this law, it is concluded that the earth was in a soft or yielding state at the time when it assumed its present form. Besides the bulk, revolutions, and configuration of our globe, science has also determined its *density* with considerable accuracy. By weighing the most prevalent rocks, it has been found that the solid crust composed of them is about two and a half times heavier than water; but from experiments made on the attraction of mountains of known bulk, compared with the attraction and bulk of the globe, it has been inferred that the density of the whole mass is five times that of water: in other words, the earth, as at present constituted, is five times heavier than a globe of water of similar dimensions, and twice the weight of one composed of such rocky substances as those with which we are acquainted. In addition to what may be called its own proper material, the earth is surrounded by a gaseous envelope or atmosphere. This *atmosphere* or air is peculiar to, and inseparable from, our globe—it rotates with the solid mass upon its axis, and does not, as may at first be supposed, occupy the space in which the rest of the heavenly bodies revolve. Like all aëriform and liquid masses whose particles press upon each other equally in every direction, the portions or strata next the earth are more pressed upon than those in higher regions; and continuing this conception, a height must be arrived at where the air becomes so attenuated, as to be inappreciable. Thus it has been determined that the atmosphere does not extend beyond forty-five miles from the mean level of the ocean.

From its planetary relations, as a part of the solar system, the earth derives its figure and motions, its light and heat, and consequently the changes of season, and the alternation of day and night; the phases of the moon, and the rising and falling of the tides; the vicissitudes of wind and weather, and all the varied results and phenomena that flow therefrom. Thus, while its figure is preserved by the laws of centripetal and centrifugal force, its motions are determined and influenced by the attraction and gravitation of the sun and other planets. From its situation with respect to



the sun, it necessarily follows that only one-half of its surface can be exposed at a time to the light and heat diffused from that orb, thereby causing day in the one part, and night in the other. The *seasons*, again, are caused by the fact, that the orbit or path of the earth round the sun is not a perfect circle, but an ellipse; and that, in performing this path, its axis preserves a slanting or oblique position, to the extent of 23° 28′

from the perpendicular. The preceding engraving illustrates the consequences of this elliptical orbit and obliquity of axis. S is the sun, with the earth represented at four different points in its annual course. At B and D, the heat and light of the sun hit at the equator or middle line, and make day and night of equal duration. At any intermediate position, day and night are respectively lengthened and shortened; when at A, the upper or north pole is in darkness; and when at C, the south part of the globe is in the same state. When the point presented towards the sun is at *e*—which is on the 22d of December—it is midsummer to all the southern parts of the earth, and winter to all the north; but as the exposed part advances towards the point *f*, the northern regions gradually enjoy more and more heat, till, on the 21st of June, it becomes their midsummer. In like manner, did our limits allow, might be explained the phases and influences of the moon, and the fluctuations of heat and cold, with their myriad consequences to animal and vegetable existence. So indissolubly connected is the whole scheme of creation, that not a shower that falls, not a particle of sand that crumbles away from its parent rock, or a spikelet of grass that turns sunward, but may be traced to the one great law which originally set the sun and its attendant orbs in motion.

The solar system, however, vast as it seems, is but a unit in space, which is peopled with other systems and orbs circling and encircling beyond the bounds of human conception. What we term *fixed stars* are but suns and centres of revolution; and the solar system, as a whole, may revolve in space round some vast centre, just as its individual planets have their motions round the sun. From such a revolution may arise cycles of heat or cold, life or death, exuberance of certain living forms, and annihilation of others—cycles which meet with a faint analogy in the recurrences of our summers and winters. We know nothing of the constitution of what we call space, or of the ethereal essences which pervade it; and it is not unlikely, that as the solar system passes through successive regions, that causes may operate on a scale sufficiently vast to impress new conditions upon the whole of the planets which constitute that system. But whether our earth be or be not affected by causes so remote and universal, we know for certain that its history, from the beginning of time, has been one of incessant mutation and progress.

The materials of which the earth is composed present a history not less curious than that of its planetary relations. Superficially speaking, the globe consists of land and water; the water occupying the extreme depressions of the land, and this land composed of solid or rocky materials. That the same kind of rocks which appear at the surface do not constitute the interior or central portions, we have evidence from the mean density of the earth; for were the law of gravitation to exert itself uniformly towards the centre, the lightest substance at the surface would be so compressed at the depth of a few hundred miles, as to give to the whole a greater density than astronomical calculations will allow. The interior, therefore, must consist of very different material from the exterior, and this has led geologists to speak of the earth's *crust*, whose composition we know, in contradistinction to the central portion, concerning which we can only form conjectures. This crust, or external shell of solid matter, consists of rocks, differing not only in their appearance and arrangement, but in their mineral and chemical characters; some being compact and crystalline, as marble, others soft and dull, as chalk; some lying in layers or strata, others occurring in huge irregular masses; while, mineralogically and chemically speaking, we have such rocks as granite, quartz, slate, lime, coal, rock-salt, chalk, and clay. But the crust so composed, compact and solid as it may seem, is far from being permanent and stable; in other words, the dry land, which now appears with all its irregularities of hill and valley, plain and ravine, lake and river, is not the dry land which existed many thousands of years ago. Strictly speaking, indeed, the aspect of the globe is ever changing. Here the sea encroaches on the land, there the debris borne down by rivers silts up bays and estuaries; here earthquakes sink, and volcanoes elevate the surface; lakes are dried up, and rivers change their course; and, greater than all of these, vast regions gradually subside, and are covered by the ocean, while others as gradually emerge from the waters, and become dry land. All these changes, past and present, form the subject of geological consideration.

Geology, in its aim to decipher the physical history of our globe, has determined that all the known rocks may be ranked under two great sections—the *stratified* and the *unstratified*. The former appear in layers or beds, and have evidently been deposited in water, hence said to be *aqueous* or *sedimentary;* the latter appear in vast irregular masses, generally disrupting the stratified

rocks, and have all the appearance of having been formed like the lavas of the present day, hence they are called *igneous* or *volcanic*. Of the sedimentary rocks, sandstone, limestone, slate, and coal may be taken as illustrative examples; of the igneous, granite, basalt, greenstone, and lava are the most familiar. As at present, so in all time past, the surface of the earth has been subjected to atmospheric, aqueous, and other influences, the effects of which are to wear down the exposed material; and this, borne away by floods and rivers, is deposited in the ocean, where, consolidated by pressure, heat, and chemical agency, it forms new strata of rocks, which in time are brought to the surface by volcanic and other elevatory forces. Thus, then, one set of agencies degrade, and another reconstruct and elevate; and in proportion as either of these preponderate, so will any portion of the earth be low and level, or high and precipitous. Such, then, is the origin of the stratified and unstratified rocks—the one but the reconsolidated matter of pre-existing rocks, which have been worn and battered down by rains, frosts, waves, and rivers; the other the cooled and hardened material sent forth from the interior of the earth by volcanic agency. But while rivers and floods bear down mud, sand, and the like, they also carry such vegetable and animal remains as lie in their course; and in this manner plants and animals are entombed in the newly-formed layers or strata. As at present, so in former eras, such remains have been enclosed in the stratified rocks, where, subjected to certain chemical agencies, they have become petrified, and are thus preserved as records of the former Flora and Fauna which peopled the globe. Geologists have accordingly found that the earth has not always been occupied by the same kinds of plants and animals that now exist; but that different eras, in its onward history, have had very different Flora and Fauna, and that at present not one, perhaps, of its former genera is in existence.

Aided by the mineral composition of the rocks themselves, and by these fossil organisms which are found in them, geologists have arranged the strata composing the accessible crust into *formations;* that is, into series of strata which seem to have been deposited under the same terrestrial conditions. Thus the *primary* formation includes the hard crystalline and slaty strata, as gneiss, mica-schist, clay-slate, &c. in none of which organic remains have yet been found, and whose material has evidently been derived from the granitic rocks on which they rest as a basis or foundation. Next in succession above the primary are the *transition* rocks, so called from their containing remains of vegetable and animal life, and as indicating the transition of the globe from an unpeopled to a peopled condition. This formation consists of hard quartzose sandstone, certain indurated slates and limestones, and of the marls, shales, and sandstones known by the name of the "old red sandstone." Its fossils consist chiefly of infusory animalcules, corals, shell-fish and fishes, and of sea-weeds, and of few lowly-organised terrestrial vegetables. Then comes the *secondary* formation, subdivided into the older and younger; the former comprehending the mountain limestone, coal, bituminous shales, ironstone, clays, and soft thick-bedded sandstones; and the latter the new red sandstone, magnesian limestone, and those calcareous groups known as the lias, oolite, and chalk. In the older secondary, corals, shell-fish, and fishes are exceedingly prevalent, and vegetation during that era was so prolific, as to furnish the material of which coal is formed; in the younger secondary, vegetation is less abundant, but shell-fish, fishes, and strange gigantic fish-like reptiles are everywhere to be found, and of forms not now in existence. Next in ascending order lie the beds of the *tertiary* formation, consisting of clays, marls, soft sandstones, limestones, and gypsum; and in which the remains of birds, mammalia, and vegetables somewhat like existing genera are for the first time discovered. Above all these formations are scattered the clays, gravels, sands, peat-mosses, and marls which constitute the *superficial accumulations* of the current era; and in these are found the remains of existing races of plants and animals, some species of which, however, have already become extinct in several regions. Intermingled with these formations — now throwing them up in hills, or depressing them in valleys; now overlying them in mountain masses, or breaking and contorting them in the form of veins and dikes —are the igneous rocks, the granites, basalts, and traps of past ages, and the lavas of the present era.

All this succession and accumulation of strata, this appearance and disappearance of different races of plants and animals, indicate the lapse of innumerable ages—ages through which the earth has progressed from phase after phase to that which it now presents. What a strange and chequered history! Nor does it yet present, in any of its physical relations, a single aspect of rest or stability. The conditions of its constitution forbid this; and while we write, rocks are wearing down, rivers are laden with debris, new strata are being deposited, volcanoes are elevating, earthquakes are depressing, and land and sea are gradually changing places, as they have done in all times bygone. All the stratified rocks which we have enumerated have been deposited in the ocean, in estuaries, or in fresh-water lakes; and could we accurately map out the sites and limits of these deposits, we should find that, at no two periods in its history, has our planet presented the same distribution of land and water. All that we know for certain is, that, from the earliest dawn of the stratified formations up to the current moment, there has been sea and dry land, rains, springs, rivers, and all those degrading and transporting agents which are in incessant operation around us. What the altitude and irregularities of this dry land, what the depth and constitution of this ocean, we may never ascertain. We know, however, that the same rocky material has undergone successive rounds of disintegration and reformation; that this material is essentially made up of siliceous, calcareous, argillaceous, bituminous, metallic, and saline constituents; and that these constituents, as well as those of plants and animals, are compounded of *fifty-four* elementary substances; of which, at the ordinary pressure and temperature of the atmosphere — five are *gaseous*, seven *non-metallic* liquids and solids, thirteen *solid metalloids*, and twenty-nine *metals*.

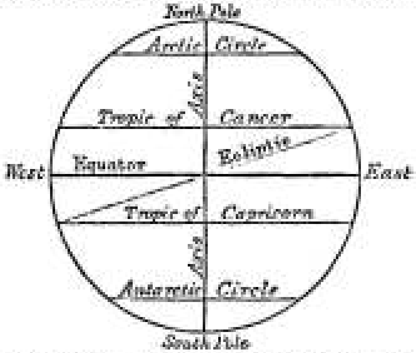
Of the constitution of the ocean, or watery portion of the earth's superficies, chemical research affords us equally accurate data. When pure, water is composed of 1 hydrogen and 8 oxygen by weight, or of 2 hydrogen and 1 oxygen by volume. In motion, however, water is generally found to contain many impurities—such as clay, sand, animal and vegetable matter, &c.—which, if left at rest, by their own weight soon fall to the bottom. Such substances are said to be *mechanically suspended*, and when deposited at the bottom, form sediment. Besides impurities of this description, water may contain matter which will not fall down, and which is said to be held in *chemical solution*. Sea water of the Atlantic, according to Dr Marcet, contains $4\frac{4}{10}$th grains of saline matter in every hundred; while, according to Dr Murray, the water of the German Ocean contains only $3\frac{4}{10}$ths. This saline matter consists chiefly of chloride of sodium (common salt), sulphate of soda, muriate of lime, and muriate of magnesia. It has been also ascertained that the Southern Ocean contains more salt than the Northern; that this saltness is greater towards the tropics than at the equator, and less towards the poles; that small inland seas, though communicating with the ocean, are less salt than the ocean; that the Mediterranean contains a greater proportion of saline matter than the Atlantic; and though the saltness of the sea be pretty uniform at great depths, still, at the surface, owing to the admixture of rain, river, and iceberg water, it is not quite so salt. A knowledge of the constitution of the ocean is necessary to the explanation of numerous facts in geology and biology. The saline constituents must influence more or less all chemical changes, rock deposits, and animal and vegetable life, which take place in the ocean. From these constituents shell-fish and coral animalcules obtain the material of which shell-beds and coral-reefs are constructed; and by this same constitution marine plants and animals are made to assume a character which distinguishes them from the inhabitants of fresh waters.

The atmosphere, the next great constituent of the globe, plays an equally important part in the organic and inorganic economy. Pressing with a weight of about fifteen pounds upon every square inch at the ordinary sea level, and diminishing in density in the duplicate ratio of the altitude, it is evident that animals and plants fitted to live at small elevations will die if removed to great heights—a circumstance corroborated by the fact, that travellers experience difficulty in respiration on very high mountains, and that blood has been known to start from their ears and other tender parts under the diminished pressure. Calculating from data afforded by its density, a limit has been assigned to the atmosphere at the altitude of forty-five miles—or about forty miles above the top of the highest mountains. Notwithstanding its transparency, the air intercepts and reflects the sun's rays, multiplies and propagates them by an infinity of repercussions; and were it not for this property, objects would never be illuminated unless exposed to the direct light of the sun. It is also the recipient and retainer of the solar heat reflected from the earth; and were it not so constituted, the solar rays would be returned to space, and an excessive cold continually prevail. Besides, according to the general physical law, that the capacity of gases for heat increases with their rarity, bodies placed in the upper regions of the atmosphere have their heat so rapidly abstracted, that they are ever beneath the freezing point; hence the perpetual snows and glaciers of the higher mountains. Chemically speaking, it is a gaseous admixture—every hundred parts of which are composed of 79 nitrogen, and 21 oxygen—with about one part in a thousand of carbonic acid. In addition to these, which are the permanent constituents of the atmosphere, there is always a certain amount of aqueous vapour, amounting from 1 to 1·8 per cent.; and in certain localities, traces of ammonia, sulphurous acid, muriatic acid, and other ingredients are to be occasionally detected. The atmosphere may therefore be regarded as the laboratory in which clouds, rain, snow, and other vapours are formed—the medium through which the light and heat of the sun are diffused and equalised—an element without which animal and vegetable life could not exist, for both incessantly inhale and exhale its elements; and an agent indispensable to those innumerable physical operations which constitute the progressive history of our planet.

Thus assisted by the determinations of astronomy, geology, chemistry, and meteorology, as regards the general constitution of the globe, physical geography proceeds to describe and account for its superficial appearance and conditions, and these, again, as influencing the life and distribution of the plants and animals by which it is peopled. Before entering, however, upon these interesting but complicated details, it will be necessary to explain the principal terms and technicalities usually employed by geographers.

GEOGRAPHICAL TERMS.

The direction from which the earth moves, in its daily rotation, is called the *West;* that towards which it moves the *East;* the point which is on the right hand of one standing with his back to the east is called the *North;* that on the left hand the *South.* The imaginary line on which the earth turns is called the *Axis;* its termination towards the north is known as the *North Pole;* that towards the south the *South Pole.* The early cultivators of geography dwelling on a part of the earth nearer the north than the south pole, supposed the former to be uppermost, though, in reality, such ideas as upper and under do not belong to astronomy; and it is for this reason that in globes and maps the northern part is always placed at the top, the east being towards the right, and the west towards the left hand, with the south at the bottom. Exactly between the two poles, and consequently dividing the earth into two equal portions, is a line called the *Equator;* all north and south of which are respectively



called Northern and Southern Hemispheres or Half-spheres. In the same way, an encircling line, at right angles to the Equator, divides it into Eastern and Western Hemispheres. The circuit of the earth, both in its girth between east and west, and between north and south, is divided into 360 parts, called *degrees,* each degree being equal to about 69½ British miles. At the distance of 23½ of these degrees from the Equator, in both directions, are two parallel lines called the *Tropics,* in reference to the sun's declination; known respectively as that of *Cancer* and *Capricorn,* from these constellations being situated in a corresponding part of the sky. At the same distance from each pole is a parallel line—that on the north being styled the *Arctic,* and that on the south the *Antarctic Circle.* The spaces between the tropics are called *Torrid Zones,* because the sun, being always vertical in some part of that space, produces a greater degree of heat than is felt in regions where his rays strike more obliquely. The spaces between the tropics and the Arctic and Antarctic Circles are styled the *Temperate,* and the spaces within these latter circles the *Frigid Zones.* Lastly, a line, which cuts the Equator obliquely, touching upon opposite points of the tropics, is called the *Ecliptic.* The points where the Ecliptic cuts the Equator are termed *Equinoctial Points* or *Nodes;* and when the sun is in that part of his course, the day and night are of equal length. These equinoxes of course occur twice during the year—namely, the 21st March and 21st September. The Ecliptic and Equator are sometimes called *Greater Circles,* because they encircle the earth at the thickest parts; the others above enumerated are all *Lesser Circles.* A series of lines drawn from pole to pole over the earth's surface, and cutting the Equator at right angles, are called *Meridians,* from the Latin *meridies,* mid-day. Every place upon the earth is supposed to have one of these passing through it, although it is usual to describe only twenty-four upon the surface of the terrestrial globe. When any of these is opposite the sun, it is then mid-day, or twelve o'clock, with all the places situated on that meridian, and consequently midnight with those on the opposite meridian, on the other side of the earth. Thus, when it is twelve o'clock at noon in any particular part in Britain, it will be twelve o'clock at midnight in a corresponding part on the opposite side of the globe—that is, with our *Antipodes*—near New South Wales; and the intermediate hours, sooner or later, will all lie in the countries between these two points, exactly according to their position or degrees of longitude.

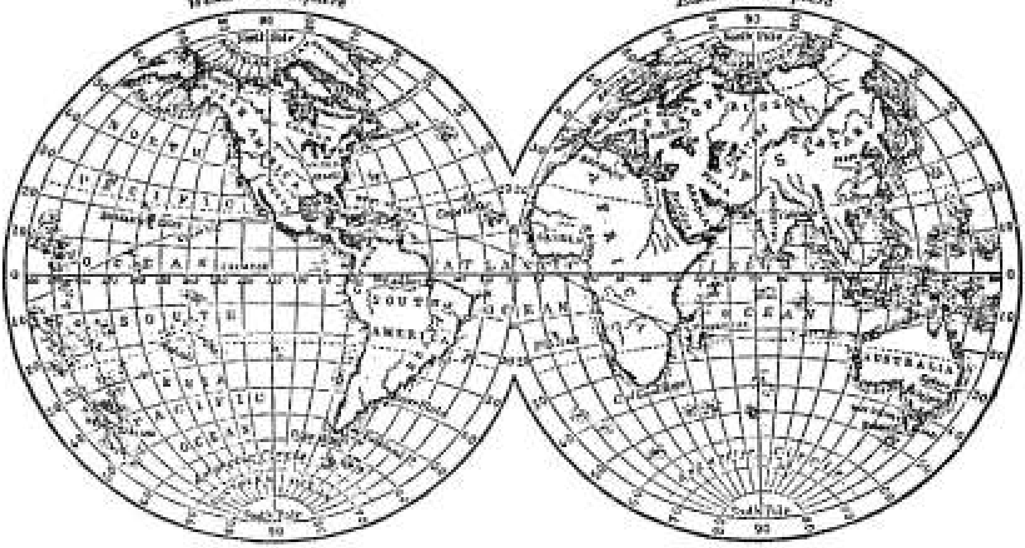
The exact situation of a place upon the earth, or its latitude and longitude, is determined by means of these circles. They are all divided, as already stated, into 360 parts, which parts are called *degrees;* these degrees again into 60 equal parts, called *minutes;* the minute into 60 others, called *seconds;* and so on. They are usually indicated by certain signs—thus, 8° 5′ 7″ is 8 degrees 5 minutes 7 seconds. The *latitude* of a place is its distance measured in that manner from the Equator. If it lies north of that line, it is in north latitude; if south of it, in south latitude. There being only 360 degrees in the circumference of the earth, and the distance from the Equator to either of the poles being only a fourth part of it, a place can never have more than 90 degrees of north or south latitude. The *longitude* of a place is the distance of its meridian from another, which is called the *first meridian.* The first meridian is quite arbitrary, and it is a matter of indifference through what point we draw it, provided it be settled and well known which one we adopt, so as to prevent mistakes. Foreigners fix upon the principal observatories of their respective countries. In Germany, the island of Ferro is generally adopted; in France, the observatory of Paris; and in England, that of Greenwich. Longitude is reckoned either east or west of the first meridian; and 180 is therefore the utmost degree of longitude. Some geographers, however, reckon longitude all the way round the globe. From the meridians all tending to a point at either pole, the degrees of longitude decrease as we approach these points from the equator.

Besides these terms and technicalities, which refer to the earth as a whole, there are others employed to designate its separate portions of land and water. Thus, of the land, a *continent* is any vast region uninterrupted by seas; an *island,* any smaller portion surrounded by water; a *peninsula,* a portion nearly surrounded by water; an *isthmus,* the narrow neck which connects a peninsula with the mainland; a *cape, promontory,* or *headland,* a point of land jutting out into the sea. As to the water, a large uninterrupted extent of sea is called an *ocean;* smaller portions are known as *seas;* a bend of the sea into the land, a *bay;* a deeper indentation, a *gulf;* a narrow stripe of sea, a *strait* or *channel;* and where the sea stretches inland to receive the waters of some large river, it is termed a *firth* or *estuary.* Referring to the surface of the land, without any reference to water, extensive flats are known as *plains, steppes, pampas,* &c.; smaller ones as *valleys, straths,* and *dales;* elevated land is spoken of as rising into *hills,* or, still higher, into *mountains;* and level elevated tracts are known by the name of *table-lands* or *plateaux.* Running water makes its appearance in *springs,* many of which conjoined form *streams,* and streams *rivers;* and where these become stagnant, and spread out into inland sheets, they take the name of *lakes.* The bounding-line of land and water is termed the *shore,* and the land bordering on the sea in any place is generally spoken of as the *coast* or *sea-board,*

DISTRIBUTION OF LAND AND WATER.

To exhibit the earth's surface at one view, it is usual to map it into two halves or hemispheres—the Eastern, comprehending the one great continent of the *Old* World, or that known to the ancients; and the Western, or *New* World, discovered and explored since the close of the fifteenth century. To these modern geographers add a third—namely, *Oceania*, or the Maritime World, partly situated in both hemispheres, and comprising Australia and the vast group of islands which stud the Pacific Ocean. It will be seen at one glance that the sea and land are very unequally distributed—that they preserve no regularity of outline or form—and that either is placed indifferently as to position on the earth's surface. Many fanciful conjectures have been offered to account for the configuration of the existing continents, but none of them seem to have any foundation in fact. The elevating and depressing causes mentioned under the head of GEOLOGY, are too violent and

Western Hemisphere — *Eastern Hemisphere*



capricious, to leave anything like regularity in their results, while it is a matter of indifference as to the planetary relations and equilibrium of the globe what portion of its surface be land or water. And yet, seeing that everything in nature is regulated with such order and harmony, there may be, though beyond our present means of detection, a progression as to the time and manner in which the various portions of the solid crust shall be elevated into dry land, or submerged beneath the ocean. It has been already stated, on geological authority, that the land and water have frequently changed places—and this changing implies vast revolutions in the kind and amount of the vegetables and animals which people the earth. Did the greater portion of the dry land exist between the tropics, for example, the Fauna and Flora of the world would be essentially different from what obtains at present, and still more so from that which could flourish were that land distributed chiefly in the polar regions. The distribution of land and water, therefore, though unimportant as regards the physical relations of the globe, is all-essential to the character of its life and humanity.

Though we are thus unable to account for the present relative arrangement of sea and land, there is one determining principle sufficiently clear—namely, that so long as the same quantity of water remains on the globe, a fixed amount of space will be required to contain it. If the difference between the elevations and depressions of the solid crust be small—in other words, if the hollows in which lakes and seas are spread out be shallow—their waters must extend over a greater space; and if these hollows be deep, the waters will occupy less extensive areas. The operation of this principle should be borne in mind; for if the elevation of the land were less general, the waters would occupy larger spaces, and this more extended area of shallow water would act in various ways. It would render the climate more genial and uniform; and, extending a greater surface to the evaporating power of the sun, rains and atmospheric moisture would be more prevalent. These, again, would influence the amount and kind of animal and vegetable life on dry land; while the shallow waters themselves would be more productive of life—it being a well-known fact, that marine plants and animals flourish only at limited depths. Of terraqueous distribution at any former period of the world, we can only infer from the appearances which the surface and rocky strata present; but of the present distribution we have pretty accurate information, with the exception of those inhospitable regions surrounding either pole.

The proportion of dry land to water, as at present known, is about one to three—that is, two-thirds of the whole surface of the globe may be assigned to water. Estimating the entire superficies to contain 196,943,750 square miles, nearly 147,000,000 are occupied by water, and only 51,000,000 by dry land. Others, reckoning the entire area of the globe at 197,000,000 of square miles, assign seven-tenths as the proportion of space occupied by the ocean—that is, about 136,000,000 of liquid superficies, and somewhat less than 60,000,000 of solid dry land. Of this land, the greater portion lies in the northern hemisphere, or north of the equator; while south of that line, the ocean spreads for thousands of leagues unbroken by a single islet. It will no doubt greatly alter this estimate should the indications of land within the antarctic circle hereafter prove to be portions of one great polar continent. The following is given as an approximation to the amount of land (in square miles) in the different latitudinal zones of the earth's surface:—

Northern Hemisphere.		*Southern Hemisphere.*	
Arctic Zone, -	2,250,000	Antarctic Zone,	—
Temperate Zone,	28,530,000	Temperate Zone,	3,830,000
Torrid Zone, -	11,620,000	Torrid Zone,	12,210,000
Total,	42,400,000	Total,	16,040,000

The relative configuration of land and sea, we have said, is so extremely irregular, that no conception can be formed of it unless from the study of a well-constructed map; but whatever the character of this configuration, it exercises a most important influence on the physical operations of the globe, by determining the direction of oceanic and tidal currents, and by modifying the direction and force of waves. Oceanic currents influence the temperature, and consequently the life of the ocean; they carry along with them every species of floating debris—and this they deposit wherever the configuration of the land presents an obstruction. Tides also exercise a powerful transporting influence; they rise to greater or less heights, according as they are obstructed by the outline of the land; and while they sweep headlands and promontories bare, they lay down sand and gravel in sheltered bays. Waves also wear away the land, according as the line of coast obstructs or favours the violence of their progress. Since, therefore, these oceanic agents are wearing away dry land in one quarter, and filling up shallow bays and creeks in another; since rains and rivers are wearing down inland regions, and carrying the material to the sea; and since, moreover, earthquakes and volcanoes are here submerging land, and there elevating the bottom of the ocean—the relative distribution of land and water must be continually fluctuating. However imperceptible this shifting may be—little affected as the existing continents may have been within the historic period, or even within the era, of man—still the change goes forward; and we are no more entitled to regard the present distribution as a thing fixed and enduring, than an inhabitant of the old red sandstone era (had any such existed) would have been to declare the then arrangement of land and sea as a thing immutable.

CONTINENTS AND ISLANDS.

The quarters or continents (though, strictly speaking, there are only the two great continents already mentioned) into which it is usual to divide the dry land, are *Europe*, *Asia*, and *Africa* in the Eastern Hemisphere; North and South *America* in the Western; and *Oceania* (including Australia, Malaysia, and Polynesia), situated partly in both hemispheres. By referring to the map, it will be perceived that there are traces of land still unexplored both in the arctic and antarctic regions; but whether these may be islands or masses worthy to be ranked as new continents, we have yet few means of conjecture. At present, the comparative areas (in square miles) of the established quarters—including their respective islands—are calculated as follows:—

Old World, or eastern continent,		31,230,000
Europe,	3,724,000	
Asia,	16,152,000	
Africa,	11,354,000	
New World, or western continent,		15,000,000
North America,	8,200,000	
South America,	6,800,000	
Maritime World, or Oceania,		4,632,000

The superficies of this vast expanse presents an amazing diversity of character; some portions being little elevated above the sea-level, others rising into mountains of more than five miles in height; some tracks swampy, others arid; certain regions tame and flat, others diversified by the wildest irregularities; districts teeming, under tropical influences, with life and growth, others buried in the perpetual solitude of ice and snow. This diversity of character forms the especial object of our arrangement and description.

Although the above division into "quarters" be convenient, and even justifiable enough, yet so much do these sections run into each other, so largely do portions of one or more of them lie within the same parallels, and so frequently are their other conditions akin, that it is not very easy to draw a series of broad and well-marked physical and vital distinctions between them. And yet there is something peculiar in the external conditions of Africa—for example, something in its climate and superficies, its river-systems, its Fauna and Flora—that serve to distinguish it as a whole from any of the other continents. The same may be said of South America, of North America, and of Oceania; and in a less degree of Asia and Europe, which are separated by no great natural boundary. Retaining, therefore, these generally-acknowledged divisions, let us glance at their respective positions and superficial characteristics as influencing the vitality of our planet.

Europe—lying almost wholly within the northern temperate zone, diversified by a happy blending of mountain and plain, marked by no geographical feature on a scale so large as to give to its surface the character of monotony, and surrounded and intersected by seas which greatly influence its climate—affords, in proportion to its area, a habitat to a more varied and highly-developed existence than any other quarter. Widely connected, however, with Asia on the east, as much of the two continents as lie within the same parallels present considerable similarity, at the same time that every facility to the dispersion of species is afforded by a land communication. Asia, situated partly within the torrid, temperate, and frozen zones, and presenting an area almost five times that of Europe, exhibits every species of geographical diversity—vast mountain-chains and elevated table-lands, broad level steppes and sand deserts, luxuriant plains watered by the largest rivers, tracts doomed to everlasting snow or to scorching sterility, salubrious valleys of incessant verdure, and noisome jungles of the grossest growth. With such a variety of character, it is impossible to treat of it as a whole, and consequently geographers divide it into five well-marked regions—namely, *Central* Asia, consisting of a series of ascending plateaux, diversified by mountain ridges of stupendous height, and intersected by narrow valleys; *Northern*, including the whole of the continent north of the Altai Mountains—a flattish region traversed by large rivers, bleak and barren, suffering under an intense cold, thinly peopled, and almost physically incapable of improvement; *Eastern*—upon the whole a low-lying and somewhat arid region, though traversed by several of the largest rivers in the world, and occasionally diversified by spurs from the central table heights; *Southern*, including the two peninsular projections of India within and without the Ganges—decidedly the finest region of the continent, diversified by minor hill-ranges and well-watered valleys, enjoying a high though not an oppressive temperature, having only a rainy season for its winter, and, except during long drought, presenting in every district an unfailing verdure; and lastly, *Western* Asia (from the Indus westward and north to the Caspian), which, with a few minor exceptions, may be said to consist of high sandy plains, studded with salt lakes, very inadequately watered by rivers, and on the whole a hot and arid region. A continent marked by such a diversity of surface and climate, presents an appropriate field for the exhibition of almost every form of vitality known in the other continents, and thus has belief ever pointed to it as the cradle of organic existence. Africa, the next great division of the old world, is almost entirely insular, the isthmus connecting it with Asia being only 72 miles across, of no great elevation above the sea-level, and even in part occupied by lakes and salt marshes. Respecting the physical appearance and construction of Africa, our information is extremely limited; all that is known with any degree of certainty being some patches along the sea-board, and a few tracks or lines across the Sahara, or Great Desert, of the north. Little known, however, as it is, its isolation, its intertropical position, and its general configuration, must stamp it with *vital* peculiarities; and yet its connection with Asia on the one hand, and its proximity to Europe on the other (the Straits of Gibraltar being only about 8 miles in width), offer numerous facilities to the interchange of vegetable and animal species. Thus the southern and northern sea-board of the Mediterranean present many similar forms; the Flora and Fauna of Egypt and Nubia are identical in many instances with those of the adjoining tracts of Arabia; while the intertropical regions offer numerous genera allied to those of Birmah and Hindoostan.

Turning now to the new world, we find too the two Americas, so slenderly attached by the narrow, rocky Isthmus of Panama, which at one part is little more than 16 miles across, that they may safely be regarded as separate and distinct continents. This separation is rendered still more decided by the irregular character of the isthmus and the adjoining high tableland of Mexico, which form an almost impassable barrier to the migration either of animal or of vegetable races. South America lies chiefly within the tropics, a third part or less stretching southward into the temperate zone; its superficies is broadly marked by mountain and plain, exhibiting along the entire western coast a flat arid region, from fifty to one hundred miles in breadth; then rising boldly up into the Andes, which stretch along its whole length, and present a rugged irregular region of variable breadth; and ultimately falling away to the north and east in the *llanos* of the Orinoco, the *plains* of the Amazon, and the *pampas* of La Plata. Nor are its physical features more broadly marked than the plants and animals by which it is peopled, these exhibiting typical peculiarities only next in degree above those of the somewhat anomalous continent of Australia. Respecting the entire configuration and extent of North America, we have as yet no determinate knowledge. If we adopt the opinion of Mr Simpson—who traversed the coast from Point Barrow to Point Turn-again—that the waters of Melville Sound are connected with the Gulf of Bothnia, then is North America distinct from the arctic regions of Cumberland Island, N. Georgia, and Greenland, which will require to be erected into a new geographical division. Following, however, the usual course of including these regions, and leaving the "north-west passage" as still problematical, the area of the known continent may be stated at 8,500,000 square miles—the great mass of which lies within the northern temperate zone. The general physical characteristics of the continent are remarkable for the magnitude of the scale upon which they are presented—the plains, lakes, and rivers being superior to those of all other countries. Though lying chiefly within the temperate zone, its southern and northern regions are respectively placed under tropical and arctic influences, and thus it presents in some measure the threefold variety of Fauna and Flora which characterises the greater continent of Asia. This greater diversity of climate renders it less peculiar in its living forms than the sister continent, at the same time that its proximity to Asia—being separated by Behring's Straits, which are only 36 miles broad, and annually frozen over—renders the immigration of old-world species by no means improbable.

The insular portions of the globe are not less worthy of notice than the continents themselves, though these, in reality, are but islands of greater extent, washed on all sides by the ocean. Meaning, however, by the term *island*, those smaller masses of land lying in the midst of seas and lakes, we find them sometimes solitary, oftener collected into groups or *archipelagos:* in some cases they are little more than low sand-banks, ledges of rocks, or coral reefs; and in others—rising to a considerable elevation above the surface of the water, and spreading to a considerable extent—they present in miniature all the features of the continents to which they belong. They are often the summits of submarine mountain chains, and, as such, are intimately connected with each other, and with the neighbouring mainland. Many of them are evidently the production of volcanic forces—the dawn of new continents emerging from the waters, as others are the gradually-submerging relics of former terrestrial regions. The most important island-groups are the British, Japan, Philippine, and East Indian, in the eastern hemisphere; and the West Indian and Polynesian in the western. The largest individual islands (regarding Australia as a continent) are—Borneo, with an area of about 300,000 square miles; Madagascar, 234,000; New Guinea, whose outline is yet imperfectly known; Sumatra, 128,000 square miles; Niphon, 109,000; Great Britain, 83,020; Nova Zembla, yet imperfectly known; Newfoundland, 57,000; Cuba, 43,400; and Iceland, 30,000 square miles.

Islands, we have said, are either connected with existing continents, are portions of former continents now submerged, or are new and independent elevations. Thus, if an island is of the same geological formation with the adjoining mainland, we must regard it either as a portion separated by depression, or as a belated portion only rising into dry land. In either case, we are bound to consider it in all its relations—vital as well as physical—as belonging to the adjacent continent. Again, islands of totally different formation from that of the nearest continent, may in most cases be regarded either as relics of former lands, or as new lands rising into day; and we are not to be startled at the fact of their exhibiting (like Australia) races of plants and animals altogether peculiar. Lastly, with respect to far distant and solitary islets, whether of volcanic origin or not, we must view them as indices of operations past or future, and as proofs of the fact, that the sea bottom presents the same irregularities as the surface of the land—these islets towering above the general configuration like lofty peaks of existing mountain ranges.

Such is a brief glance at the partition of the dry land (so far as it is known) into continents and islands—a partition which exercises an all-important influence over organic existence, and which, after all, is dependent on very minute geological operations. A general elevation of the solid crust in the eastern hemisphere, for example, would connect Britain with the continent of Europe, the Loffoden islands with the Scandinavian peninsula, enlarge the connection between Asia and Africa, elevate the Sunderbunds of the Ganges into a vast plain, the Laccadive and Maldive reefs into extensive islands, and the bed of the Yellow Sea into an alluvial plain. A depression to the same amount, on the other hand, would sever Scandinavia from Europe, lay the Netherlands and part of Central Europe under water, sever Africa from Asia, convert a large portion of Arabia, Egypt, and Northern Africa into an extension of the Mediterranean; in fact, totally overturn the existing relationship of the dry land in the old world. Similar phenomena would be presented under similar circumstances in the new world; and more strikingly still in connection with the island-groups of the Pacific. Equally important results depend upon the relative positions of the continents and islands. Had South America, unaltered in a single square yard, lain parallel with, instead of crossing, the equator, or had Africa been intersected by seas as Europe is, it requires no stretch of imagination to conceive the radical difference which their Flora and Fauna would have presented. Whether the present arrangement of continent and island is that which admits of the greatest amount and variety of vital development, is what we have not yet sufficient data to determine; but this we know, that the existing irregularity and varied subjection to arctic, temperate, and tropical influences, is much more favourable to these results than any single influence, however gigantic its operation. Nay, more, as regards man, and the highest aim of creation—the civilisation of man—the present arrangement is of the first importance. The theatre of his operations all arctic, and he would never have risen above the condition of the Laplander or Esquimaux; all antarctic, and behold his condition in that of the miserable Fuegian; all tropical, and see him in a state of languid, enervated, semi-civilisation; while balanced as conditions are, see his progress mainly in one broad zone, where Chinese, Indian, Persian, Chaldean, Syrian, Egyptian, Greek, Roman, Frank, and Anglo-Saxon have successively, or simultaneously, figured in the march of improvement.

MOUNTAINS AND TABLE-LANDS.

As elevation above the waters of the ocean is the origin of the dry land, so its most prominent features are those peculiar upheavals known by the name of *hills* and *mountains*. They are the framework, so to speak, upon which the solid crust is built and compacted; they are the immediate results of the elevating forces mentioned under GEOLOGY, and according to their character, so is that of the regions to which they belong, generally speaking, determined. They subserve numerous and important purposes in nature. Rising into regions of perpetual ice, they serve, in hot climates, to temper the air with the breezes generated around their heights; they are the reservoirs of rivers, supplying the shrinking streams, in the dry seasons of the lower countries, with copious torrents from their melting snows; they are, in most instances, the storehouses of the richest minerals; they increase and diversify the surface of the earth; and, by presenting impassable barriers between opposite regions, they give variety and richness to animal and vegetable life: we say impassable barriers, for the broadest seas are not half so effective in obstructing the dispersion of vegetable and animal life, as lofty snow-clad mountains. Seas have their tides, and currents, and drifting winds, and waves—even the polar seas have their firm ice-fields and drifting ice-floes, on which plants and animals may be borne; but the snow-clad summit is enduringly inapproachable to all that partakes of vitality.

Isolated mountains of great height are of rare occurrence, and when they do appear, are usually active or recent volcanoes. Hills and mountains, whether rising to the height of one thousand or twenty thousand feet, generally appear in chains or ranges, consisting either of one central chain, with branches running off at right angles, or of several chains or ridges running parallel to each other; and in both cases often accompanied by subordinate chains of minor elevation. Several chains constitute what is called a *group*; and several groups a *system*. Geology views these systems as so many axes of elevation, necessary to the rise of certain formations from the bottom of the ocean; ascertains the direction and centre of the elevating force; explains the phenomenon of "crag and tail;" speculates on the cause of the steep side being generally turned towards the older formations, while the gradual slope looks towards the newer; and further determines the respective eras when they rose into existence, by examining the nature of the stratified deposits broken through and carried up with the elevatory masses. Thus the Grampians, flanked and crested by no secondary rocks, long preceded the Pyrenees; the Pyrenees the Alps, which displaced the youngest secondary strata; and the Alps, again, had risen into form while the site of Ætna was a shallow sea of tertiary deposit. The relative ages of mountain chains appertains more especially to the province of the geologist; but with their epochs is connected their physiognomy or contour, a subject eminently interesting to the geographer. So persistent is the contour of mountains, whether associated with the primitive, secondary, or more recent formations, that the practised eye of the geologist can generally determine at a glance the era of their upheaval. The bold, but bald and massive heights of a granitic mountain, differ widely in aspect from the abrupt and splintery crags and pinnacles of a primitive; while the rounded, undulating, and terraced outline of the secondary trap-hills distinguish them at once from the conical crateriform heights of the tertiary era. Nor is it in appearance alone that these distinctions are interesting; the cold barren subsoil of a granitic district, altogether independent of elevation, differs as widely in its vegetable exhibitions from those of a fertile and congenial trap as a cultured garden does from a moorland wild.

Respecting the classification of mountains, various plans have been adopted by continental writers; but most of them are objectionable as involving geological theories: we shall adhere to that simpler arrangement which takes into account merely their geographical position and connection:—Those of Europe have been classified into a number of systems, some of which are continental, others insular. Laying aside minutiæ, the following seem to be distinct and natural:—1. The *Hesperian*, embracing the mountain ridges of the Spanish peninsula—all of which maintain a wonderful parallelism in position, as well as unity of character, and whose extreme culminating point is Maladetta in the Pyrenees, 11,424 feet. 2. The *Gallo-Francian* system, including all the hilly eminences in France which lie to the north of the Garonne, west of the Rhone, and south of the Rhine. None of these are of great age, or of great elevation, the highest being a peak of the Plomb de Cantal in Auvergne, 6113 feet. 3. The *Alpine* system, embracing all those ridges and branches which radiate from the great Alpine range of Switzerland, such as the Maritime, Cottian, Pennine, Rhotian, Noric, and other Alps; the Apennines in Italy, and the Balkan or Hæmus group in Turkey. This is the great mountain development of Europe, under which, as one system, geographers used to comprehend the whole of the southern groups and chains: the highest or culminating point is Mont Blanc in Switzerland, 15,732 feet. 4. The *Hercynio-Carpathian* system, including all the mountains and eminences comprehended between the Rhine, Dnieper, and Danube, the plains of Northern Germany and Western Poland. The highest point in this system is Ruska-Poyana in the Eastern Carpathians, 9912 feet. 5. The *Scandinavian*, a system of the highest antiquity, embracing the well-defined chains of Norway, Sweden, and Lapland, the extreme height of which does not exceed 8350 feet. 6. The *Ural* system or chain, which forms the boundary-line between Europe and Asia, and rises in its highest part to between 5000 and 6000 feet. Lastly, the *Britannic system*, consisting of a number of detached chains, as the Grampians, Cheviots, and Welsh mountains, the highest point of which is Ben MacDhui in Aberdeenshire, 4390 feet. All of these systems, as axes of elevation, have long ago become fixed and permanent; none of them has for the last two thousand years shown symptoms of volcanic activity: Hecla, Vesuvius, and Ætna, the only active volcanoes in Europe, seem to point to future upheavals.

The mountains of Asia may be all traced from that vast central plateau already adverted to, which forms, as it were, the nucleus of the continent. Omitting ranges of minor altitude, we may enumerate—the *Altai*, forming the boundary between the Chinese empire and Siberia, one of the bleakest ranges in the world, stretching unbroken for 500 miles in length, and reaching an extreme altitude of 11,500 feet; the *Iablonnoi* and *Stanovoi*, which may be regarded as prolongations of the Altai, stretching onwards to Behring's Straits, and attaining a height probably not exceeding 6600 feet; the *Khing-khan* range, bounding the Desert of Kobi, extending about 600 miles in length, but of unknown altitude; the *Chang-pe-shan*, skirting the east coast of Mandshuria, and rising abruptly from the sea to a height of 5000 feet; the *Pe-ling* and *Yun-ling* ranges, on the west of China Proper, ramifying variously, probably attaining a culminating height of 11,000 or 11,500 feet, and branching southward through Birmah and Annam in several parallel ridges which fall to 4000 and 3000 feet; the great *Himaleh* mass, extending about 1300 miles in length, and from 200 to 250 across, rising from the Indian side by stages of 4000, 8000, and 11,000 feet, then swelling generally to 14,000, in about 200 points reaching a height of 18,000 feet, and in Dhwalagari and Chumulari to 20,000 feet—the greatest known altitude of the terrestrial surface; the *Hindoo Koosh*, with their southern ramifications, which may be regarded as prolongations of the Himaleh; the *Thian-chan*, in Central Tartary, rising to an absolute height of 11,000 or 12,000 feet, but only from 3000 to 4000 above the surrounding table-land; and lastly, the *Tauro-Caucasian system*, diversifying the west of Asia with numerous ridges and peaks, the highest of which is Elburz, 17,786 feet. In connection with these systems and ridges are active volcanoes, as in Kamtchatka, Japan, the Thian-chan ranges, the plateau of Mongolia, &c.; and we are therefore not entitled to regard those so connected as having yet attained their ultimate elevation.

Of the mountain-systems of Africa we know nothing with certainty; a few detached facts are all that geography can offer. The hills of Cape Colony rise from Table Mount 3582 feet, to the Sneeuveldt, 7400 feet, and thence to the Nieuveldt, 10,000 feet, the intervening spaces being shrubby *kloofs* or valleys, and broad grassy terraces or *karoos*. Of the *Lupata* chain, or "Backbone of the World," as it is called by the older geographers, nothing is known, save that it skirts, almost unbroken, the entire eastern sea-board of the continent; and information is equally deficient respecting the clustering ridges of Abyssinia and Nubia, and the more linear ranges of Kong, Donga, and Cameroon. The last, it has been ascertained, rise to an elevation of more than 13,000 feet; but whether this be the maximum, or whether the whole may not belong to one system, further exploration can alone determine. On the north, between the Sahara and the Mediterranean, the *Atlas* system is well-defined, and here an elevation of 11,400 feet has been ascertained; but some peaks in the chain rise much higher, and, according to recent accounts, seem to be permanently covered with snow—a fact which would seem to indicate an altitude of more than 15,000 feet.

The mountains which traverse South America may be ranked under two systems—the *Cordilleras* or *Andes* proper, and the Brazilian Andes. The former, in several parallel chains, extend from the Straits of Magellan to the Caribbean Sea, in many places spreading out over a breadth of several hundred miles, embracing lofty table-lands, containing mountain lakes, and everywhere intersected by steep narrow ravines, passes, and lofty waterfalls. At Popayan, the main chain divides into three ridges, one of which, shooting off to the north-west, passes into the Isthmus of Panama; a second separates the valleys of the Cauca and Magdalena; and a third, passing off to the north-east, separates the valley of the Magdalena from the plains of the Meta. The highest summits of the system are between 15 and 17 degrees south, where Sorata reaches the elevation of 25,350, and Illimani that of 24,200 feet; throughout Chili and Peru they range from 15,000 to 23,000 feet; in Columbia, from 14,000 to 16,000 feet; and in Patagonia, from 4000 to 6500. Altogether, the Andes present a most magnificent spectacle to the voyager on the Pacific; the snow, which permanently covers their lofty summits, even under the burning sun of the equator, contrasting beautifully with the deep blue of the sky beyond; while occasionally another contrast is exhibited in vast volumes of smoke and fire, emitted from some of the numerous volcanoes which stud the entire range. The Brazilian Andes occupy a great breadth of country, but seldom exceed an elevation of 6000 feet.

The mountains of North America are scarcely in proportion to the other physical features of that continent, either in point of continuity or of altitude. Regarding the Cordilleras of Panama and Mexico, the Californian or Maritime range, and the Rocky Mountains, as portions of the great system of the *Andes* proper, we have in Guatemala a culminating point of 14,900 feet; in the Mexican volcano of Popocatepetl, of 17,735; in the table-land of Mexico, a general height from 4000 to 8000 feet; and in the Californian range, an average altitude of 8000 or 10,000 feet, which suddenly rises to 12,630 in Mount St Elias. The *Rocky Mountains*—the greatest and most continuous of the North American chains—rise from 8000 to 10,000, occasionally to 12,000, and only between 52 and 53 degrees north, to 16,000 feet; while the *Alleghanies* reach their extreme height at 6470 feet, and sink down in their branches to 3000 and 2000 feet.

In Oceania we have several minor groups and ranges; but the principal elevations are in detached volcanic heights, the index-fingers, as it were, to future mountain systems. In Malaysia, the highest known point is Mount Ophir in Sumatra, 130,50 feet; Australia has no eminences of importance; but Polynesia has the verdant and wooded heights of Tahiti, rising to 10,000 feet; and the active craters of Owhyhee, respectively 13,000, 14,000, and 16,000 feet above the sea level.

Such are the more prominent mountain systems as known to geography. Those who regard them as mere ridges, rising on one side, and descending as abruptly on the other, and at most intersected by a few narrow passes, gorges, and ravines, form a very erroneous conception of the physical contour of the globe; for, so far from this being the case, most of these systems are but the escarpments or ramparts of elevated expanses known as *plateaux* or *table-lands*, which form in some instances the nucleus of continents, and the source from which the rivers of such continents flow. Thus, on examining the map of Asia, it will be seen that all the rivers flow—north, east, south, and west—from the central region, which, in reality, forms a succession of remarkable plateaux. These plateaux may be termed the Persian, which ranges from 3000 to 6000 feet above the sea; the Mongolian, at an elevation of from 8000 to 12,000 feet; and that of Thibet, which is still more elevated. There are some masses of this kind in Europe, but of comparatively small extent—as the central part of Spain, which is about 2200 feet in height; and the Swiss table-land, between 3000 and 4000 feet. We know too little of Africa to speak of its interior; but a large part of New Granada and Ecuador, in South America, is situated at an elevation of from 5000 to 9000 feet, and contains populous cities, such as Quito, Bogota, &c. One of the most noted of these table-lands is that of Mexico, not less remarkable for its elevation than for its extent. "On the eastern and western coasts are low countries, from which, on journeying into the interior, you immediately begin to ascend, climbing, to all appearance, a succession of lofty mountains. But the whole interior is, in fact, thus raised into the air from 4000 to 8000 feet. The conformation of the country has most important moral and physical results; for while it gives to the table-land, on which the population is chiefly concentrated, a mild, temperate, and healthy climate, unknown in the burning and deadly tracts of low country into which a day's journey may carry the traveller, it also shuts out the former from an easy communication with the sea, and thus deprives it of a ready access to a market for its agricultural productions." As with the Mexican, so with all other table-lands, according to their latitude and elevation. Under the tropics they become theatres for the exhibition of temperate or even of arctic species; while under a temperate zone they are inhabited solely by boreal forms.

EARTHQUAKES AND VOLCANOES.

These are rather agents than effects—rather the cause of geographical diversity than geographical features themselves; and in this respect belong more properly to the province of geology: still, as by far the greater portion of superficial irregularity is the direct result of their operations, and as it is often impossible to separate cause from effect, it will be necessary here to give them some further consideration. An earthquake may produce a momentary undulation of the ground, followed by no perceptible result; it may simply elevate one region or depress another; it may be attended by a vast destruction of animal life, and the submergence of forests; it may alter the course of rivers, and produce new shores and beaches; it may create vast tidal waves, which give rise to accumulations of debris; open new springs and fissures, from which issue various products differing from those hitherto known in the district. Innumerable instances of such changes could be cited; a few, however, will suffice to convince the reader of the importance of this class of physical agencies:—By the great Chili earthquake of 1822, an immense tract of ground—not less than 100,000 square miles—was permanently elevated from two to six feet above its former level; and part of the bottom of the sea remained bare and dry at high water, with beds of oysters, mussels, and other shells adhering to the rocks on which they grew, the fish being all dead, and exhaling most offensive effluvia. By an earthquake in 1819, a tract—the Ullah Bund—in the delta of the Indus, extending nearly 50 miles in length, and 16 in breadth, was upheaved ten feet; while adjoining districts were depressed, and the features of the delta completely altered. The earthquakes of Calabria, which lasted for nearly four years—from 1783 to the end of 1786—produced numerous fissures, landslips, new lakes, ravines, currents of mud, falls of the sea-cliffs, and other changes, which, taken in conjunction, afford one of the finest examples of the complicated alterations which may result from a single series of subterranean movements, even though of no great violence. In 1743, the town of Guatemala, in Mexico, with all its riches, and eight thousand families, was swallowed up, and every vestige of its former existence obliterated; the spot being now indicated by a frightful desert, four leagues distant from the present town. In 1692, a similar calamity overtook the town of Port-Royal in Jamaica, when the whole island was frightfully convulsed, and about 1000 acres in the vicinity of the town submerged to the depth of fifty feet.

Volcanic forces act in a similar manner, in as far as they elevate, depress, and break asunder portions of the earth's crust; indeed earthquakes and volcanic throes, considered as subterranean movements merely, produce precisely the same results. But volcanoes, properly so called, act in another and equally important manner in producing geographical changes. They elevate the crust into long continuous ridges or mountain chains, form isolated cones, and discharge accumulations of lava, scoriæ, ashes, loose stones, and other igneous debris. Geologists and geographers often amuse themselves by enumerating volcanic vents to the amount of 300 or thereby; but this is of little moment compared with the determination of the centres of elevation to which they belong. In Europe, there appears to be three centres of volcanic action—namely, that of the Levant, to which Ætna and Vesuvius belong; that of Iceland, represented by Hecla and the craters of Jan Meyen; and that of the Azores in the Atlantic. In Asia there is abundant evidence of volcanic action on the borders of the Mediterranean, the Black Sea, the Caspian, and the Persian Gulf; while along the eastern borders of that continent there is a range not less than 5000 miles in length and 250 in breadth, including Sumatra, Java, the Eastern Moluccas, and the Philippine Islands; the same range bearing farther northward, though less distinctly, for several thousand miles, and terminating in the volcanic cones of the Aleutian isles. The whole extent of the two Americas is also traversed by a volcanic range, manifesting itself by eruptions along the whole line, from the Rocky Mountains through Mexico and the Andes, onward to Patagonia and Terra del Fuego. The islands of the Pacific further attest the presence of similar forces, as in the New Zealand, Sandwich, and other groups; as do those —namely, the Canaries, Cape de Verd, Ascension, St Helena, Madagascar, Bourbon, &c.—which surround the continent of Africa. In these centres of igneous action many of the volcanoes are *extinct*, others are merely *dormant*, while many are incessantly *active*.

The cause of volcanoes, earthquakes, and other subterranean movements, has been the subject of several theories, but is yet by no means very satisfactorily determined. The most prevalent opinion is that which connects them with one great source of central heat—the residue of that incandescent state in which our globe originally appeared. By this hypothesis it is assumed that the crust of the earth is of various thickness, that it contains vast caverns, and is extensively fissured—primarily by unequal contraction from cooling, and subsequently by subterranean agitations. Through these fissures water finds its way to the heated mass within; this generates steam and other gases, and these exploding, and struggling to expand, produce earthquakes and agitations, which are rendered more alarming by the cavernous and broken structure of the crust, and the yielding material upon which it rests. Occasionally these vapours make their way through fissures and other apertures as gaseous exhalations, or as hot springs and jets of steam and water, like the geysers of Iceland. On the other hand, when the expansive forces within become so powerful as to break through the earth's crust, discharges of lava, red-hot stones, ashes, dust, steam, and other vapours follow; and repeated discharges of solid material gradually form volcanic cones and mountain ranges. It does not follow, however, that volcanic discharges must always take place at the point where the greatest internal pressure is exerted, for volumes of expansive vapour press equally upon the crust and upon the fluid mass within, so that the latter will be propelled towards whatever craters or fissures do already exist. This theory of central heat is further supported by the occurrence of igneous phenomena in all regions of the globe, and by the fact, that most volcanic centres are in intimate connection with each other—a commotion in one district being usually accompanied by similar disturbances in another. The only other hypothesis which has met with countenance from geologists, is that which supposes the internal heat to be the result of chemical action among the materials composing the earth's crust. Some of the metallic bases of the alkalies and earths, as potassium, the moment they touch water, explode, burn, melt, and become converted into red-hot matter, not unlike certain lavas. This fact has given rise to the supposition that such bases may exist within the globe, where, water finding its way to them, they explode and burn, fusing the rocks among which they occur, creating various gases, and producing caverns, fissures, eruptions, and other phenomena attendant upon earthquakes and volcanoes. As yet, our knowledge of the earth's crust at great depths is excessively limited; we know little of the chemical and magnetic operations which may be going forward among its strata; and we are equally ignorant of the transpositions which may take place among its metallic and earthy materials; but judging from what we do know, this theory, however ingenious, seems by no means adequate to the results produced. It is true that there occurs nothing among the products of volcanoes at variance with its assumptions; but the magnitude, the universality, and the perpetuity of volcanic action, point to a more stable and uniform source—that source being the internal heat or residue of that igneous condition in which our planets originally appeared.

PLAINS—VALLEYS—AND OTHER DEPRESSIONS.

The plains, or level portions of the earth's surface, form a feature in its physical aspect equally important with that presented by its mountain systems. The name is given to extensive tracts, whose surface, in the main, is level, or but slightly broken by elevations and depressions. They are found at all elevations above the sea, and of every degree of fertility; from the exuberant tropical delta just emerging from the water, to the irreclaimable sterility of the desert of ever-shifting sand. In the economy of nature, they constitute the chief theatres of vitality: there plants, from the lowliest herbage to the most gigantic timber trees, flourish in greatest perfection and abundance; there animals, governed by food instincts, congregate most densely; and there man, led by similar instincts, and by the higher purposes of social life, has chiefly planted his habitation.

The noblest of these expanses are the river plains of the new world, drained by such waters as the Mississippi, the Amazon, and La Plata. In North America, the basin or drainage of the Mississippi is estimated at 1,300,000 square miles, and that of the St Lawrence at 600,000; while northward of the 50th parallel, extends an inhospitable flat of perhaps still greater dimensions. Much of the former expanse is rolling or undulating in its surface, well watered by minor rivers, exhibiting broad grassy *prairies* and extensive pine forests; the second is more irregular in surface, largely occupied by lakes, and cumbered with forest growth; while the last is a bleak and desolate waste, overspread with innumerable lakes, and resembling Siberia in the physical character of its surface and the rigour of its climate. In South America, we have first the low belt of country skirting the shores of the Pacific, from 50 to 100 miles in width, and about 4000 in length, fertile at its extremities, but in the middle sandy and arid; next the basin of the Orinoco, consisting of extensive plains called *llanos*, either destitute of wood, or merely dotted with trees, but covered during part of the year with tall herbage; then the basin of the Amazon, a vast plain, embracing a surface of nearly 2,000,000 square miles, possessing a rich soil and humid climate, and almost entirely covered with dense forests and impenetrable jungle marshes by the river sides; and lastly, the great valley of the Plata, occupied chiefly by open plains called *pampas*, in some parts saline and barren, but in general clothed with weeds, thistles, and tall grasses. Next in order of importance is that section of Europe extending from the German Sea, through Prussia, Poland, and Russia, towards the Ural Mountains, presenting indifferently tracts of heath, sand, and open pasture, and regarded by geographers as one vast plain. So flat is the general profile of this region, that it has been remarked "it is possible to draw a line from London to Moscow, which would not perceptibly vary from a dead level!" Passing the Ural ridge, a plain of still greater dimensions stretches onward through Siberia, towards the shores of the Pacific. This region is of no great elevation, and though diversified by occasional heights, consists chiefly of gravelly steppes, covered with coarse herbage, lakes, and morasses. In Africa, the northern and central portion, so far as explored, appears to be a vast expanse of Sahara, or sandy desert, broken at scanty intervals by oases of life and verdure.

Besides these wide expanses, which may be said to counterbalance the mountain systems, there are plains of minor extent, which often stamp the countries to which they belong with a peculiar character. These are the verdant *prairies* of North America, already noticed, the *pampas* and *llanos* of South America, the *steppes* of Asia and Northern Europe, the *tundras* or bog-marshes of Siberia, the grassy *karoos* of Southern Africa, the tangled *jungle* of India, the alluvial *straths* or *dales* of our island, and the low muddy, but gradually-increasing *deltas* of such rivers as the Ganges, Nile, Niger, and Mississippi. To lesser flats and depressions—as valleys, glens, ravines, &c.—which give character to the landscape of minor districts, our space will not permit us to refer. Physically, they produce results akin to those of larger depressions; and whether they be the subsidences occasioned by earthquakes, the sites of silted-up lakes, valleys of erosion, or ravines of volcanic rupture, it is the province of geology, not of geography, to determine.

Under this head it is usual to describe *fissures*, *caverns*, and other *subterranean* openings; but as these are interesting more on account of their curious structures, than from any effect they produce on the aspect or conditions of the globe, we shall leave them to be noticed, as occasion may offer, under the respective countries in which they occur. This only we may observe, that they owe their formation either to earthquakes and volcanic convulsions, to the erosion of subterranean springs and streams, or to the action of waves and tides, when the cliffs in which they are situated formed the shores of the ocean. They become indices, in this way, to bygone operations; and are not unfrequently the catacombs, as it were, of animals long ago extinct, whose remains had either been drifted thither, or who, while alive, had fled there for a last shelter during some of nature's extraordinary convulsions.

THE OCEAN.

The ocean, though in fact a single mass of fluid resting in the hollows of the solid crust, surrounding the dry land on all sides, and indenting it with numerous bays and gulfs, is generally divided by geographers into the following great basins:—The *Pacific* Ocean, 11,000 miles in length from east to west, and 8000 in breadth, covering an area of 50,000,000 square miles; the *Atlantic*, 8600 miles in length from north to south, and from 1800 to 5400 in breadth, covering about 25,000,000 square miles; the *Indian* Ocean, lying between 40 degrees south and 25 degrees north latitude, is about 4500 miles in length, and as many in breadth, covering a surface of 17,000,000 square miles; the *Antarctic* Ocean, lying round the South Pole, and joining the Indian Ocean in the latitude of 40 degrees south, and the Pacific in 50 degrees, embraces an area (inclusive of whatever land it may contain) of 30,000,000 square miles; and the *Arctic* Ocean, which surrounds the North Pole, and lies to the north of Asia and America, having a circuit of about 6400 miles. Besides these great basins, there are other *seas* of considerable extent, as the Mediterranean, covering an area of 1,000,000 square miles; the German Ocean, 153,700; the Baltic, 134,000; the Black Sea, with its subordinate gulfs and branches, 181,000; but these and other minor sections will be more appropriately described when we come to treat of the respective countries with which they are politically as well as physically associated.

Respecting the *depth* of the ocean we have no very definite knowledge; but this we may assume, *a priori*, that it possesses great irregularity of depth and shallowness, just as the terrestrial surface presents diversity of hill and plain, and that, as the loftiest mountains rise about five miles in height, so the extreme depth of the ocean may not greatly exceed that measure. In the North Atlantic, Lord Mulgrave did not touch the ground with a sounding line of 4680 feet, and Mr Scoresby was equally unsuccessful with one of 7200 feet; while in latitude 15° 3' S., and longitude 23° 14' W., Sir James Ross tried, but did not obtain soundings, with a line of 27,000 feet! Having nearly ascertained its superficies, and assuming average depths, many have amused themselves with calculating the probable quantity of water in the ocean; but all such calculations, in the absence of anything like data, are worse than worthless. This only we know, that the quantity, whatever it may be, remains, by the unalterable laws of evaporation and condensation, always at a fixed point, there being neither increase nor decrease. It has been remarked by La Place, a French astronomer, that if the existing waters of the ocean were increased only one-fourth, the earth would be drowned, with the exception of some of the highest mountains; and that if, on the other hand, the waters were diminished in the same proportion, the largest rivers would dwindle to the capacity of brooks, and some of the principal arms of the sea would entirely disappear, while at the same time the earth would be deprived of its due proportion of humidity, and the face of nature be dried up and rendered desolate. The *pressure* of the ocean (which depends on its depth) exerts an important influence, inasmuch as it renders it impossible for plants or animals to exist beyond a comparatively limited distance from the shore or depth from the surface. Teeming as the ocean is with life, its greater depths seem to be as void and desolate as the peaks of the snow-clad mountains.

Water being a slow conductor of heat, the *temperature* of the ocean is less affected by seasonal influences, and much more uniform, than that of the atmosphere, while the action of currents and counter-currents tends to equalise its heat in all latitudes. Within the tropics, the surface temperature ranges between 77 and 84 degrees Fahrenheit; but at the depth of 300 feet or thereby, the solar influence is unfelt. In the torrid zone, the temperature diminishes with the depth; in the polar seas, it increases with the depth; and about the latitude of 70 degrees, it is nearly constant at all depths. Taking the month of March as one of those during which the heat of the sun must be equally determined in both directions by latitude, we find that in that month the sea has been found, at 11° 32′ S., of 80·6 Fahrenheit; at 31° 34′ S., of 75·7; at 40° 30′ S., of 59·9; though in some instances it has been found several degrees more or less at the same season, and under nearly the same latitude. A small difference is discovered between the observations on temperature in the two hemispheres. For the first 25 degrees towards the south, the decrease of heat is slower, and after that more rapid, than towards the north. It must be evident to every one who considers the great mass of waters composing the ocean, and the interchange of position which must always be taking place, to a greater or less extent, between the warmer and colder portions, that this comparative equability of temperature is unavoidable, even if there were no other causes to account for it. The uses of that equability are still more obvious: by it the natural result of high latitude is more or less corrected. A milder air breathing from the sea softens the climate all over the adjacent land, and produces a congeniality which is of the greatest service. On the other hand, in those torrid regions where both animated and vegetable nature is apt to sink beneath the vertical rays of the sun, the cooling breath of the ocean comes, generally at fixed times, communicating freshness and vigour to all around.

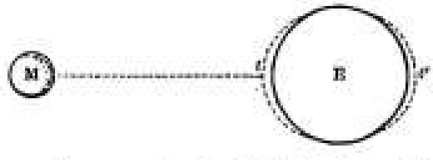
The *saline property* of the ocean, to which we have already adverted in general terms (p. 51), has never been scientifically accounted for; it baffles all human investigation. Some have alleged that it is caused by fossil or rock salt at the bottom; others that the saline constituents are carried down by springs and rivers from the land; but neither hypothesis will account for all the phenomena, while, if the latter were true, the ocean would be gradually becoming salter in consequence of incessant contributions. The most reasonable conclusion is, that the sea is a homogeneous salt body, that its waters were created, and have continued, and ever will continue, in this saline condition, in the same manner that the atmosphere has been created and exists as a compound body. The inquiry, therefore, why the sea is salt, is just as needless as why the atmosphere is composed of two or three gases. The two questions are equally shrouded in mystery. All that we know for certain is, that the ocean is not of uniform saltness; that the Southern Ocean, for example, contains more than the Northern; that inland seas are generally more saline than the open ocean; and that the surface water is somewhat fresher than that obtained from considerable depths. The gravity conferred on the water of the ocean by its saline property is 1·027, reckoning distilled water at 60° Fahr. equal to 1; and to this density it owes its superior buoyant powers. Again, fresh water, under ordinary circumstances, freezes at 32 degrees Fahrenheit, whereas the water of the ocean requires a degree of cold equal to 28 degrees; and the ice then formed is irregular, porous, and charged with vesicles of a dense briny liquid.

The *colour* and *phosphorescence* of the ocean are the next sensible properties requiring attention. When examined in small quantities, sea-water is colourless; but when viewed in the mass in the wide ocean, it appears to be of an azure or blue tint. The cause of this generally blue colour has not been as yet clearly explained; but it seems to be in some degree accounted for by reference to certain principles connected with the science of optics. Probably most are aware that light consists of the set of colours which we see so beautifully displayed in the rainbow. Now it is a law of light, that when it enters any body, and is either reflected or transmitted to the eye, a certain portion of it, consisting of more or less of its colours, is lost in the body. The remainder, being reflected, strikes our vision, and whatever colour that may be, the object seems of that colour. Now it chances that the portion of light most apt to be reflected from masses of transparent fluid is the blue; hence it is, or supposed to be, that the air and sea both appear of this colour. While there can be no doubt that the ocean is generally of a blue colour, it is equally certain that there are many portions of sea in which a different hue appears. The causes of these exceptions from the rule seem to be of various kinds. Frequently, the ordinary colour of the sea is affected by the admixture of foreign substances, these being sometimes of a living and organic nature, and sometimes the reverse. The most simple example of the latter class of cases is the common flooding of any stream, when quantities of mud and earthy particles are introduced into the river, and emptied into the sea. What is thus strikingly seen on every coast, on a small scale, will readily be conceived to be of infinitely wider extent in the mighty rivers of the principal continents of the globe. Some seas are coloured *yellow* from a similar cause. Vegetable matter is known to have a colouring effect; but more usually the peculiar tint, whether red, green, &c. of the sea, results from the presence of infusorial animalcules. Another class of cases in which the ocean appears to be tinged with a peculiar colour, is referable to the reflection of rays of light from the bed or bottom; and hence, in shallow and clear seas, the colour of the ground is a main cause of any particular tint which the water may assume.

The phosphorescence of the ocean, described in such glowing terms by almost every voyager in tropical seas, is now satisfactorily ascertained to arise sometimes from the presence of zoophytes and infusorial animalcules, and at others from the decomposition of vegetable and animal matter. Similar phenomena, arising from similar causes, exist on land—the glow-worm, firefly, certain fungi, putrid fish, &c.—and their appearance in the one element need not excite greater surprise than their exhibition in the other.

TIDES—CURRENTS—WAVES.

The waters of the ocean are subject to various motions and fluctuations, such as tides, currents, whirlpools, waves. That regular ebb and flow known by the name of *tides*, and which confers on the ocean one of its most interesting features, is caused by the attraction of the sun and moon. By the universal law of gravitation, all masses of matter have a tendency to be attracted or drawn towards each other. The moon, therefore, as a mass of matter, in passing round the earth, has a tendency to draw the earth after it, or out of its natural relative position, and it really does so to a small extent. As it passes round, it draws up the waters in a protuberance, or, in common language,



draws a huge wave after it. But it also draws the land beneath the protuberance, and so causes the opposite side of the globe to be drawn away from the ocean, leaving the waters there to form a similar protuberance or high wave. In the one case, the water is drawn directly up or towards the moon (M); in the other, the water is in some shape left behind by the land being pulled away from it. In both a similar effect is produced; two tides (*t t′*) are caused at opposite extremities of the earth. Where the higher part of either of these great billows strikes our coasts, we have the phenomenon of high water; and when the lower touches us, it is low water. Each of the waves is brought over any given place in the circumference of the earth in twenty-four hours, so as to cause high water twice a day. The sun is also known to have a certain attractive influence on the waters of the ocean; but from the great distance of that luminary, the effect is comparatively small. But when this minor influence of the sun coincides with that of the moon, or acts in the same line of attraction (*Mt*), we perceive a marked increase in the tides; on such occasions we have what are called *spring*, or *large* tides. When the solar and lunar attractions act in opposition, we have *neap*, or *small* tides. The spring tides happen twice a month, when the moon is at full and change; and the neap when the moon is in the middle of its orbit between those two points. A tide requires six hours to rise, which it does by small impulses or ripplings of the water on the shore, and six hours to ebb or fall; but every successive high water is from twenty to twenty-seven minutes later than the preceding, or, on an average, about fifty minutes for two tides, in consequence of the earth requiring that time above the twenty-four hours to bring any given point again beneath the moon. The tides are thus retarded by the same reason that the moon rises fifty minutes later every day. It is evident that the tides will be greatest at that point of the earth's surface which is nearest to the moon, or where the latter is vertical. She is so between the tropics; and accordingly the tides are there greatest, and they diminish as we approach either poles. It is further to be remarked, that the moon does not anywhere draw up the tides immediately. Three hours elapse before the waters are raised, in consequence of the law of inertia, or a disposition which every body has to continue in the condition of rest or motion in which it happens to be placed. This stubbornness to resist the moon's influence is only overcome by a three hours' action upon the waters; and thus the tidal wave is always three hours behind the moon in its passage. Twice a year—namely, in March and September—the tides are higher than at other times, because then the attraction of the sun and moon is strongest. In some of the firths or arms of the sea on the east coast of Scotland, it has been occasionally noticed that there have been four high waters in the twenty-four hours. These, however, are not simple tides. The double risings are caused by the irregular passage of the tidal wave from the Atlantic round the north and south points of the island of Great Britain. When that portion of the wave which proceeds by the south reaches the east coast sooner than that by the north, or *vice versa*, there will be two risings of the water instead of one. Moreover, in consequence of all the great seas and oceans forming, as we have seen, only one sheet of water variously distributed, the ebb and flow in each depend not on its own proper tide, but are the result of the combination of that tide with currents mingling with it from tides of other seas—a result depending upon inequalities of sea-bottom, the configuration of its coasts, their inclination under water, the size and direction of the channel which connects it with other seas, and occasionally upon winds and currents which are not tidal. So much do these circumstances affect the astronomical or *primary* tidal wave, that while it rises in the expanse of the Pacific to one or two feet only, the *derived* wave often rises in confined or obstructed seas to elevations of thirty, forty, or even seventy feet! This circumstance has given rise to the determination of *cotidal* lines, or lines which mark the contemporaneous position of the various points of the great wave which carries high water from shore to shore. Inland expanses of water, like the Baltic, Mediterranean, and Caspian Seas, and the lakes of North America, have no perceptible tides.

Besides being affected by the regular motion of the tides, the ocean, in many parts of its extended bounds, is influenced by currents, which act continually in particular directions. Currents are the result of various causes—such as temperature, winds, peculiar construction of coasts and inlets—but chiefly, as is believed, of the rotatory motion of the earth. The globe in its diurnal motion leaves, as it were, the fluid behind; and hence there is a perpetual flow of the sea from the western coasts of Europe and Africa towards the eastern *land-board*, as it is called, of America, and from the west of America to the eastern coast of Asia. This movement is chiefly confined to the tropics, unless where the sea is turned aside by the land, and caused to diverge towards the north or south. If we start in a survey of this motion from the western coast of America, we find it producing a constant current across the vast expanse of the Pacific, till it is turned off by Asia and Australia. A great division of its force is directed through the seas on both sides of the latter continent, and so on through the Indian Ocean, and round the Cape of Good Hope, till it reaches the free expanse of the Atlantic, across which it proceeds in the same manner as across the Pacific. The current of the Atlantic strikes the coast of Brazil, and breaks at Cape St Augustine into two divisions, one of which proceeds round Cape Horn into the Pacific, while the other advances through the Caribbean Sea, and so on into the Gulf of Mexico. This latter branch conspires, with the vast issue of fresh waters which pours into the Gulf of Mexico, to raise the level of that sea above that of the neighbouring ocean; and causing the surplus to force its way out between Florida and Cuba, produces the celebrated *Gulf Stream*, which is by far the most powerful marine current known.

Besides the grand equatorial or tropical current, there is one of a less decided character from the poles to the equator. The sea under the tropics evaporates to a greater extent than elsewhere, by the influence of a vertical sun. The vapours are apt to proceed towards the north and south, where they descend in rain. A surplus of water is thus produced in the high latitudes, which naturally flows back towards the equator. Hence a constant but comparatively slight flow from the north and south towards that warmer region of the earth. Under the influence of this stream, large masses of ice are constantly becoming detached from the polar stores, and drifted to the tropics. In some of the bays on the north side of Iceland this frigid substance comes in vast quantities, insomuch as to choke them up to the depth of 500 feet. What is still more strange, these masses of ice are sometimes mixed up with trees, some of which are known to be the produce of the torrid zone in America; this is accounted for by the action of the northern division of the great current which parts at Cape St Augustine. That northern division, after rushing into and out of the Gulf of Mexico, proceeds northward to Newfoundland, and thence at a high latitude returns athwart the Atlantic, finally sweeping along the western coasts of Europe, and rejoining the current which gave it its first impulse.

The operation of the tides is less observable in the great currents we have alluded to, than in those which prevail in the more secluded seas. The abstraction of water from a secluded sea by the recess of the tide, and the rush inwards produced by its flow, are sufficient of themselves to cause very impetuous currents, more particularly in the narrow channels by which the inland seas are connected with the ocean. We find it stated, in a pamphlet respecting the condition of the Orkney Islands, that the Pentland Firth, which separates the continent of Great Britain from Orkney, "has no fewer than four-and-twenty contrary currents of the tide at the flood of spring, besides numerous sets and eddies, which, under the local names of *wells*, *swelchies*, and *roosts*, boil more madly on the Orcadian shore than ever did witch's caldron on the kindred coast of Norway, if we may believe old tradition and Bishop Pontoppidan. 'The Boar of Papa,' at the opposite extreme of Orkney, is another terrible tide; when he gets a vessel in his tusks, he shakes the masts out—an operation which, in the country phrase, goes by the name of *hackling*." The contrariety of influences which are sometimes brought into play by polar and equatorial currents, and those produced by the tides, occasion many phenomena extremely perplexing, and sometimes very dangerous, to the navigator. In the Cattegat, by which the Baltic is connected with the German Ocean, one current always goes in by the side next Jutland, while another issues forth by that nearest to Sweden. In like manner, a current seems to proceed along the eastern coast of Britain towards the south; while another, flowing in an opposite direction, advances along the coast of Holland. What is still more curious, under-currents are sometimes found going in a contrary direction to those upon the surface. At the Straits of Gibraltar, it is said there is always a surface current setting in, as if to supply a want in the Mediterranean, while at a certain depth there is another flowing outwards to the Atlantic.

Two currents of equal force, but of different directions, meeting in a narrow passage or gut, will cause a *whirlpool*, a phenomenon which has ignorantly been said to be produced by subterranean rivers, gulfs, chasms, &c. but essentially is only an eddy, produced by the contact of two currents meeting on a centre. The whirlpool named the Euripides, near the coast of Greece, alternately absorbs and rejects the water seven times in twenty-four hours. Charybdis, in the Straits of Sicily, absorbs and rejects the water thrice in twenty-four hours: and the Maelstroem, on the coast of Norway, which is considerably the largest, absorbs, every six hours, water, ships, whales—in short, everything that approaches its malignant influence—and the next six hours is employed in casting them up again. These eddies are sometimes augmented by the force of contending tides, or by the action of the winds.

Being an elastic and mobile fluid, water is readily acted upon by winds; and thus *waves* are produced, varying in height and velocity according to the force and continuity of the wind, extent of uninterrupted surface, depth of the ocean, contending currents, and the like. "The common cause of waves," says Dr Arnott, "is the friction of the wind upon the surface of the water. Little ridges or elevations first appear, which, by continuance of the force, gradually increase, until they become the rolling mountains seen where the winds sweep over a great extent of water. In rounding the Cape of Good Hope, waves are met with, or rather a swell, so vast, that a few ridges and a few depressions occupy the extent of a mile. But these are not so dangerous to ships as a *shorter* sea, as it is termed, with more perpendicular waves. The slope in the former is so gentle, that the rising and falling are scarcely felt; while the latter, by the sudden tossing of the vessel, is often destructive. When a ship is sailing before the wind, and riding over the *long swell*, she advances as if by leaps; for while each wave passes, she is first descending headlong on its front, acquiring a velocity so wild, that she can scarcely be steered; and soon after, when the wave has glided under her, she is climbing on its back, and her motion is slackened almost to rest before the following wave arrives. The velocity of waves has relation to their magnitude. The large waves just spoken of proceed at the rate of from thirty to forty miles an hour. It is a vulgar belief that the water itself advances with the speed of the wave; but in fact the *form* only advances, while the *substance*, except a little spray above, remains rising and falling in the same place with the regularity of a pendulum. A wave of water, in this respect, is exactly imitated by the wave running along a stretched rope when one end is shaken; or by the mimic waves of our theatres, which are generally undulations of long pieces of carpet, moved by attendants. But when a wave reaches a shallow bank or beach, the water becomes really progressive; for then, as it cannot sink directly downwards, it falls over and forwards, seeking the level." Sailors and others speak of waves running "mountains high;" but it is questionable if, even in the dreaded Bay of Biscay, they ever attain an altitude of thirty feet, measuring from the trough of the sea to the crest of the succeeding wave.

LAKES AND RIVERS.

Lakes are inland bodies of water not connected with the ocean or any of its branches: they are generally fresh, but are occasionally brackish, or even decidedly salt. They are classified according as they are fresh or saline, and according to the manner in which they receive and discharge their waters—namely, those that both receive and discharge running water; those that receive waters, but have no visible outlet, as the Caspian Sea; those which receive no running water (being fed by springs), but have an outlet; and such as neither receive nor discharge running water. Lakes are distributed over the globe according to the inequalities of surface; and all tend to annihilation, partly by silting up their basins, and partly by deepening their outlets, thereby effecting an entire drainage of their waters. By far the most gigantic are those of North America—such as Superior, Huron, Michigan, Erie, and Ontario, which respectively occupy 35,000, 20,000, 10,000, 10,000, and 7200 square miles. Next in order are the lakes of Asia, of which the largest are Aral and Baikal; the surface of the former is estimated at 9930, and the latter at 7540 square miles. Of the African lakes we have no definite information; but Europe can boast of a vast number, which, though generally small, give beauty and diversity to her landscapes. Those of Ladoga and Onega, in Russia, are the largest; the former having a surface of 6330, and the latter of 3280 square miles. A comparative estimate of the extent of these vast sheets may be formed, when we mention that the area of lake Geneva does not exceed 340 square miles.

Lakes subserve important purposes in the economy of nature. They serve as reservoirs for the waters which rivers would too speedily carry away from the land; they are the tanks, as it were, in which the impurities of streams subside; they refresh, irrigate, and enliven the landscape; and as they all tend to silt up their own sites, these sites become in time tracts of the most fertile alluvium, and such has been the origin of some of our finest plains. They are also the scenes of extensive and varied vital operations. The plants which spring from their bottoms, or flourish by their margins, differ widely from true terrestrial and maritime vegetation; and the animals which people their waters exhibit structural peculiarities not less distinct and characteristic.

Rivers, streams, springs—whether flowing with a volume several miles in breadth, or trickling in a tiny rill which a child's hand might obstruct—constitute a class of the most valuable agencies in the physical history of our globe. They are the irrigators of its surface, adding alike to the beauty of the landscape and the fertility of the soil; they carry off impurities and every sort of waste debris, to be deposited in the ocean as the strata of future continents; and when of sufficient volume, they form the most available of all channels of communication with the interior of continents. Man has ever located himself by their banks—using their waters for his domestic purposes, making their bosoms the highway of his commerce, and applying the force of their currents to the abridgment of his toil. They have ever been things of vitality and beauty to the poet, silent monitors to the moralist, and agents of comfort and civilisation to all mankind. The manner of their origin is this:—The sun's heat, acting upon the ocean and other exposed surfaces of water, converts that element into vapour; this vapour, invisible, and of less specific gravity than the atmosphere, ascends, and forms clouds, mists, &c.; and when condensed by cold or electric agency, as described under METEOROLOGY, falls by its specific gravity to the surface in the form of dew, rain, hail, and snow. Falling on the surface indiscriminately, these percolate the soil, find their way through the rents, fissures, and pores of the rocky strata, and ultimately escape at some lower level in the form of *springs*. Some of these springs are perennial, others temporary or intermittent; some are limpid, and almost absolutely pure; others are impregnated with metallic, earthy, and saline ingredients, according to the nature of the strata through which they have percolated: some are cold, others tepid; while many issue, with bubbling and steam, near the ordinary boiling point of water. Springs, naturally tending to lower levels, unite, and form *streams;* and these again falling still lower, conjoin in valleys, and form *rivers*—creating in their course rapids, cataracts, and waterfalls, ravines and dells, lakes, swamps, and marshes, alluvial plains, and low terminating deltas. The valley in which a river flows is usually termed its *basin;* and its *drainage* is that portion of country drained by its streams or tributaries. It is the custom of geographers to compare rivers by their lengths; but this does not always convey a correct idea either of their physical or economical importance; for some main trunks, of limited length, may drain a vast extent of country, and others of great length may offer few or no facilities for commercial transport. The following is an approximation to the proportional length, area of basin, and quantity of water discharged per annum by some of the principal rivers, reckoning the Thames as 1:—

	Rivers.	Length.	Basin.	Discharge.
EUROPE.	Thames,	1	1	1
	Rhine,	4½	12½	13
	Loire,	4	8½	10
	Elbe,	4½	9	8
	Vistula,	4½	13½	12
	Danube,	9¾	86	65
	Dnieper,	7¼	36	36

	Amazon,	22½	365	1210

CLIMATOLOGY.

The climatology of the globe relates to the degree of heat and cold to which its respective countries are subject, the dryness and moisture of the air, and its salubrity or insalubrity as influenced by these and other causes. As yet the minutiæ of climate are but imperfectly determined; the following general causes, however, have been sufficiently ascertained:—1. The action of the sun upon the atmosphere; 2. The internal heat of the globe; 3. The height of the place above the sea; 4. The general exposure of the region; 5. The direction of its mountains relatively to the cardinal points; 6. The neighbourhood of the sea, and its relative position; 7. The geological character of the soil; 8. The degree of cultivation which it has received, and the density of the population collected upon it; and 9. The prevalent winds. These causes, acting together or separately, determine the character of a climate as moist and warm, moist and cold, dry and warm, dry and cold, &c.; and this climateric character is the main influence which determines the nature and amount of vegetable and animal development.

The torrid zone has two seasons—the wet and the dry. The latter is considered as the summer, and the former as the winter of the regions within this zone; but they are in direct opposition to the astronomical seasons, as the rains follow the sun. In some districts there are two rainy and two dry seasons every year. In the temperate zones, the year is divided into the four seasons whose changes are so agreeable and salubrious. This regular succession of the annual changes, however, can hardly be considered as extending farther than from 35 to 60 degrees of latitude. In the frigid zones two seasons only are known—a long and severe winter, and a short but fervid summer. This abrupt and harsh transition is occasioned by the great length of the day in summer, when the sun never sets, and by the total absence of that luminary in winter. The decrease of heat as we recede from the equator is greater in the southern than in the northern hemisphere. According to Humboldt, continents and large islands are warmer on their western than on their eastern sides. The extremes of temperature are more felt in large inland tracts than in islands and situations near the coast. The sea absorbs and radiates heat more slowly than the land; and thus, after the land has given out its last particle of caloric, the ocean is radiating its tempering influences. For these reasons, climatologists have found it necessary to construct *isothermal lines* round the globe; that is, lines along which the annual mean temperature is the same. Again, places which have the same mean annual temperature vary considerably in their mean summer and winter temperature; hence *isocheimal* lines, or lines of equal winter temperature, and *isotheral* lines, or those which show equal summer over points upon different isothermal curves. Another set of lines or curves, called *isogeothermal*, connect points where the temperature of the soil is equal at or beneath the surface.

Since the temperature of the atmosphere diminishes with the altitude, a limit must be reached where water will remain in perpetual congelation, independent of all seasonal influences. This limit is called the *snow-line*, and is found at various heights, according to latitude, proximity to the sea, and other causes, which affect the general climate of the region. In the Himaleh and Andes, it is found at an elevation of about 17,000 feet; in the Swiss Alps, at 8500 feet; and in the Scandinavian range, at 3500 feet. Generally, in those countries which are near the equator, the snow-line is found about 16,000 feet, or three miles, above the sea-level: about the 45th parallel in either hemisphere, it occurs at an elevation of 9000 feet; under 60 degrees of latitude, at 5000 feet or thereby; under 70 degrees latitude, at 1000 feet; and under 80 degrees, the snow-line comes down to the mean sea-level, for countries which are 10 degrees distant from the poles are covered with snow all the year round. From snow and glacier-clad mountains cold breezes rush down to cool the adjacent plains; and similar winds blow from the arctic to the tropical regions. Indeed, wherever the air of one region becomes heated or rarefied, the colder and heavier air of the surrounding regions will rush in to restore the balance. Such is the cause of all aërial currents, and in particular of those blowing within the 25th degree of latitude on either side the equator, known as the *trade-winds*. *Monsoons* are merely the trade-winds diverted north or south by the land that lies within these parallels. The *simoom*, *harmattan*, *sirocco*, and other local winds, *sea and land breezes*, and in fact every species of aërial current, may be traced to similar causes.—See METEOROLOGY.

The amount of rain which falls on the earth's surface is exceedingly varied, ranging from twenty or thirty inches to several feet per annum; but the moisture of a climate does not wholly depend upon the amount of rain registered by a rain-gauge; for some climates are humid, and yet not rainy; others dry, and yet subject to periodical torrents. These torrents give rise to inundations; hence the peculiar seasonal floodings of such rivers as the Nile and Ganges.

DISTRIBUTION OF PLANTS AND ANIMALS.

The *life* of the globe—that is, its vegetable and animal productions—constitutes its most important and exalted feature as a creation. All the varied materials of which it is composed, all the complicated actions, reactions, and mutations to which they are subject, are humble phenomena compared with the production of the lowliest organism. This life is everywhere: the waters teem with it, the dry land from pole to pole is clad with it; nay, there is life within life, and perhaps there exists not a single plant or animal but becomes in turn an abode for others of more diminutive dimensions. Speculations as to the origin and generic classification of vegetable and animal life belong not to our subject. Geography views them simply as they exist, and endeavours to determine the laws which regulate their distribution.

Vegetables—of which about 100,000 species have been described—are regulated in their terrestrial distribution by conditions of soil, heat, moisture, light, height of situation, and various other causes; *in the waters* by depth, heat, light, nature of bottom, and the presence of mineral and saline ingredients. Were it not for these causes, there is no reason why the tribes and genera of one region should not be identical with those of another—why the palms of India should not flourish alongside the oaks of England, the oaks of England with the pines of Norway, or these again with the dwarf birches of the arctic regions. As it is, the tropics have genera unknown to the temperate zone, and every advance poleward brings us in contact with new and peculiar species. Temperature in this case seems to be the grand regulating condition; and as this is effected by elevation, as well as by increase of latitude, we find the mountain ranges near the equator presenting all the features of a tropical, temperate, and even arctic vegetation. Thus, palms and plantains may luxuriate at their bases; then appear oranges and limes; next succeed fields of maize and wheat; and still higher commences the series of plants peculiar to temperate regions. In temperate latitudes, though the variety of vegetation be less, similar phenomena present themselves. "We may begin the ascent of the Alps, for instance, in the midst of warm vineyards, and pass through a succession of oaks, sweet chestnuts, and beeches, till we gain the elevation of the more hardy pines and stunted birches, and tread on pastures fringed by borders of perpetual snow. At the elevation of 1950 feet the vine disappears; and at 1000 feet higher the sweet chestnuts cease to thrive; 1000 feet further, and the oak is unable to maintain itself; the birch ceases to grow at an elevation of 4680, and the spruce fir at the height of 5900 feet, beyond which no tree appears. The rhododendron ferrugineum then covers immense tracts to the height of 7800 feet, and the herbaceous willow creeps two or three hundred feet higher, accompanied by a few saxifrages, gentians, and grasses, while lichens and mosses struggle up to the imperishable barrier of eternal snow." Besides these great climatic effects, there are others depending on soil, moisture, light, &c. which, though limited, are not less imperative. Thus the southern slope of a hill is generally clothed with species distinct from those on the north; a limestone district presents a carpet of vegetation widely different from that of the clayey moorland: some tribes flourish in the moist valley, which would die on the open plain; some tribes thrive in the marsh, others on the dry upland; some luxuriate under the influence of the sea spray, which would be instant destruction to others. But whilst most species are subject to these laws, there exists in the constitution of many a certain degree of elasticity which admits of their adaptation to a wider range—a beneficent arrangement, which permits man to extend through cultivation those grains and fruits upon which his subsistence so essentially depends. [For further and more minute information respecting the laws which regulate the dispersion and distribution of plants, see VEGETABLE PHYSIOLOGY.]

The animals which people the globe are subjected to somewhat similar laws of distribution. Some are strictly tropical, others confined to the temperate zone; while not a few are destined to find their subsistence wholly within the polar circles. Besides this general distribution, we find a more particular restriction to certain continents and tracts where peculiarities of soil, climate, and food, seem to be the governing conditions. Thus, the elephant roams only in India, Birmah, and Africa; the ostrich in Africa; the rhea in the pampas of South America: the kangaroo in New Holland; the reindeer within the arctic circle; the polar bear amid the snows of Greenland and Labrador; and so on, as will be more minutely shown under ZOOLOGY. Similar laws are impressed on the life of the ocean. The whale of the Greenland seas is not the same with the whale of the Pacific; the herring finds its chosen habitat in the Northern Sea; the oyster clings to a peculiar bottom, at a certain depth; the cod inhabits the same banks and shoals for ages; and a few fathoms of greater or less depth would be more fatal to many species of shell-fish than the dredge of the fisherman. As on plants, so on animals altitude exerts a very decided influence; and we do not exaggerate when we affirm that a lofty mountain range presents a more impassable barrier to vital distribution than the widest expanse of ocean. Though presenting a close analogy in the manner of their distribution, plants and animals differ in this respect, that many tribes of the latter—birds, fishes, and mammalia—make periodical migrations of vast extent; food and proper breeding-places being the objects of their search. These migrations must not be confounded with that adaptability of constitution which fits the horse, the dog, the ox, the sheep, the pig, and other domestic animals, to be the companions and supports of man in his onward possession of the globe. The one is but a change of place in search of food, under a congenial temperature; the other amounts to a constitutional change, irrespective of climateric influence.

Man, of all animals, has the widest geographical distribution. This he enjoys not only from the greater adaptability of his constitution, but from that superior intelligence which enables him to counteract the effects of climate by clothing, houses, fire, and the storing of provisions. It may be justly affirmed, therefore, that there is no region where man may not exist and carry on the purposes of life, in a higher or lower degree of civilisation. Though generally regarded as a single species of a single genus, naturalists have divided mankind into several varieties, according to their more prominent physical features; and ethnologists, extending the subject according to minor features, language, and so forth, have subdivided these varieties into branches, types, tribes, and families. That the external conditions to which man, like all other animals, is subjected, may in the course of ages have stamped the inhabitants of certain regions with certain physical characteristics, is nothing more than what may be expected; but that every little difference of dialect, every tint of skin or colour of hair, every mould of nose or contour of skull, is warrant sufficient for a new subdivision, is an absurdity not to be tolerated. At present, *five* great divisions are admitted by ethnologists, and these we shall merely enumerate—premising that the branches, types, tribes, and families into which mankind have split in their dispersion over the globe, the causes and modes of that dispersion, and other kindred particulars, will be fully treated in a separate sheet, devoted to the PHYSICAL HISTORY OF MAN:—1. The *Caucasian* variety, inhabiting Turkey, Arabia, Persia, part of Tartary, Affghanistan, and Hindoostan in *Asia*; Egypt and Abyssinia in *Africa*; and the whole of Europe. 2. The *Mongolian* variety, spread over the north and central parts of Asia, China, Japan, Birmah, Annam, Siam, Cochin-China, and, according to some ethnologists, comprising the Esquimaux both of the Asiatic and American continents. 3. The *American* variety, comprising all the aboriginal races which peopled the new world before its discovery by Columbus. 4. The *Ethiopian* race, inhabiting the whole of Africa, with the exception of Egypt, Abyssinia, and the northern coasts. And 5. The *Malay* race, which is made to include the inhabitants of the Malaysia, Polynesia, and Australasia.

Such are the recognised *varieties* of the human race; and here it may be remarked, that in whatever stage of civilisation they now appear, the time seems to be approaching when some of them will altogether vanish, their place being occupied by the higher and more intelligent—a result quite in consonance with the whole scheme of creation, whether in its physical or social progress.

VEGETABLE PHYSIOLOGY.

Every one is acquainted with the common forms of vegetation—herbs, shrubs, trees—for they exist in all situations suitable to their growth, and constitute not only a highly ornamental covering to the surface of the earth, but, as is well-known, afford an inexhaustible supply of nourishment to the animal races. The science which embraces the study and investigation of the vegetable kingdom is known by the name of Botany, from the Greek word *Botané*, a plant. That department of the subject which explains the organisation and vital functions of plants we call *Vegetable Physiology*, and that which recognises their arrangement into orders, tribes, genera, and species, according to their respective forms and qualities, *Systematic Botany*. The one relates to functions which are common to all vegetables, the other takes notice only of such peculiarities and attributes as serve to distinguish one individual from another, or one family from another family. It is to the former of these departments that we now direct the attention of the reader.

GENERAL ECONOMY OF VEGETATION.

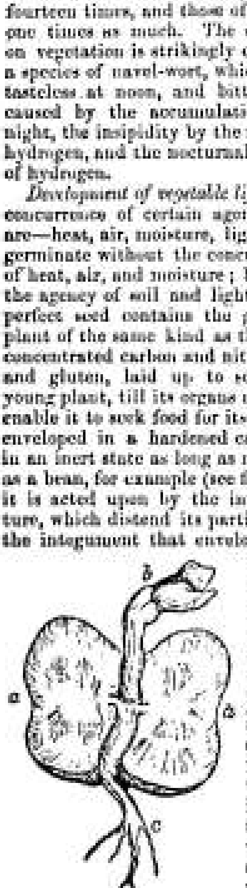
Nature and functions of plants.—Minerals, plants, and animals are all formed by the chemical combination of certain elements. In minerals these elements combine by the force of chemical affinity only, but in plants and animals they are held in combination by vital action. Of the nature of life, or the vital principle, science does not attempt to explain the cause, but restricts itself to a mere exposition of its phenomena. Vitality enables plants and animals to absorb and assimilate food, consisting of the elements necessary for their increase, and also to reproduce beings of their own kind, by means of certain organs: hence they are said to be *organised*, and the substances of which they are composed are known by the general name of *organic matter*. Minerals not possessing vitality have no organs, and consist only of *inorganic matter*. Animals feed partly on other animals, and partly on plants; and plants feed partly on organic matter when decomposed, and partly on inorganic. Thus mineral substances, by the beautiful economy of nature, contribute towards the support of animals through the medium of vegetation.

The simplest forms of life are observable in certain plants and animals, whose economy is limited to the absorption and assimilation of nutriment, and the power of reproduction; and the difference between these inferior plants and animals is so trifling, that in them the animal and vegetable kingdoms seem to pass into each other. Thus, certain tribes of zoophytes, and some kinds of algæ, or sea-weed, are so very nearly allied both in appearance and habits, that they can scarcely be distinguished from each other scientifically; and, indeed, the same object has been occasionally classed as a plant by one naturalist, and as an animal by another. The scientific differences between plants and animals are indeed difficult to define, when they are to be applied to all plants and to all animals. Few plants possess the power of locomotion; but the aquatic plant called the Fresh-water Sailor detaches itself from the mud in which it grows originally, and rises to the surface of the water to expand its flowers. Plants are propagated by division, which most animals are not; but the polypes of the coral-reef grow united like the buds of a plant clustering round a common stem from which they receive their nutriment, and, when separated, become each perfect individuals. Plants are said to have no stomach; but the lobe-like leaves of Venus's fly-trap possess the power of digesting the flies they catch; and though plants are said to be without feeling, the leaves of the sensitive plant shrink from the slightest touch. In like manner the pith of young trees and shrubs has been compared to the spinal marrow of animals; the upward current of the sap in spring, and its descent in summer or autumn, to the circulation of the blood; and the exhalation of oxygen, and absorption of carbonic acid gas in the leaves, to respiration; but beyond a faint analogy, there is nothing like identity between the respective functions of plants and animals. Indeed, all the vital functions of plants are performed in a manner different from those of animals; the instances of locomotion, sensitiveness, and power of digestion in the former being very rare and imperfect, while the power of propagating by division in the latter is equally so. On the whole, the two lines or systems of life seem to start, as it were, from a common point at the base, the inferior forms bearing a certain similarity in structure and functions, which gradually disappears as we ascend in the scale of development.

Plants derive their food partly from the soil and partly from the air; and whatever they take must either be reduced to a liquid, or to a gaseous state. The elements of which plants are composed are—carbon, oxygen, hydrogen, and nitrogen. Of these, carbon, which is a solid substance, is the principal; and as it is insoluble in water, it must be combined with oxygen, so as to form *carbonic acid gas*, before it can be taken up by plants. Oxygen is the next in abundance, and it is absorbed principally when combined with nitrogen, in the form of atmospheric air. Hydrogen is not found in a free state in the atmosphere, and therefore it can only be taken up by plants when combined with oxygen, in the form of water, or with nitrogen, as ammonia, in which last form it exists in animal manure. Nitrogen, though found in very small quantities in plants, is an important element, as it constitutes the principal ingredient in the *gluten*, which is the most nutritive part of corn and other seeds, and which is essential to the germination and nourishment of young seedling plants. Nitrogen also appears to be a principal agent in the production of colour in leaves and flowers, especially when they first expand. As oxygen is imbibed by plants in combination with all the other elements of which they are composed, it is not surprising that the plant takes up more of this gas than it requires; and consequently, it has been furnished with a remarkable apparatus in the leaves, to enable it to decompose the carbonic acid and other gases which it has absorbed, and to part with the superfluous oxygen. Plants are thus found to improve the air by the removal of carbonic acid, which is injurious to animal life, and by the restoration of oxygen, which is favourable to it; and so to maintain a necessary equilibrium in the atmosphere, as animals are continually absorbing oxygen, and giving out carbonic acid. In hot swampy countries, however, where vegetation is extremely rapid, and the soil surcharged with decaying vegetable matter, plants absorb more carbonic acid than they want, and give out the superfluity through their leaves; hence warm moist climates, such as those of some of the West India islands, though extremely favourable to vegetation, are highly injurious to human life.

Light being essential to the decomposition of carbonic acid gas in the leaves, oxygen is not exhaled by plants during the night; but, on the contrary, a small quantity of carbonic acid gas escapes, and oxygen is absorbed. These processes have been called the respiration of plants; but they are very different from the respiration of animals, the first being mechanical, and the second chemical, and both totally unconnected with the assimilation of food. When the soil abounds in carbonic acid gas and in moisture, the roots of a plant must continue constantly absorbing that moisture mixed with the carbonic acid; and this carbonic acid rising to the leaves, escapes in its original state when there is no light to decompose it. The absorption of oxygen is a chemical process, which appears to go on whenever the process of assimilation has ceased—in dead plants as well as in living ones. When leaves have ceased to act in decomposing carbonic acid, and assimilating or fixing the carbon in autumn, oxygen is absorbed so rapidly as to change their colour to some shade of red; fruit, when fully swelled, ceases to assimilate carbon, and becomes intensely acid by the absorption of oxygen; and, finally, the decay of all vegetable texture is hastened by the absorption of the same element. Thus, as the assimilation of carbon ceases during the night, oxygen is absorbed at that period in quantities that vary according to the nature of the plant; those plants which have acid, or highly-flavoured juices, absorbing most. Baron Liebig tells us that the tasteless leaves of the American aloe, if kept in the dark twenty-four hours, absorb only 0·3 of their volume of oxygen in that time; while the leaves of the spruce fir, which contain volatile and resinous oils, absorb ten times, those of the common oak, which abound in tannin, fourteen times, and those of the balsam poplar, twenty-one times as much. The chemical action of oxygen on vegetation is strikingly exemplified in the leaves of a species of navel-wort, which are acid in the morning, tasteless at noon, and bitter at night. The acid is caused by the accumulation of oxygen during the night, the insipidity by the mixture of the oxygen with hydrogen, and the nocturnal bitter flavour by an excess of hydrogen.

Development of vegetable life.—This depends upon the concurrence of certain agents, the principal of which are—heat, air, moisture, light, and soil. No seed can germinate without the concurrence of the three agents of heat, air, and moisture; but in the *growth* of plants, the agency of soil and light is also necessary. Every perfect seed contains the germ or embryo of a new plant of the same kind as the parent, and a portion of concentrated carbon and nitrogen, in the form of starch and gluten, laid up to serve as nutriment for the young plant, till its organs are sufficiently developed to enable it to seek food for itself. The seed is generally enveloped in a hardened case, in order to preserve it in an inert state as long as may be necessary. As soon as a bean, for example (see fig.), is put into the ground, it is acted upon by the influence of heat and moisture, which distend its particles, and make them burst the integument that envelopes them. The agency of the air is next required to combine with the store of nutriment laid up in the seed (*a a*), and to fit it for the purposes of vegetation. The first organ which expands in the embryo of a young plant is the root *c*; and nature has provided a small opening in the covering of a seed, towards which the point of the root is always turned, in order that it may be protruded without injuring its soft and delicate texture. The root takes up water and air, and transmits the liquid thus formed to the seed-leaves *b*, in which it is exposed to the influence of light. The nutritive substances laid up in the seed become quite changed during the process of germination. The starch, which is insoluble in water, is rendered soluble by the action of a peculiar substance called *diastase*, derived from the gluten. This substance has so powerful an effect upon the starch, as to render it instantly soluble in the sap, and thus the nutriment is gradually prepared for the use of the infant plant. As the sap ascends, it becomes sweet; the starch is changed into sugar, and this sugar, again, into woody fibre as the tip of the plant emerges into light. When the store of starch and gluten has been exhausted, the plant is able to live by its own assimilating powers, at the expense of the air and the soil.



Heat, though essential to germination, is injurious, unless it be combined with moisture. A high degree of dry heat will parch seeds, and destroy their vitality; hence, when they are to be kept for food, it is not unusual to dry them in an oven, to prevent them from germinating. When combined with moisture, a very high temperature is not injurious to vegetation; and, indeed, some kinds of moss have been found growing near hot springs in Cochin China, where they must have vegetated in a heat equal to 166 degrees; on the other hand, in cold climates, mosses, some kinds of grass, and chickweed, are found to vegetate at 35 degrees, or even only just above the freezing point. Warmth is not only necessary for the germination of the seed, but also for the growth and after-development of the plant. The sap will not rise without a certain degree of heat; and it is well known that frost stops its current. Cold will also check the development of the flowers and fruit, and even of the leaves, and will prevent the full flavour being attained by the fruit. The secretions of plants are diminished by cold. The fruit of the walnut and the beech produce oil in the south of Europe, which it will not do in Britain; and the leaves of the mulberry grown in this country will not afford the same quantity of caoutchouc to the silkworm as in France and Italy.

Moisture must be combined with heat and air to render it useful to vegetation. An excess of moisture without heat, and combined with air, induces decay in seeds, instead of exciting them to germinate; and an excess of moisture is injurious even to growing plants, as it destroys the delicate tissue of the spongioles of their roots. When trees are grown in situations where they have abundance of heat and moisture, but where the roots are beyond the reach of air, they have a tendency to produce leaves instead of fruit and seeds, and all their secretions are weakened. On the other hand, too little moisture prevents the leaves and fruit from attaining their proper size and form.

Air is essential both to the germination of the seed and the development of the plant. Without oxygen from the atmosphere, the carbon laid up in the seed cannot be made available for the use of the infant plant, as carbon in its concentrated state is insoluble in water, and requires to be combined with oxygen to convert it into carbonic acid gas, before it can be absorbed by the vessels. In like manner, air is essential through all the processes of vegetation; no wood can be formed, no seed ripened, and no secretions produced, without abundance of carbon; and this cannot enter the plant, even from the soil, without a constant supply of oxygen from the air. The greater part of the carbon in plants is indeed derived directly from the air by the leaves, in the shape of carbonic acid gas—a minute quantity of which is always found in combination with the atmosphere.

Light is not required for the germination of seeds, but it is essential to the development of plants, as it occasions the decomposition of the carbonic acid contained in the vessels of all the parts exposed to its influence; without which the plant could not assimilate the carbon to its own use. Colour also appears to depend partly on light. Plants grown in darkness are most deficient in colours which contain blue. The leaves and other parts, which should be green, are frequently reddish, from the retention of oxygen, or yellowish, from the superabundance of nitrogen, while the flowers and fruit are whitish. Frequently, the whole plant appears whitish, and of a sickly aspect, in which case it is said to be *etiolated*, or blanched.

The soil serves not only as a bed for plants to grow in, but also contributes to their nourishment. In addition to the elements of which they are principally composed, there is always found in their substance a small quantity of inorganic matter, which differs according to the nature of the plant, and which appears to be derived solely from the soil. The proportion which this matter bears to the whole will be found by burning part of the plant in the open air; when the inorganic matter, being indestructible by fire, will be left in the form of ashes. Soils are of various kinds, and they are produced principally by pulverised particles of rocks, being disengaged by the action of heat, air, and water, and mixed with decaying animal and vegetable substances. There are four primitive earths, called *clay*, *sand*, *lime*, and *magnesia*; the first three of which are found more or less in almost every soil, and generally with only a very small proportion of the latter. Clay, which is also called *alumina*, or *argillaceous earth*, or *earth of alum*, predominates in some soils, and these are generally unfertile, as the particles of clay are too adhesive to allow the free passage of either air or water to the roots of plants. A soil of this kind also offers obstacles to the expansion of fibrous roots; and when it admits water, it retains it so long as to be injurious. Sand, which is also called *silex*, *silica*, or *siliceous earth*, consists, on the other hand, of particles which have generally too little adhesion to each other; and it is injurious to plants, partly from its incapability of retaining sufficient water for their nourishment, and partly because it admits too much solar heat to their roots. Lime is never found in a pure state in nature, but always combined with some acid. The common carbonate of lime, or limestone, is of no use in vegetation till it has been burned—that is, till the carbonic acid, water, and other matters it may contain, have been driven off by heat. In this state it is called caustic lime, and is used as a manure, as it has a great affinity for carbonic acid, which it is continually drawing into the soil from the atmosphere or other sources. Chalk, or the earthy carbonate of lime, is well adapted for vegetation, but it is generally cold, as, from its whiteness, it reflects the solar rays instead of absorbing them. Magnesia is very similar to lime, but is less abundant. It generally occurs in combination with lime, in what is called magnesian limestone. Notwithstanding the whiteness of chalk, calcareous soils—that is, soils containing some form of lime—are generally black, from the quantity of vegetable matter which they contain in proportion to the depth of the soil. All soils containing a great proportion of decayed vegetable matter are black; and black soils, though generally warm, from the power they possess of absorbing solar heat, are seldom productive, unless they be dry. Thus, black peat, or bog earth, which is moist, is unproductive; while heath mould, mixed with sand, which is dry, is very useful for many kinds of crops. The reason is, that decayed vegetable matter, or *humus*, is insoluble in water, and consequently cannot be taken up by plants until the carbon it contains is combined with oxygen, so as to form carbonic acid gas, which can only be done when the humus is kept sufficiently dry to allow of its particles being exposed to the free action of the atmosphere.

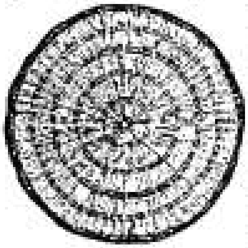
It must be observed, that no soil consists of any one of the primitive earths alone, and that most soils contain all of them combined in different proportions, and mixed with other ingredients. These are saline particles of various kinds, potash, soda, and other alkalies, iron, and several other minerals, in combination with the different acids—all of which are designated, when speaking of the food of plants, by the general name of *inorganic matter*. Plants require different kinds of inorganic matter, according to their nature, and appear to possess the power of selection, as they only take the kind they need, though it may form but a very small portion of the soil in which they grow. Thus, it is evident that any particular crop must in time exhaust the soil in which it grows of the requisite inorganic matters, unless they should be renewed by the addition of what are called mineral manures (see AGRICULTURE); and it is also clear that crops requiring another kind of earth may succeed in the same soil, after it has become unproductive for the first kind of crop. This, according to modern doctrines, explains the necessity which is known to exist for what is called *the rotation of crops*—that is, for letting crops of a different nature succeed each other in fields and gardens. The necessity for this rotation was supposed by Decandolle and others to arise from plants' poisoning the soil with the excrementitious matter which they were supposed to eject by their roots; but while this hypothesis was believed, it appeared difficult to account for the well-known fact, that the same crops may be grown perfectly well in any soil for an indefinite number of years, provided that soil be frequently and properly manured; that is, supplied afresh with the ingredients of which it has been exhausted by the plants. As to the matter which is discharged from the roots, it is generally of the same nature as the peculiar secretions of the plant—as, for example, the matter exuded by the roots of the poppy has the properties of opium—and can exercise no deleterious effect upon its growth in the manner Decandolle supposed.

Nature, when unassisted, invariably makes an effort to change the crops of plants. When a forest in North America is burnt down by accidental fires in the summer season, trees of quite a different kind spring up from long concealed seeds in place of those which have been destroyed. When, in ordinary circumstances, one kind of plant has exhausted the soil in its neighbourhood, it pushes its roots to as great a distance as possible in quest of food, and there sends up shoots, while a new race of plants grows upon the spot which it has vacated. In these, as in a thousand other circumstances, we find that one of nature's great primary laws is that of perpetual change—an alteration from one condition and appearance to another, in endless succession and variety. In the artificial cropping of the ground, the farmer, for his own sake, is impelled to take a lesson from nature, and to study what species of plants he can most advantageously produce in succession from his fields. (See AGRICULTURE.)

Term of vegetable existence.—The longevity of plants differs according to their nature and the circumstances in which they are placed. Thus, herbaceous plants, the stems of which are succulent and full of juice, are either *annuals*, that grow only one season, and die as soon as they have ripened their seed; *biennials*, which generally last for two years; or *perennials*, which last for several years. Trees and shrubs, which have ligneous or woody stems, are destined to remain undecayed for years. Shrubs are those ligneous plants which have several stems springing from the same root, all nearly of the same thickness. They seldom last above thirty or forty years, and frequently not half that time; but trees which have only one stem or trunk proceeding from the root to a considerable height before it divides into branches, generally endure for a long period of time—in several instances even for centuries. The length of time which trees live depends in a great measure on the situations in which they grow. If a tree which is a native of mountains be placed in a valley, it grows more rapidly, but the term of its existence is shortened, and its timber becomes softer and of less value. In like manner, if the tree of a valley be grown on a mountain, the term of its existence is lengthened, and its trunk, though of slow growth and small dimensions, produces timber remarkable for its toughness and durability; as, for example, the Highland oak.

The age of trees was formerly calculated by their diameter, or by the number of concentric circles or layers in the trunk; but both these modes are now found to be fallacious. According to the first, it was supposed that if a tree attained the diameter of a foot in fifty years, fifty years should be counted for every foot it measured in diameter; and thus it was supposed that the great baobab tree, found by Adanson on the banks of the Senegal, which measured nearly thirty feet in diameter, must have been about six thousand years old, or coeval with the world itself

It is now found, however, that the baobab, like all soft-wooded trees, grows rapidly, and attains an enormous diameter in less than a hundred years. The mode of counting by concentric circles only applies to exogenous trees, and even with them is very uncertain. A warm spring, which sets the sap early in motion, followed by weather cold enough to check vegetation, will give the appearance of two layers in one year, as the recommencement of vegetation will have the same appearance as a new layer in spring. In many trees, such as the oak, for example, a second growth often takes place after midsummer; so that even a third layer is occasionally formed in the course of six months. On the other hand, a moist warm winter, by keeping the tree growing the whole year without any check to vegetation, will give the appearance of only one layer to the growth of two years. Notwithstanding these anomalies, practical men find counting the concentric circles of a tree the best mode which has yet been discovered of ascertaining its age, as in ordinary cases only one growth is made in the course of a year. The accompanying figure represents a section of a stem five years old, having the pith in the centre, a cylindrical layer for every year of the growth, and the bark on the outside.



The natural decay and death of plants appear to follow the same laws as the natural decay and death of animals. When a tree approaches the term of its existence, the sap flows more feebly through its vessels, and it is no longer propelled through every part. As this takes place, the parts no longer visited by the sap die; and as soon as life has fled, the opposite principle of chemical affinity begins to act, and the various elements that composed the plant fly off, to combine with other elements, so as to form new substances. This is the natural process which takes place invariably with every organised being; the fall of the leaf, and the dropping of the ripe fruit, are but the death of both when fully matured; and in the like manner death is followed in both instances by its natural attendant—decomposition.

DISTRIBUTION OF PLANTS.

The geographical arrangement of the vegetable world is influenced by conditions of soil, heat, moisture, light, altitude of situation, and various other causes; for, did they flourish independently of those conditions, then there were no reason why the vegetation of one part of the globe should differ from that of another. We know, however, that the flowers, shrubs, and trees which adorn the plains of India are not the same with those which clothe the valleys of Britain; and that these, again, are totally different from the scanty vegetation of Iceland or Spitzbergen. Each order is, nevertheless, perfectly adapted to the conditions under which it exists, and finds in its *habitat*, or native situation, all the elements which administer to its growth and perfection. Obvious, however, as are the effects of these external conditions, the mode in which they operate is but imperfectly known. The same elements enter into the composition of the vegetation of the tropics as those which form the vegetation of temperate regions; the same organs, tissues, modes of growth, and inflorescence, are observable; and yet, without the conditions above enumerated, a plant which has been transferred from the one region to the other will speedily languish and die. Even one which flourishes under the influence of the sea-breeze, if removed far inland, will perish; and no art can retain in healthy perfection a native of the mountain which has been transplanted to the warm and humid valley.

Certain plants, like animals, may, however, be acclimatised; that is, may be made to grow and propagate their kind in a region in which they do not naturally occur. Many of our cultivated and most useful plants are of this kind; as, for example, the potato. This plant, which is a native of tropical America, flourishes luxuriously, and is of the highest utility, in northern Europe; but this it does by a special adaptation. In South America, the warm climate enables it to propagate by the seed; hence in that region its tubers are small and insignificant; but in Europe, where the climate is unfavourable to the production of the plant from seed, it propagates by the tubers, which are consequently enlarged, so as to contain a store of nutriment for the young plant, before its stem and leaves be sufficiently developed. The acclimatising of plants does not permanently change their character, for, in being restored to their native habitats, they assume their original forms and qualities.

The habitats of plants—that is, the situations in which they naturally thrive best—are generally distinguished as follow:—*Marine* when the plants float upon, or are immersed in, salt-water, such as sea-weeds; and *maritime* when they grow by the sea-shore, or in places exposed to the influence of the sea-breeze. *Aquatic* is the general term for fresh-water habitats; and these may be either *lacustrine* when growing in lakes, *fluviatile* when in rivers, or *palustrine* when in marshes or wet meadow-lands. Plants growing in open pastures are said to be *pratensise*, in cultivated lands *arvensise*, in woods *sylvan*, in mountainous parts *alpine*, and in caves, mines, and other underground excavations, *subterranean*. The station of a plant is said to be *epiphyte* when it grows upon others, living or dead, without deriving from them the elements of nutrition; and *parasitic* when it adheres to their surface, and directly extracts its nourishment. The range of habitat is that extent of the earth's surface over which a plant is distributed by nature. The terms maritime and alpine, for example, are general in their application, and refer to all plants which grow by the sea-side or on mountains; but the plants which flourish on the sea-shores of Great Britain are not the same with those on the coast of Africa; nor are these, again, allied to the maritime vegetation of Chili. The geographical range of any plant conveys a more specific idea, and embraces only that particular spot in which the plant rejoices. This range is circumscribed by conditions of temperature, light, and elevation above the sea, and does not, as might be supposed, depend very closely upon belts of longitude, by which temperature is generally indicated. Thus, nearly all the beautiful pelargoniums and mesembryanthemums which adorn our greenhouses, are natives of a limited space near the Cape of Good Hope, as are also many of our most beautiful bulbs. The curious stapelias, that smell so much like carrion, are found wild only in South Africa. The different kinds of eucalyptus and epacris are restricted to Australia; and the trees bearing balsam grow principally in Arabia, and on the banks of the Red Sea. The umbelliferous and cruciferous plants spread across Europe and Asia; the cacti are found in tropical America; and the labiatæ and cariophyllaceæ are seldom discovered but in Europe. The peculiar ranges and centres of vegetation, as they are termed, cannot be well understood without a knowledge of the different tribes and classes of plants, the consideration of which forms the subject of SYSTEMATIC BOTANY.

Soil exercises less influence on the distribution of plants than is usually ascribed to it, though there can be no doubt that on its power of absorbing and retaining heat and moisture much of the luxurious growth of vegetables depends. They will grow to some degree in almost any soil, as the bulkier ingredients (clay, lime, and sand) always predominate; but a proper proportion of these earths is necessary to perfect vegetation; and many plants will not continue healthy and propagate, unless supplied with other elements, such as potash, soda, and various metallic salts. For this reason the natural vegetation of a limestone country differs from that of a retentive clay; while the plants which cover all sandy downs are totally different in kind and character from those of the alluvial valley. Moisture, which is indispensable to the existence of vegetation, also exercises some influence in its natural distribution. The plant which roots in the parched sand is furnished with leaf-organs to absorb moisture from the atmosphere, and retain it, while in a wet situation these organs would become diseased, and rot away; so, in like manner, a marsh plant, whose spongioles are its main organs of sustenance, would perish were it removed to an arid soil. The organic structure of such plants forms a limit to their distribution; and the same may be said of the salicorniæ, arenaria, peploides, &c. which live only when exposed to the salt spray of the ocean. Another circumstance connected with the air, and one which is worthy of notice, is whether it be more generally stagnant or in motion. It is perfectly evident that the action of stagnant air upon a plant must be every way less than that of moving air, whether we suppose the action to be of one kind or another; and therefore, up to a certain point, motion in the air must be favourable to the growth of vegetables. Of this we have abundant proofs in the variety, luxuriance, and activity of the vegetation of those regions which, like the Brazils, Oriental isles, and Malay peninsula, are constantly exposed to the steady currents of the trade-winds.

Heat and light are perhaps the most manifest agents in the distribution of vegetable life. The luxurious growth of the tropical jungle is the direct result of warmth and moisture, just as the barrenness of Nova Zembla is the effect of piercing cold; yet both situations are inhabited by plants which enjoy the conditions peculiar to their existence. No conditions of mere soil, or light, or moisture, could make the palms, tree-ferns, and jungle-flowers of India flourish in Great Britain; so neither would our oaks or pines flourish in Iceland, unless we could provide for them that temperature and seasonal influence necessary to their healthy existence. Light, though it acts most powerfully on the colours and blossoms of plants, is also an essential element in their geographical arrangement. The southern slopes of our hills and mountain ranges are always clothed with a more elaborated and more fully developed race of plants than the northern slopes; and this depends wholly upon the greater degree of light which the former enjoy. The northern side may sometimes be as green, but it never will be so flowery as the southern exposure; and the attentive observer may detect new tribes on either side almost as soon as he has passed the summit. The more free the exposure, the more readily will most plants also blossom, and yield a rich fruit. So well is this understood in the grape countries on the Rhine, that the right bank of that river, which faces the sun, is reckoned to be much more valuable than the left, and commands a higher price for its wines.

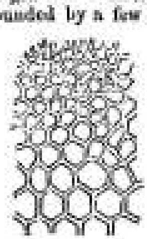
Altitude, or elevation above the ordinary sea-level, also exerts an obvious influence on the distribution of vegetable life: it is equivalent to removal from a tropical to a temperate region, or from temperate latitudes to the arctic circle. For every hundred feet of ascent, there is a proportional fall of the thermometer; so that, at the height of 5000 feet in Britain, and 16,000 at the equator, we arrive at the region of perpetual snow; in other words, to heights as destitute of vegetation as the frozen zone. This intimate relation between altitude and decrease of temperature accounts for the fact, why the base of a mountain may be clothed with the vegetation of tropical India, the sides with that of temperate England, and the summit with the mosses and lichens of icy Labrador. "We may begin the ascent of the Alps, for instance, in the midst of warm vineyards, and pass through a succession of oaks, sweet chestnuts, and beeches, till we gain the elevation of the more hardy pines and stunted birches, and tread on pastures fringed by borders of perpetual snow. At the elevation of 1950 feet the vine disappears; and at 1000 feet higher the sweet chestnuts cease to thrive; 1000 feet further, and the oak is unable to maintain itself; the birch ceases to grow at an elevation of 4000, and the spruce fir at the height of 5000 feet, beyond which no tree appears. The rhododendron ferrugineum then covers immense tracts to the height of 7800 feet, and the herbaceous willow creeps two or three hundred feet higher, accompanied by a few saxifrages, gentians, and grasses, while lichens and mosses struggle up to the imperishable barrier of eternal snow."

The circumstances which facilitate the dispersion or migration of plants are unconnected with the causes which limit their geographical distribution. Many seeds drop from the parent stalk, spring up into new series of stems, which in turn give birth to another race of seeds, and these, again, to another circle of vegetation. Thus, any tribe of plants would spread from a common centre till arrested by the influences which limit its range of habitat; and this mode of dispersion no doubt occasionally occurs. In most plants, however, the seeds are small and light, and easily borne about by the winds; some are downy, and furnished with wings; others have tufts and filaments; and many are ejected from their carpels with considerable force. All these appendages and peculiarities are evidently intended to facilitate their dispersion, which is further assisted by rivers, lakes, and tidal currents, by the wool of animals, the droppings of birds, and the economical pursuits of man, whether accidental or intentional. The seeds are arrested in their progression by various causes: some are furnished with barbs and hooks, which lay hold of objects; others become entangled amid herbage, the mud of rivers, or the softened soil of winter; while many, towards spring, are acted upon so as to emit an adhesive substance, or their fleshy pericarps melt down into the soil, carrying the embryo along with them.

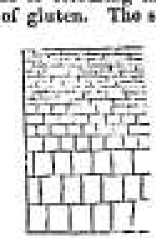
STRUCTURE OF PLANTS—SIMPLE ORGANS.

The organs with which both plants and animals are gifted to enable them to carry on the functions of life, are of two kinds—namely, *simple organs*, such as the flesh of animals and the cellular tissue of plants; and *compound organs*, such as the leaves of plants and the limbs of animals; the latter always consisting of certain arrangements or combinations of the former. The principal substance of which plants are composed is known by the general name of *tissue*; but of this there are three distinct kinds, distinguished as *cellular*, *woody*, and *vascular*, which have been compared to the flesh, bones, and veins of animals.

Cellular tissue is the fleshy or succulent part of plants, of which familiar examples may be given in the pulp of leaves and fruits. It consists of a great number of cells of irregular shape, which adhere together, sometimes quite loosely, as in the pulp of an over-ripe orange; and at other times—as, for example, in the cuticle or outer skin—so closely, as to seem to form a homogeneous mass, unless examined by a powerful microscope. Each cell consists of a small bag or bladder, filled apparently with liquid; but intermixed with this liquid, which consists of hydrogen and oxygen nearly in the same proportions as in water, there are some grains of starch and some of colouring matter, surrounded by a few particles of gluten. The starch,



a



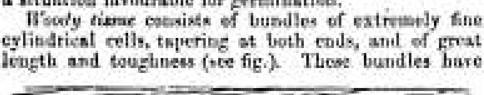
b

which has been compared to the fat of animals, consists principally of carbon, and the gluten of nitrogen. The cells of cellular tissue vary very much both in size and shape. They generally, however, present the appearance of a honeycomb when sections are cut of the pulp of the leaves, pith, or fruit (*a*); but in sections of the bark and sapwood, they take a parallelogram form, and resemble the bricks of a wall (*b*). The cells are generally small when they are first formed, but they increase in size as they become older. Thus, in the tissue of a leaf, they are at first very small; but as fresh cells are formed close to the veins, those towards the margin of the leaf dilate; and a similar process takes place in every part of the plant, the newly-formed tissue always consisting of cellules, which enlarge as they get older.

In the pulp of leaves and fruit, and in the cellular tissue of the bark, there are frequently cavities found among the cells, which are of several kinds. Those called *receptacles of secretion* are formed for the reception of the oils and other fluids secreted by plants; as, for example, the fragrant oil in the myrtle and the orange, and the turpentine in the pine and fir tribe. Other similar cavities, called *air cells*, contain oxygen nearly in a pure state; and others, which are called *intercellular passages*, are generally filled with watery fluid, and communicate with the open air by means of pores in the epidermis. All these cavities have no distinct membrane to enclose them, but are surrounded by what may be called a wall of small cells, which form part of the cellular tissue. The shape and size of these cavities vary exceedingly; the receptacles of secretion, and the air cells, are generally larger than the common cells, but the intercellular passages in very dry plants are so small as to be scarcely perceptible; though in succulent plants—as, for example, in the stem of the garden Nasturtium—they are nearly as large as the cells.

Cellular tissue readily decays when the parts composed of it fall from the tree. The carbon it contains is liberated so soon as the vital force by which it was retained has fled, and escapes with the oxygen in the form of carbonic acid gas; whilst the hydrogen, which then forms its principal remaining element, attracts fresh oxygen from the atmosphere, and becoming thus changed into water, rapidly melts away, leaving the inorganic portion to mix with the soil. In leaves, the pulpy parts disappear first, leaving behind the outer cuticle and the nerves or veins, which are of firmer texture; the latter, indeed, being composed principally of woody fibre, the tubes of which have been filled with earthy matter during the process of vegetation, decay very slowly. Those parts of a plant which nature seems to have intended not to be of long duration, such as the fleshy parts of the leaves, the flowers, and the fruit, are composed entirely of cellular tissue of very loose texture. In the stones of fruit, however, which are also composed of cellular tissue, a portion of earthy matter is deposited, which partially lines the cells, and gives them a temporary firmness, without destroying their facility of decay; so that the seeds contained in them may be preserved as long as they are kept in a dry state, and yet liberated so soon as they are placed in a situation favourable for germination.

Woody tissue consists of bundles of extremely fine cylindrical cells, tapering at both ends, and of great length and toughness (see fig.). These bundles have



Woody Tissue.

so much the appearance of fibres, that their true nature was not suspected by the elder botanists; and it was supposed that they retained their fibrous appearance even when subjected to the most minute division. It is now found, however, that the fibres of woody tissue cannot be divided beyond a certain point, and that, though they may be made so small as to take seven or eight of them to equal the thickness of a fine hair, each of these exceedingly slender fibres is, in fact, a hollow tube tapering at both ends, and adhering to other hollow tubes of a similar nature. The tubes of woody fibre, when young, serve as channels for the passage of the ascending sap; but afterwards they become filled with particles of inorganic matter, which give solidity and durability to the wood. Woody fibre is found mixed with cellular tissue in the wood and inner bark of trees; it also forms part of the veins or nerves of leaves; and in general is found in all organs which require strength, toughness, and durability.

Vascular tissue has been divided by modern botanists into three varieties—namely, *vascular proper*, *pitted*, and *lactiferous*. Vascular tissue, properly so called, consists of cylindrical cells of great delicacy and thinness, called *spiral vessels* and *ducts*. *Spiral vessels* consist of hair-like tubes coiled round and round in a spiral manner, and enclosed in tubes of transparent membrane. They are of a light elastic nature, and though coiled up naturally like a cork-screw (see fig.), they may be unrolled to a considerable extent. If a leaf of the spider-wort (*Tradescantia*), or of any kind of bulb, be doubled down first on one side, and

Spiral Vessel.

then on the other, so as to break through the outer skin on both sides, and if the two pieces of the leaf be then carefully and gently drawn asunder, the transparent membrane will break, and the spiral vessels will unrol, so as to appear, when seen with the naked eye, like fine hairs between two portions of the leaf. Spiral vessels prevail in leaves and flowers, and are found, though more sparingly, in the young green wood of trees and shrubs; but never in the old solid wood, and very rarely in the roots or in the bark. They are very few and small in coniferous trees; but they are abundant in palms and their allies. In ferns and the club mosses they occur occasionally; but the other cryptogamous or flowerless plants are entirely without them. These vessels are sometimes called *air vessels*, because their slender spiral tubes are always found filled with a kind of air, which contains seven or eight times more oxygen than the common air we breathe. *Ducts* are cylindrical tubes closely resembling those which enclose the air vessels; only the spiral vessels they contain appear to have been broken into rings, or short corkscrew-like curves, which sometimes cross each other in a reticulated manner. These rings and curves are, however, quite different from the true spiral vessels, as they have no power of unrolling, and appear only intended to keep the slender membrane which forms the duct distended. Similar rings are found in the windpipe of animals, which appear also only intended to keep that membrane distended.

Pitted tissue, sometimes called *dotted ducts*, consists of tubes which, when held up to the light, appear full of holes, from the numerous dots in the lining of their sides. The mouths of these tubes are very conspicuous in the wood of the rattan when cut across; they are also to be seen in sections of the oak and the vine; and, indeed, in most other kinds of wood, as well as in the stems of herbaceous plants. Being the channels through which the ascending sap is conveyed, the dotted ducts are larger than the vessels of the other tissues, and are distinctly visible in many kinds of wood, even when dry. Modern botanists consider them as belonging to cellular tissue, and as consisting only of elongated cells placed end to end, and opening into each other so as to form a kind of tube. Lactiferous tissue, which is the same as the proper vessels of the older botanists, consist of tubes, which are distinguished from all other kinds of tissue by being branched. They are filled with a mucilaginous fluid called the *latex*, which is, in fact, the descending sap, and is full of numerous small specks, like that which is the germ of the future chicken in the egg of a hen. These specks are always in motion while they remain in the vessels of the latex, and whenever they are deposited, they expand into cells of different kinds of tissue. From the latex, also, is formed gum, sugar, tannin, or other secretions, according to the nature of the plant. The vessels of the latex are found on the under sides of leaves, and within the inner bark, which they may be said to line: hence the peculiar secretions of a tree are generally strongest in the bark.

COMPOUND ORGANS AND THEIR FUNCTIONS.

The compound organs of plants are composed of several of the simple ones; as, for example, a leaf has woody and vascular tissue in its veins, and cellular tissue in its pulpy part; and in like manner, these elementary organs are found in the stem, flower, fruit, and, in fact, in every part of the plant. The compound organs are divided into three kinds—namely, the *general organs*, which are common to every part of a plant, such as the *epidermis* or skin, and the hairs; *the organs of nutrition*, through which the plant takes and digests its food, such as the root, stem, and leaves; and *the organs of reproduction*, which are the flowers, fruit, and seeds.

General organs.—The epidermis or skin is a thin membrane, which covers every part of a terrestrial plant, except the stigma and the spongioles, but which is sometimes entirely or partly wanting in plants which live under water. It is composed of a kind of cellular tissue; but the cells are pressed so closely together, as to make it appear homogeneous to the naked eye; and they are filled with air instead of water. The use of the epidermis is to retain a sufficiency of moisture in plants; for should the delicate membrane of which the cells of their tissue are composed become so dry as to lose its elasticity, the different organs would be unable to perform their proper functions. On this account its thickness is curiously adapted to the conditions under which a plant grows. In ordinary cases, the epidermis consists of two layers, the outer one of which, called the *cuticle*, is extremely thin, and consists of cells of oblong shape and large size, pressed closely together, and filled with air; while the secondary layer is formed of cells of a different shape and size, but still closely pressed together. In the plants of very hot countries, it consists of three, or even four layers, in order that the moisture may be retained, notwithstanding the excessive heat and dryness of the climate. Those plants which have numerous pores, or *stomata*, in their epidermis, require watering oftener than others, and are more easily affected by the heat of the sun. Thus we often see the leaves of the common lilac droop, as though the plant were suffering from want of water; while those of the apple or pear tree which grows beside it are perfectly unaffected by the heat—the latter tree not having above twenty thousand pores in the square inch, while the lilac has one hundred and sixty thousand in the same space. The epidermis of aquatic plants is extremely thin, and is entirely wanting on the under side of floating leaves.

Hairs are minute expansions of the epidermis, and are found almost upon every part of a plant. Sometimes they cover the whole of the leaf, and at others they are only found on the lower surface. They are of two kinds—namely, *lymphatic* and *glandular*; and are described as downy, silky, hirsute, bristly, ciliate, stellate, &c. according to their aspect and mode of arrangement. The use of lymphatic hairs is partly to protect the surface of the leaf from the heat of the sun and from drying winds, and partly to collect moisture from the atmosphere. It is now known that plants take in nourishment from the atmosphere as well as from the soil; and it is supposed that part of this nourishment is absorbed through the lymphatic hairs. It has been observed, that the hairs, when they do not cover the entire surface of the leaf, always grow either upon the veins or in the angles where the veins cross each other. It is thus evident that they have a direct communication with the vessels containing the sap. Glandular hairs are hollow, generally open at the point, and with a receptacle of secretion at the base. Of this nature are the stings of the nettle, and the hairs of the sweetbrier, &c. which are filled with a fragrant volatile oil. In both these cases, glandular hairs seem to act as organs of excretion, through which the plant is enabled to exude certain fluids.

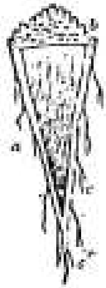
Glands are organs of secretion, or cells containing liquid different from that in the cells of the common tissue of the plant, as in the flowers of the *Hypericum*, or St John's wort, which give out a red liquid when pressed. Sometimes glands assume a wart-like appearance; thence the stems or leaves on which they appear are said to be *verrucose*; and sometimes they take the form of little watery blisters, in which case the plant is said to be *papillose*.

Besides the above-mentioned organs, there are prickles, thorns, and spines, which seem closely analogous, though much less common. *Prickles* may be called hardened hairs, as they are merely indurated expansions of the epidermis, without any woody fibre; and they may be detached from the branch which bears them without laceration. *Thorns* differ from prickles, in being formed partly of woody fibre; and they cannot be detached from the branch which bears them without lacerating its vessels. They are, in fact, abortive, or imperfectly-developed buds, and are formed instead of leaves and branches. *Spines* resemble thorns in every respect, except in being found on the leaves and stems of herbaceous plants, while thorns only grow on the trunk and branches of woody plants. When spines grow on leaves, they are always found on the veins, which are extensions of the woody fibre.

ORGANS OF NUTRITION.

The organs of nutrition are the root, the stem and branches, and the leaves; and of these organs, the root and the leaves, or some modification of them, must exist in every flowering plant, as the vital functions could not be carried on without them.

The root (*radix* in Latin) is commonly defined to be that part of a plant which attaches itself to the soil where it grows, or to the substance on which it feeds, and is the principal organ of nutrition. Exceptions to this definition occur, as in the case of some vegetables which grow floating loosely in water, as duckweed and others, having no root at all. As the nourishment of a plant is derived from the earth, the root is that part which grows in an opposite direction to the stem, and is buried in the ground. A root consists of several parts (see section), which have been called the body or *caudex* (*a*); the collar or life-knot (*b*); the branches or radicles, when such exist; and the rootlets or small fibres (*c c*), which seem to be indispensable in all roots. The body of the root assumes various forms; it may be globe-shaped, as in the turnip; conical, or tapering gradually from the collar to the attenuated fibre, as in the carrot; fusiform, or tapering at both ends, as in the radish; this latter may be abrupt—that is, as if the lower end had been cut off, exemplified in the devil's bit scabious; fibrous, or consisting of small threadlike fibres, which proceed directly from the collar, as may be seen in most grasses; tuberous, when the fibres bear globe-shaped bodies filled with starchy matter, as in the potato; fasciculated, when the fibres swell slightly in the middle; bulbous, when the round lobe consists of coats or layers, such as may be seen on cutting an onion across. A corm is similar in form to a bulb, but is not composed of layers; a palmated root consists of a number of oblong tubers proceeding from the collar, like the fingers from the body of the hand, as in the dahlia. Tuberous roots, such as the potato, are considered by some modern botanists as merely underground stems, from the circumstance of their having eyes, or buds, from which branches will spring.

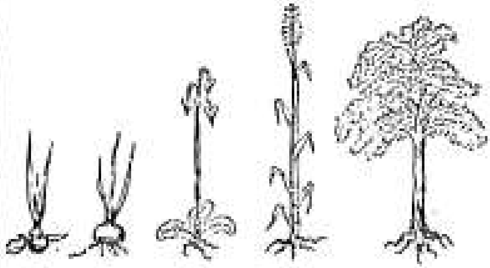


The crown, collar, or life-knot, as it is variously called, is that part which lies between the stem and the root. It is the most essential portion of the whole; for if it be removed, or seriously injured, the plant will inevitably die; whilst the small fibres or rootlets, although an essential part of a plant, may be destroyed at pleasure so long as the crown remains, for it readily reproduces them. When it is of a slender make, as the seeds form, it dries up, and the plant soon dies, as the poppy, mignionette, and other annuals. The crown, however, in some cases, by proper treatment, may be rendered so strong, that annuals can be brought to grow for two or more years. The fibrous root consists of a quantity of long thin fibres, of different lengths and thicknesses, and having still finer ones springing from them, as in the case of wheat, barley, and most grasses. These small fibres or rootlets bear a resemblance to the branches and leaves of the stem. Fibrils consist of a central fasciculus of vessels, enclosed by a cellular cortex and cuticle. Like the leaves of trees that are not evergreen, they are annually produced; in some cases dying and falling off like leaves, in others becoming thicker, harder, and forming radicles or root-branches. The spongelets, as they are called, which take up nourishment from the soil, are situated at the extremity of these rootlets. They are minute spongy bodies, of an oblong shape. We have an instance of rootlets falling off like leaves in those arising from bulbs—such as the lily, the onion, the tulip, &c. which are pushed off and perish like leaves by buds containing the rudiments of the rootlets to be evolved next season of growth.

Roots have a remarkable tendency to grow downwards, or in the direction of the earth's centre, and, from experiments, it seems not unlikely that this tendency is an effect of gravitation. The precise direction, however, is very much influenced by the condition of the soil. Both root and rootlets extend as if in quest of food, and this will penetrate sideways or obliquely to great distances. When plants are by any means prevented from fructifying by seeds, they almost invariably increase by extending their roots, from distant points of which new plants will spring up. Roots thus perform the functions of stems, and though the two differ in many respects, yet there are cases where it becomes difficult to distinguish between them. Some species of palms send down aërial roots for the purpose of strengthening their stems—these shoots partaking of the character of both stem and root. The roots sent out by cabbages and cauliflowers from above the collar, when they are transplanted to a rich soil, are of the same kind. Many herbaceous plants send out roots in a similar manner when they are earthed up; and trees which grow in unnatural situations, as on a wall or bare rock, send down roots in quest of soil and moisture, which afterwards take the appearance of stems. The maple, the gooseberry, and some others, may have their roots converted into stems by reversing the plants, and burying the tips of the shoots in the earth, so as to leave the roots in the air. In this case, the branches will soon send out fibrous roots from the joints which have been buried in the earth, and the fibrous part of the old roots withering, the roots themselves will gradually assume the character of branches.

The stem or stalk.—When a plant shows itself above the ground, it evidently manifests a strong tendency to the light. Light, in fact, is essential in bringing it to maturity, and in giving the green colour to its leaves. The stem, with a few exceptions, is always above ground, and is furnished with joints or nodes at regular distances, where the fibres and vessels take a curved direction, so as to form a little recess, plainly discernible when the branch is split in two, in the centre of which the bud is formed that afterwards expands into a branch furnished with leaves, and sometimes producing flowers and fruit. "The stem," says Rennie, "is divided from the root by the part called the crown or collar. The space between the collar and the first leaf or bud is termed the bole; but the great body of a stem is called the trunk. The stem of grasses, corn, and reeds, is termed the straw; the stem of palms, ferns, mushrooms, and sea-weeds, is termed the stalk; the stem of such flowers as the primrose, the daisy, the snowdrop, and the lily, is termed the scape, though flower-stalk is certainly better; the running stem, as in the strawberry and cinquefoil, is termed a runner; a shorter runner that does not root, as in the house-leek, is termed an offset; a longer one that does not root, as in the cucumber, a vinelet; and a small stem proceeding laterally from a root or stool, a sucker."

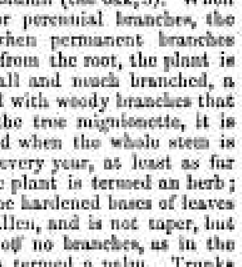
The stem, it will be observed, assumes many forms and characters as to bulk, structure, position, place,



1. 2. 3. 4. 5.

and duration. It appears as a tuber (*Gladiolus*, 1), a bulb (the onion, 2), a scape (*Dodecatheon*, 3), a culm (*Arundo*, 4), or as a woody column (the oak, 5). When a trunk bears permanent or perennial branches, the plant is termed a tree; when permanent branches arise, not from a trunk, but from the root, the plant is termed a shrub; when small and much branched, a copse-shrub; when furnished with woody branches that are not permanent, as in the tree mignionette, it is termed an under-shrub; and when the whole stem is not woody, and dies down every year, at least as far as the crown of the root, the plant is termed an herb; when a trunk is formed of the hardened bases of leaves which have withered and fallen, and is not taper, but all of one thickness, giving off no branches, as in the date and cocoa, the plant is termed a palm. Trunks which increase by successive layers of new wood on the outside of the old, as the ash, are termed *exogenous*; those which increase by the addition of fibrous matter in the centre, as the palms, are styled *endogenous*; and those formed by the adhesion of the leaf-stalks as they spring from the growing-point, as the tree-ferns, are said to be *acrogenous*.

Buds, which have various forms, but are generally oval or roundish, consist of the young shoots either of leaf, flower, or twig, and proceed from what is called the axil of a leaf. They are usually formed either early in summer or in autumn, and are so contrived as to preserve from injury the delicate foliated structure within. The outside is composed of tough scales, which are frequently covered with a gummy resin, and they are internally kept warm by a downy substance interposed between the leaves. To this envelope Linnæus applied the term *hybernaculum*, because it serves for the winter protection of the young and tender portions of the bud (see fig.). The inner scales perform the functions of leaves, until these are perfected and fully expanded, when they drop off; but in some trees, as in the apple and the almond, they are converted into leaves; whilst in others, as the rose, they are converted into the petioles or foot-stalks of the real leaves, which spring out of them. When the central part of a bud contains leaves only, it lengthens upwards as it expands into a branch;



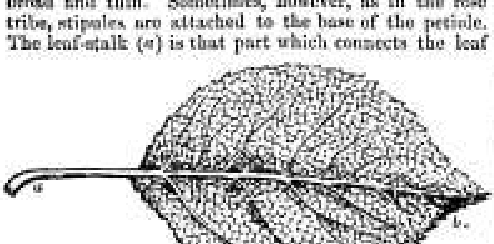
Hybernaculum, or Leaf-Bud.

thus a leaf-bud and a branch-bud may be said to be the same. When it contains a flower, this is situated as in the bulb of the tulip, in which small bulbs are formed on the edges of the crown of the root between the scales, which gradually enlarge at the expense of the scales, are detached, become perfect bulbs, and send up leaves and flower-stalks. With respect to the manner in which the leaves are folded in the bud—they may be plaited, as in the palm and birch; doubled, as in the rose and oak; embracing, as in the iris and the sage; double embracing, as in valerian, teasel, &c.; double compound, as in carrot, mimosa, &c.; rolled inwards, as in grasses; tiled, as in privet, lilac, &c.; rolled outwards, as in rosemary, primrose, &c.; rolled lengthways, breadthways, rolled from the tip to the base, or wrapped round the stalk.

The buds of trees being in a state of great sensibility, and feeling the first warmth of the sun, the vitality of the continued shoot is roused into action; it attracts the moisture contained in the neighbouring cells charged with nourishing matter; the rising sap also enters its vessels; it gradually swells, and bursting the enclosing scales, pushes into the light and air, unfolding its leaves successively as it advances, until the whole tree becomes green.

Leaves.—Leaves are the grand ornament of plants, and from their numbers, position, and delicacy of organisation, they are designed to effect an important office in the vegetable economy. Springing from the branches, and exposed in profusion to the atmosphere, they perform the functions of a breathing apparatus analogous to that of the lungs or gills of animals. A similar purpose at least is designed; for the circulatory sap of plants, like the blood of animals, requires to be exposed to the atmospheric influence, in order that it may be suitable for nutrition. This purpose is accomplished by the agency of the leaves, to which the sap, on rising from the roots through the stem and branches, is propelled or attracted, and there both air and light exercise their beneficial influences. Leaves are thus indispensable to the growth of plants, and care should be taken not to injure them; for defoliation, either naturally or by art or accident, instantly arrests the growth, and the failure or diminished expansion of foliage is a certain sign of debility.

A leaf consists generally of two parts—the petiole, or leaf-stalk; and the lamina, or that part which is broad and thin. Sometimes, however, as in the rose tribe, stipules are attached to the base of the petiole. The leaf-stalk (*a*) is that part which connects the leaf



with the branch, and at the base will be found slightly hollowed, in which a bud rests. Sometimes the leaf-stalk is wanting, as in the sow-thistle and catch-fly, and in this case the leaf is said to be sessile or sitting. The lamina, or broad part of the leaf (*b*), is frequently of a different colour on the under side to what it is on the upper. This is exemplified in the common silver-weed (*Potentilla anserina*), the leaves of which are hoary on the lower side and green on the upper. Leaves are either *caducous*, falling in summer; *deciduous*, falling in autumn; *persistent*, remaining till pushed off in the following spring; or *perennial*, when of still longer duration, as in evergreens. The forms of leaves are exceedingly varied—being *simple* or *compound*; and these again are distinguished as oval, lanceolate, hastate, sagittate, pinnate, cordate, &c.

With regard to the manner in which leaves project from the branches, and their distribution over the woody cylinder to which they are attached, every possible variety may be observed. They may be opposite—that is, two leaves growing on either side of the branch, the one directly opposite to the other; alternate, when one leaf springs out on one side of the branch, and another on the opposite side a little above it, and so on; whorled or *verticillate*, when a number of leaves grow round the stem from a common knot or joint, as in the bed straw. The distribution of alternate and opposite, however, is not regular; for in some instances it will be found that the leaves on the lower part of the stem are alternate, whilst those on the upper are opposite.

There is a numerous description of plants which have few or no leaves, as the torch and melon thistles; but their stems are much dilated, presenting a large superficies of parenchymous exterior to the air and light; or they are profusely covered with spines, which no doubt, conjointly, do the office of leaves. It may be remarked that such plants as the common garden rhubarb, which require much moisture, are provided with very broad leaves, which catch the rain that falls upon them, and also, by their umbrageous quality, preserve the soil from being parched.

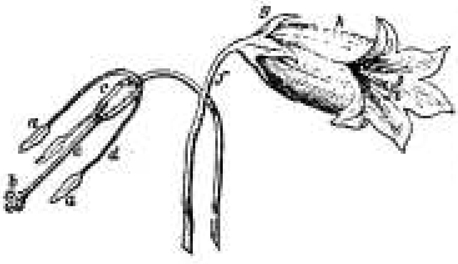
Green is the most general colour of leaves, but some are red, or purple, or yellow; some appear nearly white, in consequence of being clothed with short woolly or silky hair. They differ much in substance and structure: some are immensely thick and fleshy, as those of the genus aloe; others remarkably thin, as those of the beech. The texture of the surface is also very dissimilar; some are rough, prickly, and wrinkled, others smooth and glossy. Whatever be their form or appearance, it is found, by minute microscopic observation, that the interior of the fine membranous substance consists of cells and passages suitable to the due exposure of the sap, the inhaling of air, and the absorption of humidity from the atmosphere.

ORGANS OF REPRODUCTION.

The organs of reproduction are the flowers, the fruit, and the seed; and these, or some modification of them, must exist in every perfect *Phanerogamous* or flowering plant.

Flower-buds are produced like leaf-buds, from which they differ chiefly in containing one or more incipient flowers within the leaves; the flowers being wrapped up in their own floral leaves, or bracts, within the ordinary leaves, which have their usual outer covering of scales. The growing point is generally developed when the leaves expand, but it is short and stunted, and unlike the branches produced from the leaf-buds. Every flower-bud, as soon as formed in the axil of the old leaf, contains within itself all the rudiments of the future flowers. If a bud be gathered from a lilac or a horse-chestnut very early in spring, all the rudiments of the future leaves and flowers will be found within it, though the bud itself may not be more than half an inch long, and the flowers not bigger than the points of the smallest pins.

Flowers.—A flower consists of several distinct parts—the calyx, corolla, stamens, disk, nectarium, pistillum, and receptacle. A flower is essentially constituted by the presence of sexual organs, either male or female. When there is only one of these present, the plant is termed unisexual; but more commonly these organs are both present in the same flower, which is in this case termed a hermaphrodite. In some instances, although the same plant bears both male and female organs, it is not hermaphrodite, as these organs occur in different flowers; in others, again, the male and female flowers exist only in different plants. Lastly, male, female, and hermaphrodite flowers are sometimes found mingled together, either on the same or on different foot-stalks. Sometimes the male or female organs alone, protected in a small scale, constitute the flower; but in general they are surrounded and protected by the corolla and calyx. All these are commonly borne on a stalk called the peduncle (from *pes, pedis*, a foot), which, expanding at its extremity, forms the receptacle or torus, as it has been called, upon which the whole



a a, stamens; *d*, filament; *b*, stigma, or summit of pistil; *e*, style; *c*, ovary, or seed-vessel; *f*, peduncle; *g*, calyx; *h*, corolla.

of the parts above-mentioned are supported. What is called the berry in strawberries, appears to be nothing more than the receptacle bearing the naked seeds on its surface. It is called common when a number of florets rest on one receptacle. The round button which is exposed when the downy seeds are blown from the head of the dandelion, is an instance of the common receptacle.

The *calyx* is the external leafy envelope surrounding the flower, and in which it rests as in a cup. Sometimes it is entire, but more frequently it is divided into segments (*sepals*), which are more or less separated from each other. It is most commonly green, but in some flowers it is highly coloured, and with difficulty to be distinguished from the corolla.

The *corolla* is the true flower or blossom, and consists of several divisions or leafy parts, called *petals*, which are almost all articulated at the base, and consequently fall off at the earliest manifestations of maturity or decay. The extensive variety of tints in the flowering part of plants, is a remarkable circumstance in vegetable economy; and what may be the precise use of such gaiety of colour, has formed the subject of philosophic inquiry. Independently of the exceeding beauty to the eye, which is certainly a matter for pleasing gratulation, it is believed that the lively colours are useful in attracting insects—these creatures incidentally performing an office in the reproductive economy, and in carrying off saccharine exudations.

The lower part of the single petal of a corolla is called the claw, corresponding to the stalk of the leaf; and the broad part is called the limb. The corolla is frequently furnished with certain appendages, attached either to the throat or to the base of the petals, called nectaries. These are placed in different parts of the corolla; in the common auricula they surround the edge of the throat; in the ranunculus or buttercup tribe, they appear like scales at the bottom of the claw; and in the monkshood, in the form of a spur behind the corolla. They receive the name of nectaries from the supposition that they secrete honey, and they are always found to contain a clear, sweet-tasted fluid.

Stamens, &c.—Within the beautiful corolla are observed several small filamentous objects, on some of which are particles of fine coloured matter like dust. These are parts of the reproductive organisation, and consist of stamens and pistils. In general, a stamen consists of two parts, in most cases of a filament (from *filum*, a thread), which is usually white, and always of an anther, which is generally yellow or purple. It has been shown that the stamens are always next to the petals—that is, between their base and the base of the seed-organ. It is upon the number and arrangement of the stamens that systematic botanical arrangements have principally been founded. The following are a few characteristics of the number, length, position, direction, &c. of the stamens. The number of stamens in each flower varies from one to twenty, or more. In length, they are equal or unequal, and this disproportion is sometimes symmetrical, sometimes not. In position, they may be opposed to the divisions of the petals, or they may alternate with them. Sometimes they protrude beyond the corolla, at other times they are wholly included within it. Their direction may be erect, pendant, or horizontal, and their summit is variously inclined to or reflected from the centre of the flower. The filament which supports the anther is most commonly straight and filiform; sometimes, however, it is otherwise. It varies from being as small as a hair to be large and flat like a petal, and its summit is either pointed or obtuse. On the summit is that essential part the *anther*, which is generally formed of two small membranous sacs, attached immediately to each other, or united by an intermediate connecting body. In form, anthers are subject to great variety, and, like the filaments, they sometimes cohere so as to form a sort of tube. Their colour is often yellow, orange, violet, white, &c. but never green or truly blue.

The pollen contained in the anthers consists of numerous regularly-figured small particles, which possess in different plants a very different figure, size, and colour. The number of particles in a cell, which is very small, sometimes amounts to many thousands. In some flowers the pollen consists of transparent grains; in others they are of a white, purple, blue, or brown, and more frequently of a yellow colour. When a grain of pollen is dropped into water, it swells and bursts, and a minute quantity of matter escapes, which is supposed to be the fecundating principle of the pollen. We may illustrate the action of the pollen from the anthers, by referring to the annexed engraving, in which *a* is the filament or stalk of the stamen, *b* the anther on its summit, and *c* the pollen or dust in the act of being shaken down upon the stigma or upper part of a pistil, of which we observe three in a group.

In this figure, it may be remarked that the anther is a roundish-shaped body, delicately poised on the filament, and ready to vibrate and impart its dust to objects beneath or near it.

The pistil is a kind of tube with a communication from the stigma, through its style or stalk, to the ovary or seed-bag beneath, and down this the pollen is permitted to exercise its influence. The seed-organ or ovary occupies almost always the inferior part of the pistil, and it is there that the process of fructification is fully effected. When cut open, it exhibits one or more cavities or cells, in which are contained the rudiments of the seeds or ovula; and it is in it that the change of the ovula into perfect seeds is effected. It is of various forms, but most commonly ovoidal. It is generally seated upon the receptacle together with the stamens, but frequently it is placed below the flower. Its cavity consists of one or more cells, in which the ovula or rudimentary seeds are found. It may be remarked, that the pistils spring from a nectary or disk in the centre of the flower, and are surrounded by the stamens.

The precise mode of fructification is by no means clearly ascertained. The stigmata are in all cases moistened with a clammy fluid, which causes the pollen-cells to swell, burst, and discharge their minute granules. Some suppose that these are taken up by spongelets in the summit similar to those of the root, while others allege that the fluid matter in which the granules float is sucked up. It has been discovered that the grains of pollen, when shed on the summit, in a few hours shoot out one or more delicate tubes, which by some physiologists are supposed to extend down as far as the seed-organs, and to expand around and between the nascent seeds. Some believe them to convey thither the granules, which at least enter into the tubes; others, however, deny that this is the case. The seed-organ lies at the base of the pistil, and contains the seeds, either nascent or advanced to maturity. It bears a very strong resemblance to the egg-organ of birds and insects, and its parts have accordingly received from naturalists the same scientific names. The seed-organ is usually of an egg-oblong form, and is always composed of an outer membrane, a middle membrane, and an inner membrane, all intimately united. As every seed derives its nourishment from the inner membrane, there must be a communicating point; and this point being always on the verge of the membrane, may be so termed; that on the seed being termed the seed-scar, but popularly, though improperly, named the eye. In some species the verge bears a number of smaller verges, to each of which a seed is attached, by means of the funicle or seed-stalk. All these parts are obvious in an unripe pea or bean.

Seed-vessels are various in form—as, for example, in the case of the pea (*a*), the vessel is a *legume* or pod; in the apple (*b*), it is the body of the fruit, or *pome;* and in the filbert, it is a nut.

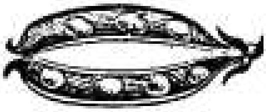


Fig. a.

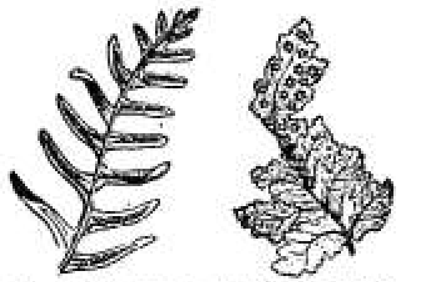
Fig. b.

All fruits, in reality, are but so many vessels, or receptacles for the seeds, and the various forms in which they appear are individually suitable to the purposes of their growth. The seed contains the *embryo* or germ of the future plant, which is generally surrounded by a nutritious substance termed the albumen, destined for the support of the young plant, before its organs are sufficiently matured to allow of its supporting itself. In most instances the albumen surrounds the embryo; but sometimes it forms part of the cotyledons or seed-lobes, and at others it is wanting altogether. Even where it exists, it varies very much in quantity, sometimes being much smaller than the embryo, while in other cases, as in the cocoa-nut, it weighs as many, or more ounces, than the embryo does grains. The albumen varies in quality as much as it does in quantity. It is generally fleshy, as in the pea and bean; but sometimes it is farinaceous or floury, as in the wheat, and in the marvel of Peru; at other times it is oily, as in linseed; horny, as in the coffee; or even stony, as in the kind of palm whose seed forms the substance called vegetable ivory. In the nutmeg and the custard apple tribes, it appears to be perforated in every direction by a mass of dry cellular tissue.

If the embryo consist of one seed-lobe or cotyledon, as the cocoa, it is said to be *monocotyledonous;* if of two, as in the beech and oak, *dicotyledonous*—and these terms are generally used indiscriminately for exogenous and endogenous; while cryptogamous or flowerless plants, from being propagated by sporules instead of seed, are said to be *acotyledonous*—that is, without any cotyledon whatever. (See SYSTEMATIC BOTANY.)

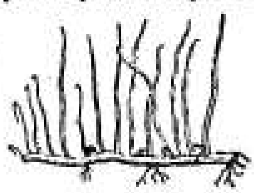
Fructification of flowerless plants.—As already stated, the lowest forms in which vegetables make their appearance are those of the *cryptogamous* or flowerless orders—such as the ferns, lichens, mosses, seaweeds, and fungi. In these the manner of fructification is very remarkable, and quite different from that of flowering plants. They have neither flowers nor seeds, but are propagated by little embryo plants, called *spores* or *sporules.*

In the ferns (*filices*), which are the largest and most highly organised of the flowerless orders, little brown spots, called *sori,* may be seen on the under-sides of the leaves or fronds (see fig.). Each of these is composed of a number of minute membranous capsules (*thecæ*), which contain the reproductive sporules, and which are often furnished with elastic apparatus for assisting in their dispersion. In some species the sori are situated merely under the epidermis of the leaf, forming little protuberances, which, on the slightest rupture, discharge their contents, to be scattered abroad by every breeze that blows. As an order, ferns are very widely distributed, generally consisting of a number of leaf-like



Ferns, showing the Sori on the back of the Fronds.

members, called *fronds,* attached by tough fibrous petioles to a subterranean stem—the fronds being the only visible portion of the plant. In some varieties, however, the stem rises above ground to the height of thirty or forty feet, forming the well-known *tree-ferns* of New Zealand and Van Diemen's Land. In the *equisetums,* or horsetails of our marshes and ditches, the capsules which contain the spores are placed on the points of bracteated spikes, arranged in rings round the stems. Each spore is furnished with an elastic filament, which is at first coiled around it, but which, in its endeavour to uncoil, makes the sporules jerk and leap as if they were alive. The horsetails are herbaceous perennial plants, having hollow striated stems, these being either simple or branched. In point of size they are now insignificant members of the vegetable kingdom; but geology has revealed the gigantic proportions they bore in ages long past, when, instead of slender stems of a foot or two high, they reared their gigantic pillar-like trunks to a height of twenty or thirty feet. The sporules of the pillworts (*marsileaceæ*) are enclosed in little ball-like receptacles at the bases of the leaves (see fig.); the club-mosses (*lycopodiaceæ*) have little cone-like spikes at the tips of their branches, under the scales of which lurk the reproductive embryos; and in the true mosses (*musci*), the spores are enclosed in urn-shaped capsules, which stand out from the leaves on slender hair-like stalks. In the liverworts and lichens there is a somewhat similar provision; and in the stoneworts and algæ (seaweeds), which are aquatic, the sporules are enclosed in the substance of the plants.



Pillwort.

The *fungi,* or mushroom tribe, which constitute the lowest forms of vegetable development, are extremely diversified in their size, shape, colour, and consistence. They are entirely composed of cellular tissue, and some are even apparently animated; so that they are regarded as connecting links between the vegetable and animal kingdoms. The common field-mushroom is one of the best known, and forms the type of the family; but the mould on cheese, stale bread, the mildew on trees, the rust on corn, and many other minute and yet unobserved appearances of a similar nature, are all fungi. They have no fronds or leaves, and are hence termed *aphyllous.* Their organs of reproduction consist of sporules, lying loose on the tissue of the plant, or collected in certain places, which are distended by their aggregation.

But though the botanist can thus detect, by the aid of the microscope, the embryos of flowerless plants, and can describe their situation and appearance, he understands as yet but little of the manner in which these reproductive organs perform their functions. "We are entirely ignorant," says Professor Lindley, "of the manner in which the stems of those that are arborescent are developed, and of the course taken by their ascending and descending sap—if, indeed, in them there really exist currents similar to those of flowering plants; which may be doubted. We know not in what way the fertilising principle is communicated to the sporules or reproductive grains; the use of the different kinds of reproductive matter found in most tribes is entirely concealed from us. It is even suspected that some of the simplest forms (of algæ and fungi, at least) are the creatures of spontaneous growth; and, in fine, we seem to have discovered little that is positive about the vital functions of those plants, except that they are reproduced by their sporules, which differ from seeds, in germinating from any part of their surface, instead of from two invariable points."

Functions of flowerless plants.—Insignificant and lowly as the cryptogamia may appear to the eye of the physiologist, they are nevertheless important auxiliaries in the operations of nature. It is true that man and his works may suffer from the ravages of fungus growth, that mildew, rust in corn, moulds, and other microscopic vegetation, by their rapid increase, and destructive effects on the substances from which they spring, may cause incalculable damage; but this very scourge provides an incentive to intelligent prevention and care, while in creation there are no more useful scavengers of decaying matter than the parasitic fungi. In a dry season, for example, and on a favourable soil, rust rarely makes its appearance: certain conditions are necessary for its development; and it is to obviating these that the farmer must look for exemption from this destructive malady in his crops. It is now placed beyond a doubt that it arises in many cases from the over-manuring of fields; the grain is overloaded with nourishment, and the dormant fungi, brought into a condition of development, speedily show their destructive properties. The tendency to rust may be neutralised by steeping the seeds before sowing in a corrosive solution, or strong brine; but the same end may be better secured by not over-manuring, or by a free use of saline manures. Again, most of the fungi existing only by the absorption of fetid exhalations, and rapidly depriving them of their insalubrious properties, execute duties analogous to those of certain tribes of insects (maggot-flies, for instance), and in this respect have been appropriately associated with these animals as the "scavengers of nature."

It will now be understood that mould is a fungous vegetation, produced by a previous deposit of germs in the tissue or on the surface of the object on which it grows. The proximate cause of its development is generally damp, and, without this condition, the embryo remains in a dormant state. Still, it may be asked, how cheese happens to have green mould at its very centre: the reply is, that the fungous germs floating in the atmosphere had various opportunities of finding admission into this article of diet. They may have been deposited on the grass of a field; the grass was eaten by the cow, and the germs were so lodged in the milk; or, what is more probable, the germs fell upon the curd, and there lay concealed till a certain dampness in the cheese brought their vegetative powers into operation. It is well known that the exposure of curd for a day to the atmosphere will have the effect of producing cheese liable to mould. A fully more surprising instance of fungous vegetation in a secluded situation, is that which occurs in the fermenting of yeast, and other substances. Fermentation is, in one respect, a chemical process, forming a first step towards dissolution; but the action is also vegetative. The whole mass of matter gradually assumes the condition of active vegetative growth. The fungous germs which had been incorporated in the material, begin to live and expand, each being a plant which grows and gives rise to new plants of the same species, until the entire fermenting principle is exhausted.

Another great object which nature has in view by the germination and dispersal of the algæ, mosses, and lichens, is clearly that of preparing the way for a higher order of vegetation. It cannot possibly escape our observation, that the tendency to vegetate is a power restless and perpetual. We hew a stone from the quarry and place it in a damp situation, on the ground or in a wall, it is all the same which, and shortly a green hue begins to creep over it. This is the commencement of a vegetable growth, produced by germs floated in the atmosphere; and being attached at random to the stone, have been brought to life through the agency of the moisture. Other stones equally exposed, but in dry situations, have also received a clothing of these germs, but circumstances not being suitable, they have not been developed: give the moisture, and they will immediately appear. We hew another stone from the quarry, and build it into the pier of a bridge, just within the surface of the water. Shortly, the same kind of green algæ will appear; but the wet being in greater abundance, and more continuous, the growth will become more luxuriant. Instead of the simple green ooze, we have the addition of long filaments resembling hairs (*confervæ*), which float and accommodate themselves to the water around.

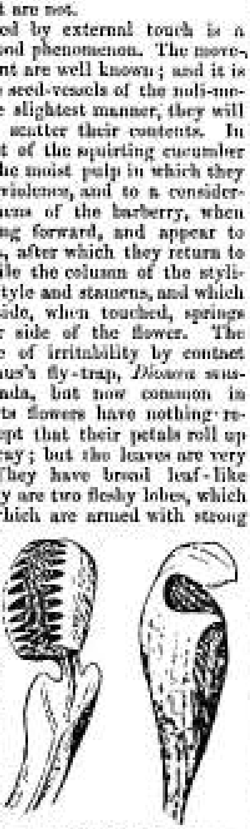
The inquiry may perhaps here be made—supposing that nature designs this species of growth to be a forerunner of a higher order of vegetation, how is that result to be brought about? To answer this we must take an expansive view of the subject, and not confine ourselves merely to one department of science. Nature is incessantly working out vast ends by humble and scarcely recognisable means. It seems to be a principle that nothing shall remain stationary or unchanged. The whole surface of our planet is every instant altering in its features. Mountains are being washed down into the plains, rocks are mouldering into soil, the sea is filling up at one place and encroaching on the land at another, and water-courses are constantly shifting their outlines. The duty of filling up seas, ponds, lakes, and rivers, is consigned to divers means within the animal and vegetable economy; and one of these is the growth of algæ and other aquatic plants. Take a pond of water, and shut off its means of supply from rivulets and springs, and then observe what an effort nature will make to fill it up. The sides and bottom become speedily covered with a luxuriant crop of confervæ; other plants, which grow only in water, begin to make their appearance, their seeds being wafted thither by winds; at length the superficial matting of herbage is able to support the weight of birds; grass grows; there is alternate vegetation and decay; finally, the pond is filled up, and a forest of the highest order of trees may in time cover the site of the original humble confervæ. What, indeed, are the extensive peat-mosses but lakes and pools choked with vegetable matter, which remains in a half-consumed condition. Thus we see that the green hair-like ooze which grows upon stones in the water, humble and apparently insignificant as it is, performs a distinct part in creation necessary to work out the important designs of Providence.

PHENOMENA OF VEGETATION.

In addition to the ordinary functions of the organs, which are the same in all plants of the same genus, there are certain anomalous functions which cannot be reduced to regular laws, and which differ in different species even of the same genus. The most remarkable of these are the occasional *irritability* of plants, their *colours*, *fragrance*, and *tastes*.

Irritability.—The irritability of animals depends entirely on their nervous system; but as plants have no nervous system, their irritability is more difficult to be accounted for. Dr Darwin, indeed, asserts that plants are only an inferior kind of animal, and that they, or at least some of them, have a brain and a stomach, and are endowed with the lower senses. According to this fanciful doctrine, the medulla or pith was made the seat of sensation, and was considered analogous to the spinal marrow of animals. The doctor, however, had no followers, as his hypothesis presented too many difficulties to be even partially believed. The principal phenomena of vegetable irritability may be divided into three kinds; namely, those caused by atmospheric influence, those depending upon the touch of other bodies, and those which appear to be perfectly spontaneous. Atmospheric influence occasions the closing of the leaves over the extreme point of the young shoot at night, as may be observed in the chickweed and several other common plants. The folding of some flowers in the absence of the sun, and the opening of others as soon as that luminary has withdrawn its beams, are ascribable to a similar cause. The white marigold closes its flowers on the approach of rain, and the dwarf calendrina folds up its bright crimson corolla about four o'clock every afternoon. The evening primrose, on the contrary, will not open its large yellow flowers till the sun has sunk below the horizon; and the night-blowing cereus only expands its magnificent blossoms about midnight. Some flowers are so regular in their hours of opening and shutting, that Linnæus formed what he called *Flora's Time-piece*, in which each hour was represented by the flower which opened or closed at that particular time. Solar light is the principal agent in producing these phenomena; but, in some cases, flowers have been known to open by artificial light. Decandolle found blossoms expand beneath a lamp nearly as well as beneath the sun itself; and the crocus-flower, which closes at night, has been known to expand as wide as possible when gently exposed to the light and heat of a fire. One of the most remarkable circumstances respecting the effect of atmospheric influences is, that the same causes do not affect all plants, and yet no peculiarity of construction has been discovered in those that are so affected to distinguish them from those that are not.

The irritability produced by external touch is a familiar but little understood phenomenon. The movements of the sensitive plant are well known; and it is also known that if the ripe seed-vessels of the noli-me-tangere be touched in the slightest manner, they will open with elasticity, and scatter their contents. In the same manner the fruit of the squirting cucumber throws out its seeds, and the moist pulp in which they are contained, with great violence, and to a considerable distance. The stamens of the barberry, when touched with a pin, spring forward, and appear to make a bow to the stigma, after which they return to their proper position; while the column of the stylidium, which includes the style and stamens, and which generally hangs on one side, when touched, springs with a jerk to the other side of the flower. The most remarkable instance of irritability by contact is that exhibited by Venus's fly-trap, *Dionæa muscipula*, a native of Canada, but now common in British conservatories. Its flowers have nothing remarkable about them, except that their petals roll up when they are about to decay; but the leaves are very curiously constructed. They have broad leaf-like petioles, at whose extremity are two fleshy lobes, which form the real leaf, and which are armed with strong sharp spines, three on the blade of each lobe, and a fringe of longer spines round the margin (*a*). When an insect touches the base of the central spines, the leaf collapses, and the poor insect is caught; being either impaled by the central spines, or entrapped by the others. The leaf then remains closed, the fringe of long spines being firmly interlaced and locked together, till the body of the insect has wasted away. This apparatus being the nearest approach to a stomach which has been yet observed in plants, an experiment was tried some years ago of feeding a dionæa with very small particles of raw meat, when it was found that the leaves closed in the same way as they would have done over an insect, and did not open again till the meat was consumed. Saracenia, or side-saddle flower, the leaves of which have a pitcher-shaped petiole (*b*), also decomposes flies and other insects caught in the pitcher—a peculiarity which seems to belong to all plants having pitcher-shaped leaves.



a, Leaf of Venus's Fly-trap; *b*, Leaf of Saracenia.

The spontaneous movements of plants are much more difficult to be accounted for than those occasioned by atmospheric phenomena, or by external touch. It is true that the leaves elongate, the flowers expand, the anthers burst, and the seed-vessels open spontaneously; but these are movements caused by the progressive development of the plant, and subjected to regular laws. The spontaneous movements which arise from irritability are quite different—as, for example, those of the leaves of *Hedysarum gyrans*. This plant has compound leaves, the terminal leaflet of which never moves except to fold itself close down to its own stalk; but the side leaflets have such eccentric movements, as to render it difficult, if not impossible, to explain them, and which might appear, indeed, to a fanciful mind as though the whole plant were actuated by a feeling of caprice. Generally, all the leaflets twist and whirl themselves about in an extraordinary manner, though the air of the house in which they grow is perfectly still; but frequently the leaflets on only one side will be affected, and sometimes only a single leaflet will move, or all will become motionless together; and when this is the case, it is quite in vain to attempt to set them again in motion by touching them; though sometimes in a moment, as if from the pure love of mischief, after the touching has ceased, the leaflets will begin to move again as rapidly as before. In the like manner, the side leaflets frequently continue their eccentric movements all night, while the terminal leaflet remains quietly folded up, and apparently fast asleep. Cold water poured upon this plant stops the motion of the leaves, but it is renewed as soon as the heat of the stove in which the plant grows has converted the water into vapour. Movements analogous to those of the hedysarum and other foreign plants have been detected by M. Dutrochet in several common vegetables, as the garden pea and cucumber; and he attributes them to an interior and vital excitation, and not at all to the action of light, which is opposed to, and, if vivid, arrests them.

Plants may be deprived of their irritability by keeping them without water, when they become flaccid; or by watering them with a poisonous liquid, in which case they lose not only their irritability, but their lives. Life, indeed, appears to be intimately connected with irritability, as the latter quality exists only in plants in a vigorous and healthy condition. The functions of vitality and irritability may be merely suspended without destroying life, by administering to them the same substances—opium, vapour of ether, &c.—which produce stupor in animals.

Colour.—The colour of plants generally depends on the presence of a substance called *chromule*, which is deposited in minute granules in the vesicles of the cellular tissue. This substance consists of pure carbon, which has been *fixed*, as physiologists term it, by the decomposition of the carbonic acid gas absorbed by the plant; the oxygen escaping again into the atmosphere, while the carbon is permanently assimilated. Both the absorption and decomposition of carbonic acid take place most effectively under the influence of solar light; hence plants grown in darkness become etiolated, or blanched. The chromule in all plants being the same, it is difficult to explain why leaves should be green, and flowers of so many varied hues; indeed, the cause is as yet but very imperfectly understood. It is found, however, that when the leaves first expand, and are of the brightest green, the grains of chromule are always surrounded by a thin film of gluten, the principal ingredient in which is nitrogen. In autumn, the gluten and carbon generally have both disappeared, particularly in plants which contain a notable amount of acid, the basis of which is oxygen. In proportion as the oxygen predominates, the leaves become red; hence the beautiful tints of red and crimson taken by some leaves in autumn. When the carbon disappears without the nitrogen, as is frequently the case, the leaves become yellow in autumn. It has been observed that the leaves of plants always turn yellow, red, crimson, or violet, and never blue; and this corresponds with the above theory, as the carbon, which is dark, is carried out of the leaves by the descending sap, and its place partially supplied by oxygen. Thus red, which is the colour produced by oxygen, predominates in decaying leaves; and violet, which implies a mixture of carbon, is only found in the dying leaves of the American white oak. The lime, and other trees which abound in mucilage, or gluten, further corroborate this theory, in having their decaying leaves yellow. In all cases, the colouring matter is not in the sap, which is either colourless, or tinged faintly with yellow, but in the cellular tissue; and thus, while the stem consists chiefly of cellular tissue, it is as green as the leaves.

The colours of flowers are more difficult to be accounted for than those of leaves, as they are evidently influenced by the soil in which the plants are grown more than by solar light. Mineral substances, particularly iron and manganese, are found abundantly in white flowers when burned; and it is known that many a common British weed, particularly the herb "Robert," varies from a dark rose colour to almost white, according to the soil in which it grows. Flowers grown in the shade are, however, seldom different in colour from those fully exposed to the air and light. The petals of the common buttercup, and the lesser celandrine, are of as brilliant a yellow in town gardens enveloped in the smoke of London, as on any country hill; and roses always maintain their brilliant tints, even when the bushes on which they are produced are evidently dying for want of a clear atmosphere. Flowers may be made to change their colours by the influence of the soil in a most remarkable manner. The petals of the common hydrangea, which are naturally pink, may be made blue by planting the shrub in soil impregnated with iron. The change produced in tulips, carnations, heart-eases, &c. is still more extraordinary. The flower of a seedling tulip is generally of a dull brownish crimson; and after remaining of this colour two or three seasons, it will suddenly *break*, as the florists term it, into the most brilliant and varied tints of rose, white, yellow, brown, or purple, without leaving any trace of the original colour. To produce this change, florists try a variety of means, all of which have relation to the soil; for example, they sometimes keep their tulips in poor soil, and then suddenly transplant them into one exceedingly rich; or they reverse the process: at other times they change them suddenly from a sandy to a clayey soil. As a further proof that light is not the sole cause of colour in plants, it is well known that ferns and mosses have been found green in mines where they have grown in total darkness; and green and red seaweeds of the most brilliant tints are frequently washed up from the bottom of the sea, where the light, being weakened by passing through such an immense body of water, can have but little effect in producing colour.

The colouring matter extracted from vegetables is of great economical value, being extensively used in the art of dyeing. Some of these dyes are the same with the natural colour of the parts from which they are derived; such as saffron, which is the yellow stigma of a species of crocus; but others are totally dissimilar, being blue or black, when the native vegetable texture is green!

Fragrance.—The cause of fragrance in flowers has never yet been fully explained. We know that all organised bodies consist partly of volatile matters, and thus we can readily account for the odours given out by decaying animal and vegetable substances, as they evidently proceed from the volatile parts being liberated by decomposition. The fragrance of flowers, however, escapes while the plants are in a living state, and that most abundantly when they are in vigorous and healthy condition. Besides the flowers, other parts of living plants frequently exhale fragrant odours—such as the leaves of the myrtle and geranium, and the wood and bark of pines. All these odours proceed from oily or resinous matters contained in the receptacles of secretion; but the laws which regulate their liberation, and define their physiological uses, are as yet imperfectly known. Some botanists consider them to be part of the excrementitious matter which is thrown off by plants, when it is no longer necessary to their growth; but if this were the case, the exhalation would continue the same during the whole period of growth, and not vary, as it does, at different seasons, and according to the state of the weather. It is well known that plants are most fragrant in damp weather; and some botanists have attempted to account for this by supposing, that the tissue being relaxed at such seasons, the stomata, or pores, open wider than at other times, and thus permit the escape of a greater quantity of the fluid. Trinchinetti thinks that the use of the odours of flowers is to ward off vapour, which might prevent the diffusion of the pollen; and it is thus that he accounts for the increase of the odour by damp. This explanation appears plausible; but neither it nor any of the others which have been suggested, will explain why the petals of roses, and other flowers, retain their fragrance when dried. The use of fragrance in leaves, bark, and wood, is apparently to preserve them from the attacks of insects; as we find that the smell of the red and Bermuda cedars, of which pencils are made, and of camphor (also a vegetable product), are sufficient to keep the moth from attacking substances with which these are in contact.

The odours of plants are of three kinds—permanent, fugitive, and intermittent. Permanent odours are those given out slowly by the plant, not only whilst it is living, but also after the fragrant part has been separated from the root, though it be not in a state of decay. Of this kind are the odours of fragrant wood, of the dried petals of roses, and some other flowers. In these cases the receptacles of secretion are generally buried so deeply in the tissue, that the essential oil with which they are filled can only escape slowly, and in very small quantities. In some cases, indeed, the receptacles of secretion are so deeply seated, that the wood to which they belong appears devoid of scent, till its essential oil is volatilised by exposure to heat. Fugitive odours arise from essential oils contained in receptacles just below the epidermis; and when there is only a minute quantity of oil in each cavity, the duration of the fragrance is correspondingly short. Intermittent odours are the most difficult to be accounted for by the vegetable physiologist. It is only known that the night-smelling stock, the Indian jasmine, and several other plants, which are entirely devoid of scent during the day, are delightfully fragrant during the night. One of the orchideous plants produces its powerful aromatic scent only when exposed to the direct rays of the sun; and the night-blowing cereus is fragrant only at intervals of about half an hour during the time of its expansion, preserving the same kind of intermittence even when separated from the stem.

Tastes.—The tastes produced by vegetable substances are generally recognised as sweet, acid, bitter, astringent, austere, or acrid. The juice of the sugar-cane, for example, is sweet, that of an unripe apple acid, the aloe bitter, the leaf of the bramble astringent, and the cranberry austere. It has been already stated that the ascending sap is at first insipid, and that it gradually acquires the peculiar taste of the plant; but it is only in the descending juice that the taste-yielding principle is fully developed. Why the taste of one vegetable should differ from that of another grown in the same soil, the physiologist is unable to determine;

he as yet only understands a few of the causes by which tastes may be modified or destroyed. The principal influences which modify the tastes of plants are atmospheric and solar; light, exposure, and warmth, being those under which taste, as well as all other qualities of vegetables, are most fully developed. Every one is acquainted with the blanching effects of *earthing*, as exhibited in celery, or in the shoots of the common rhubarb. The fruits grown in our own island during a wet and sunless season are insipid compared with what they are in a dry and bright summer; and the general vegetation of the arctic and temperate regions is less powerful in kind than that of the tropics. Even the successive periods of a day exercise an influence on the tastes of growing plants, according as they are stimulated by solar light to absorb or exhale oxygen—the principle on which the peculiarities of taste greatly depend. As a general law, it may be stated, that the drier and warmer the situation, the more exposed to light, and the slower the growth of any vegetable, the more intense is its peculiar flavour. The physiological uses of the different tastes are as imperfectly understood as the causes which produce them. Some of them may be given for the preservation of the vegetable against the attacks of animals at certain seasons of its growth, whilst others seem as directly bestowed to render plants agreeable to the animals destined to consume them.

Luminosity, heat, electricity.—The luminosity of plants—that is, the evolution of light either from living or dead vegetable structure—is a rare and curious phenomenon. Flowers of an orange colour, as the marigold and nasturtium, occasionally present a luminous appearance on still, warm evenings; this light being either in the form of slight electric-like sparks, or steadier, like the phosphorescence of the glow-worm. Certain fungi, which grow in warm and moist situations, produce a similar phosphorescence; and decaying vegetables, like dead animal matter, have been observed to emit the same kind of luminosity. This phenomenon seems connected with the absorption of oxygen; and the parts emitting it are most luminous when immersed in pure oxygen, and cease to emit it when excluded from that element. Luminosity is sometimes occasioned by actual combustion of the volatile oils, which are continually flying off from certain plants: those of the *Dictamnus albus* will inflame upon the application of fire.

The evolution of heat by living plants is a more common phenomenon. We are aware that warm-blooded animals have the power of keeping up a certain temperature within them, which varies at certain stages of their growth, and perhaps periodically. This result is obtained by respiration—the oxygen of the atmosphere uniting with the carbon of their blood, and producing a species of combustion. A similar, though less understood phenomenon, seems to take place in the respiration of plants. In germination, heat is sensibly evolved: a piece of ice placed on a growing leaf-bud will dissolve, when it would remain unchanged in the open air; and experiment has proved that the surface of plants is three or four degrees higher than the surrounding medium. Again, the internal temperature of a large trunk is always higher than the surrounding atmosphere, and though young shoots are sometimes frozen through, the general structure both of the wood and bark is such as to conduct heat so slowly, that the internal warmth is never reduced beyond what seems necessary to vitality. Generally speaking, it may be asserted that plants possess an internal vital temperature, and that, in the process of respiration (the giving off of carbonic acid or oxygen, as the case may be), a certain degree of heat is always evolved.

The connection of electricity with vegetable growth has recently excited the attention of physiologists; but little positive information has yet been ascertained. It has been long known that growth takes place with great rapidity during thundery weather; but this may result from the nitrogenised products of the showers which then fall, as well as from the effects of electricity. The progressive states of vegetable growth are the result of chemical changes; and as these changes are more or less accompanied by electricity, it is supposed that plants evolve electricity as well as heat. The conversion of water into steam is followed by a sensible evolution of electricity; and the evaporation which takes place from the surface of rapidly-growing leaves, produces the same phenomenon. The general electric state of plants is said to be *negative;* and some have attempted to connect the luxuriant vegetation of the tropics with the thunder-storms of these regions, on the supposition that when the atmosphere is *positively* electrified, the two opposite states will give rise to such commotions. Of late years attempts have been made to apply the principle to agriculture; conducting wires have been laid around experimental plots, but with such varied, and even contradictory results, as to preclude anything like a determinate conclusion.

SECRETIONS OF PLANTS.

Substances possessed of various properties are secreted by plants, according to their respective natures, and their healthy or diseased condition at the time of secretion. Some of these substances are produced by the ascending sap; but the greater number are deposited by the elaborated or proper juice, and consequently are never secreted during spring or early summer. The intensity of those derived from the latter source depends in a great measure upon the influence of solar light; hence they are much stronger, and more abundantly produced, in tropical than in temperate climates. Most of them being derived from the true or arterial sap, they would seem to serve some purpose in the reproduction or nourishment of the plant; but others, from the manner in which they are deposited or ejected, appear to be of no utility in the vegetable economy. Some of them are *excretions* as well as *secretions;* but whether they are to be considered as essential components of the sap, or evacuations necessary to the healthy condition of the secreting organs, has not yet been determined. Being exceedingly varied in their properties, they are of great utility to man, either as articles of food, clothing, medicine, ornament, or luxury.

The economical applications of vegetable secretions and excretions are so numerous, that it would be absurd, in our limited space, to enter upon anything like details. It is even difficult to attempt any classification of them; for, though differing in their properties and external appearance, many of them are identical in chemical composition, and, subjected to peculiar treatment, readily pass into new and similar combinations. Some, for instance, are farinaceous, as barley; while others are saccharine, as the juice of the sugar-cane; and yet both, when subjected to fermentation, produce similar liquors. Many are oleaginous, balsamic, or resinous; some are narcotic, aromatic, or mucilaginous; while others are astringent, purgative, or poisonous. For examples of these divisions, the reader has only to recall to mind such substances as palm and olive-oil, myrrh, resin, opium, camphor, gum-arabic, tannin, gamboge, prussic-acid, aloes, colocynth, and a thousand others of every-day familiarity.

Besides the proper excretions and secretions, there are several adventitious substances found in plants, which are not the products of vital organisation. Lime, for instance, is found in the ashes of many plants in union with acids, and sometimes it is excreted in the form of a thin crust on their leaves. Silica also occurs in considerable quantities, especially in the stems of reeds and grasses; it forms the glossy pellicle of the cane, and is sometimes found in the joints of the bamboo, where it is deposited in a soft pasty mass, called *tabasheer*, which ultimately hardens into pure semi-transparent silica. Besides these earths, there are various metallic oxides and salts, and the well-known alkalies—potash and soda. The physiological uses of such products are but imperfectly known to physiologists. Many of them—such as starch, gum, sugar, and the fixed oils—directly administer to the support of the young plant and to the formation of new tissues; while those which yield flavour and aroma seem to be connected with the preservation of plants, by protecting them from the depredations of insects and other animals. Others, again, such as silica and metallic oxides, give hardness and stability to the stems and branches; some give elasticity and pliancy to the young shoots, thereby preventing them from being broken by winds; and several seem to administer to the durability of the woody fibre, by their properties of resisting putrefaction.

METAMORPHOSES OF PLANTS.

The metamorphoses of plants forms one of the most interesting sections of vegetable physiology. Technically, it is termed *Morphology*—that is, a consideration of the changes and transformations which various parts of plants undergo, either from natural or artificial causes. We know, for instance, that many plants are made to change their appearance and qualities by cultivation; that by grafting, hybridising, and so on, the gardener can change the size, colour, and qualities of his fruits and flowers; and that analogous changes take place in a state of nature—such as the conversion of leaves into petals, and leaves and branches into thorns and spines. It is also well known that flowers become double by changing their stamens into petals; and it is from a knowledge of these facts, that botanists have asserted that all the appendages of the stem or ascending axis are modifications of a single organ, and may be considered *as leaves adapted to a special purpose.* This doctrine, at first broached by Linnæus, and subsequently expounded by the German poet Göthe, is now very generally adopted. It is usual to treat of this subject under two heads—namely, *regular* metamorphosis, or that connected with the structure of all vegetables; and *irregular* metamorphosis, or that which influences only a particular class of plants, or parts of these plants, and which occur under peculiar circumstances.

Regular metamorphosis seeks for facts to establish the doctrine, that all the appendages of a plant have a common origin with the leaf, and may therefore successively assume the form and appearance of that primary organ. The first protrusion of the plumule from the embryo is leaf-like, subsequently true leaves are developed, and from a succession of these are formed the stem. The branches of the stem take their origin from leaf-buds, and are again clothed with branches and leaves by the same process as in the main stem. As a branch proceeds towards the point of fructification, the leaves assume the form of bracts; these, again, are succeeded by the leaf-like sepals of the calyx; and next by the petals of the corolla. Within the petals are the stamens—which sometimes assume a leafy form—next the pistil, and ultimately the seed-vessels. Even the seeds are but leaves in another form, embalmed and preserved, as it were, for the reproduction of another plant; and in many, such as the beech-mast, the leaflets of the embryo may be distinctly seen, folded and imbedded in their future nutriment. Thus the growth and reproduction of plants may be regarded as a circle of leaf-like changes, the leaf, or some modification of it, being in all cases the organ which administers to the functions of vitality. We need not enumerate instances of these conversions, for every one who has intelligently observed the common garden-plants around him, must have sometimes felt the difficulty of distinguishing between calyx and corolla, must have seen stamens assume the aspect of petals, and not unfrequently the whole floral organ appear green and leafy. And just as there is an indubitable passage from leaves to every other organ, so may any one organ be found to revert to the primary form of the leaf.

Of irregular metamorphosis, or those changes which parts of plants, or classes of plants, may be made to assume, little is absolutely known. In a state of nature, certain tribes are limited to certain localities, these situations being characterised by some peculiarity of soil and atmospheric influence. If the conditions of soil and climate to which they are subjected remain the same, the character of plants is nearly uniform or stationary; and this may be always said of them in their natural state. But if they be removed from a poor to a rich soil, from a dry to a moist habitat, from a warm to a cold climate, or *vice versâ*, then their internal structure will undergo a change; and this change will manifest itself in one or other of their external characters. In some classes, this change is most evident in the roots and tubers; in others, in the stems and leaves; while in many the organs of fructification (the flowers and fruit) are the parts most affected. Sometimes this change of situation merely produces a more luxuriant development of all the parts of a plant, without causing any abnormal growth of a particular organ. Cultivation, and other artificial treatment, may be considered as the cause of these irregular metamorphoses, which assume in some plants a wonderful degree of permanency, and may be transmitted to successive races; though, generally speaking, if the artificial stimulus be not kept up, plants will return to their normal or natural condition. There are no such roots or tubers in nature as our cultivated beet, carrot, potato, and parsnip; no leaves like the thick succulent *hearting* of the cabbage; no flowers like our double roses, carnations, and ranunculuses; and no fruits or grains like our delicious pears, apples, and cereals.

The hybridism of plants is closely allied to the subject of morphology, and is, in fact, a transformation of character produced by artificial means. As among animals two distinct species of the same genus will produce an intermediate offspring—such as the *mule*, which is the offspring of the horse and ass—so among vegetables two species belonging to the same genus can be made to produce a *hybrid;* that is, a new plant possessed of characters intermediate between its parents. This power of hybridising is more prevalent among vegetables than animals; for the different species of almost every genus of plants are capable of producing this effect, if the pollen of one species be put upon the stigma of another. The union, however, can only take place between nearly allied species, occurs rarely among plants in a wild state, but is quite common among cultivated species. According to modern botanists, the character of the female parent predominates in the flowers and organs of fructification of the hybrid, while its foliage and general constitution are those of the male parent. Hybrids have not the power of perpetuating their kind like naturally-distinct species; for, though occasionally fertile in the second and third generations, they have never been known to continue so beyond the fourth. But though incapable of propagating themselves beyond a very limited period, the pollen of the parent species may be made to fertilise them, or their pollen to fertilise the parent; but in either case the new offspring gradually merges into the original species. Thus nature has wisely set a limit to the intermingling of species, by which they are preserved from ultimately running into confusion and disorder.

In an economical point of view, hybridism is of great value to man. By a knowledge of its principles he has been enabled to modify the characters of natural species, so as to adapt them to his special purposes; and thus have arisen most of those beautiful sorts and varieties of blossom which now adorn the flower-garden. So, also, by crossing varieties of the same species, our grains, fruits, and kitchen vegetables have been brought to a high state of perfection. The size of one species has been assiduously amalgamated with the durability of another; the beauty of a third with the flavour or odour of a fourth; and so on with other qualities. The principles of hybridism will yet be more extensively applied; and it is not too much to expect that the perfection of our field and forest produce will yet rival that of our orchards and gardens.

SYSTEMATIC BOTANY.

Botany—derived from the Greek word *Botané*, a plant—is that science which includes the study and investigation of the vegetable kingdom. *Vegetable Physiology*—treated in the preceding sheet—is that department of the subject which explains the organisation and vital functions of plants; *Systematic Botany* that which recognises their arrangement into orders, tribes, genera, and species, according to their respective forms and qualities. The former relates to functions which are common to all vegetables, the latter takes notice only of such peculiarities and attributes as serve to distinguish one individual from another, or one family from another family. The vegetable kingdom is supposed to contain upwards of 100,000 species; and therefore, without some system of arrangement into smaller groups and orders, it would be difficult to acquire a knowledge of the special characteristics of plants, or to convey that knowledge to others by any process of description. It is the aim of Systematic Botany to obviate this difficulty, by classifying plants according to certain types and resemblances which are common to a number of individuals; thus making one description equally applicable to a class as to an individual.

The advantages of classification, in lessening the labour of memory and description, become strikingly apparent when we reflect on the difficulty which would exist were each plant to be known by an entirely distinct name. For example, there are many species of roses, all of which are known by the generic term *Rosa*, each having a second or specific name to designate it separately, as *R. centifolia*, *R. damascena*, &c. Now, if a botanist hear of a plant called *Rosa*, though its specific name be quite new to him, he has instantly a general idea of what sort of plant it is, from his previous knowledge of the common characteristics which belong to the *genus Rosa*. The principle of classification is to assemble those plants which bear most resemblance to each other; and this has been done in different ways by different botanists; each method being called the *system* of the individual who devised it—as Tournefort's system, Linnæus's system, Jussieu's system. Of the several systems which have been suggested, only two are in use at the present time—namely, that of Linnæus, the great Swedish naturalist (1707-1778); and that of Jussieu—or rather a modification of that of Jussieu—an eminent French botanist, who, during the long period between 1770 and 1836, was closely engaged in improving the nomenclature and arrangement of the vegetable kingdom.

The system of Linnæus is founded solely on what are called the *sexes* in plants—that is, on the number, situation, proportion, and connection of stamens and pistils, which are regarded as respectively the male and female organs. This system appears at first sight extremely simple, as it depends entirely on counting so many visible parts; but it is very uncertain, as the number of stamens often differ, from accidental circumstances, in plants of the same genus; and it tells nothing of the plant but its class and order, which lead only to the discovery of its technical name, as plants of the most opposite qualities frequently agree in the number and disposal of their sexual organs. This mode of classification is known among botanists as the Sexual System, or the *Artificial System*, because it is founded on mere artificial enumeration, and not upon natural qualities or resemblances of the plants so arranged. That of Jussieu, on the contrary, is founded on the natural analogies of vegetables; and the botanist who is acquainted with its principles, can at first sight assign any plant to its proper class and order, as there is always a general resemblance among the plants belonging to the same natural order. Again, knowing the order, which is usually typified by some common plant, he can predict as to its qualities—a species of information which the artificial system does not attempt to convey. Jussieu's method has been greatly improved since the time it was suggested, particularly by the late Professor Decandolle of Geneva; and it is his modification of the original plan, with some further improvements, which constitutes the most generally adopted *Natural System* of the present day.

According to both systems, plants are divided into classes, orders, genera, species, and varieties. A *class* consists of plants resembling each other in some grand leading feature, and as strongly differing from another class as mammalia do from birds. Thus flowering plants with one cotyledon, whose trunks increase in thickness from within, as the palm, form a distinct class; while flowering plants with two cotyledons, and whose trunks increase by external layers, constitute another class. An *order* consists of plants still more closely allied, so that many orders may be found in the same class. Thus, as ruminant or cud-chewing animals form an order of mammalia, so do the leguminous or pod-bearing plants constitute an order of dicotyledonous vegetation. A *genus* consists of plants so very closely allied, that they may be compared to members of the same family. The pea, for example, constitutes a genus of leguminous plants, just as sheep form a family of the ruminants. A *species* may be compared to one of the members which compose the family; thus the garden-pea and sea-pea are different species of the same genus. A *variety* is merely a departure from the common appearance of the species, as regards colour of the flower, height of stem, or the like—differences which arise from climate, situation, greater or less humidity of soil, and other accidental causes. The boundaries between species and varieties are often very vague, some botanists regarding those plants as species which are mere varieties; but much doubt might be removed by attending to the fact, that a species reproduces itself from seed, and is always persistent under the same circumstances, whereas a variety has always a tendency to revert to its parent species, unless propagated by cuttings, and fostered by other artificial means. A *hybrid* is a plant raised by fecundating the stigma of one species with the pollen of another—a process which rarely occurs among plants in a wild state, though quite common in cultivation. In gardeners' catalogues, hybrids are generally ranked as species; but unless perpetuated by artificial processes, they all soon die out, or revert to their original stock. A *cross-breed* is a plant raised between two varieties of the same species, and generally ranks as a variety.

When there are two botanic names to a plant, the first is that of the genus, and the second that of the species—as, for example, *Quercus alba*, the white oak. When three names are given, the third signifies that the plant is a variety; and this is sometimes more strongly marked by using the contraction *var.* before the third name—as *Quercus ilex* var. *crispa*, the curled-leaved variety of that tree. Unless, however, the variety be of considerable importance, the third name is for the most part omitted in botanical catalogues, and the varieties indicated by figures, or by letters of the Greek alphabet—observing that the species is always reckoned as one, and that the varieties begin with the figure 2, or the letter β.

The primary arrangement of plants, according both to the artificial and natural system, is into those with flowers and those without flowers. The first division, or that which includes the flowering plants, is distinguished by the name Phanogamia, because in them the organs of reproduction are apparent. It comprehends all the trees and shrubs used in the economical arts, all the ornamental plants of our gardens, and, in short, all those that have distinct organs—as leaves, branches, flowers, and seeds. The second division, known by the term CRYPTOGAMIA, embraces, as the name implies, those plants in which the organs of reproduction are not apparent—as the lichens, mosses, and seaweeds. They have no leaves, flowers, or seeds, in the common acceptation of these words, their *fronds* or leaves being very different from those of flowering plants; and instead of flowers, fruit, and seed, they are furnished with little cases or *thecæ*, attached to their fronds, and in these are lodged the spores or embryo plants, minute as the particles of the finest dust. Here the resemblance between the two systems ceases—their classes and orders being arranged on totally different principles. We shall present, in the first place, an outline of the Linnæan system, both on account of its priority and simplicity, and as an initiatory step to gaining a knowledge of the different forms of flowers. It is true that it is now disused by most men of science; but for the reasons stated, as well as from the fact, that many excellent works have been arranged on its plan, it is necessary that the general reader should have some acquaintance with its leading features.

We must premonish, however, that Systematic Botany has no very alluring aspect to a beginner. The great number of titles of the classes and orders, to say nothing of the generic and specific names, is a bar to commencing the study; but when set about in earnest, first difficulties quickly vanish—the subject becomes every day more and more interesting; every new plant is sought and examined with avidity; research is no longer toil; and every accession to the previous stock of knowledge is attended by fresh gratification. 'The standing objection to botany has always been,' says White of Selborne, 'that it is a pursuit which amuses the fancy, and exercises the memory, without improving the mind or advancing any real knowledge; and where the science is carried no farther than a mere systematic classification, the charge is but too true. But the botanist who is desirous of wiping off this aspersion, should be by no means content with a list of names; he should study plants philosophically; should investigate the laws of vegetation; should examine the powers and virtues of efficacious herbs; should promote their cultivation; and graft the gardener, the planter, and the husbandman, on the phytologist: not that system is by any means to be thrown aside: without system, the field of nature would be a pathless wilderness; but system should be subservient to, not the main object of, our pursuit.'

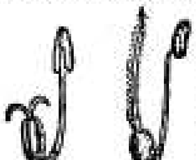
THE LINNÆAN SYSTEM.

The sexuality of plants had been discovered long before the time of Linnæus; but as far as is now known, he was the first who suggested the adoption of this characteristic as a basis of classification. According to his system, the vegetable kingdom is divided into twenty-four *Classes*, founded upon the number, the proportionate lengths, the connection, or the situation of the stamens. These classes are again subdivided each into one or more *Orders* depending upon the number of the pistils, the presence or absence of a seed-vessel, its shape, or the number and connection of the stamens, or on the arrangement of the florets. Terms compounded of the Greek numerals and the word *andria*, signifying man or male, are, for the most part, used to designate the classes; and similar compounds of these numerals, and the word *gynia*, which signifies woman or female, are employed to designate the orders. The following synopsis presents at one view an outline of the system:—

CLASSES.			ORDERS.
1. Monandria,	1 stamen,	has 2	— Monogynia and Digynia, or 1 and 2 pistils.
2. Diandria,	2 stamens,	... 3	— Monogynia, Digynia, and Trigynia.
3. Triandria,	3 ...	... 3	— Monogynia, Digynia, and Trigynia.
4. Tetrandria,	4 ...	... 3	— Monogynia, Digynia, and Tetragynia.
5. Pentandria,	5 ...	... 7	— Mono., Di., Tri., Tetra., Pentagynia, and Polygynia.
6. Hexandria,	6 ...	... 4	— Monogynia, Digynia, Trigynia, and Polygynia.
7. Heptandria,	7 ...	... 4	— Monogynia, Digynia, Tetragynia, and Heptagynia.
8. Octandria,	8 ...	... 4	— Monogynia, Digynia, Trigynia, and Tetragynia.
9. Enneandria,	9 ...	... 3	— Monogynia, Trigynia, and Hexagynia.
10. Decandria,	10 ...	... 5	— Monogynia, Digynia, Trigynia, Pentag., and Decagynia.
11. Dodecandria,	from 12 to 19 ...	... 7	— Mono., Di., Tri., Tetra., Penta., Hexa., and Dodecagynia.
12. Icosandria,	... 20 or more ... on the corolla or calyx,	... 3	— Monogynia, Digynia, Pentagynia, and Polygynia.
13. Polyandria,	... 20 or more ... on the receptacle,	... 6	— Mono., Di., Tri., Tetra., Pentagynia, and Polygynia.
14. Didynamia,	4 ... 2 long and 2 short,	... 2	— Gymnospermia and Angiospermia.
15. Tetradynamia,	6 ... 4 long and 2 short,	... 2	— Siliculosa and Siliquosa.
16. Monadelphia, all the filaments united,		... 8	— Tri., Pent., Hex., Hept., Oct., Dec., Dodec., and Polyand.
17. Diadelphia, filaments united into two sets,		... 4	— Pentandria, Hexandria, Octandria, and Decandria.
18. Polyadelphia, filaments in three or more sets,		... 2	— Decandria and Polyandria.
19. Syngenesia, five stamens united by their anthers,		... 5	— Polyg., Æqualis, Superfl., Necess., Frustan., Segregata.
20. Gynandria, the stamens growing on the pistil,		... 3	— Monandria, Diandria, and Hexandria.
21. Monœcia, flowers with stam., others with pist. on same plant...		10	— Mon., Tri., Tet., Pen., Hex., Oct., Icos., Polyan., Monad.
22. Diœcia, stamens on one plant, and pistils on another,		... 13	— Mo. Di. Tr. Tet. Pen. Hex. Oc. En. Dec. Do. Ic. Polyand., [and Monadelphia.
23. Polygamia, unisex. or bisex. flowers on same or diff. plants,...		2	— Monœcia, Diœcia.
24. Cryptogamia—inconspicuous flowers,		... 4	— Filices, Musci, Fungi., and Algæ (now extended).

I.—MONANDRIA.

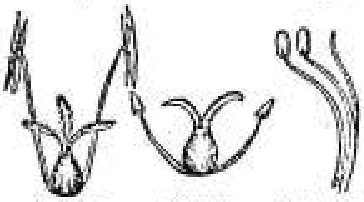
Flowers with one stamen, and with one or two pistils; thus constituting two orders, of which there are thirty-three genera, and above two hundred and fifty species. The first order, MONOGYNIA, contains many highly ornamental exotics, chiefly reed-looking herbaceous plants, with large leaves and showy flowers. The seeds and roots of many of these are used in medicine, as well as by the dyer—as galangale, tumeric, arrowroot, zedoary, and *Zingiber officinale*, the common ginger of commerce. Their predominating qualities are aromatic. Several of the genera are British—as hippuris, glass-wort, and wrack-grass. The second order, DIGYNIA, contains seven genera, one of which is *callitriche*, the water starwort, frequently met with in our ditches. There is another plant, sometimes sown in borders as an ornamental annual, which also belongs to it—namely, *Blitum capitatum*, the strawberry blite. Its chief ornament is its fruit, which is thickly set on its branches, resembling strawberries; hence its name.



Digynia. Monogynia.

II.—DIANDRIA.

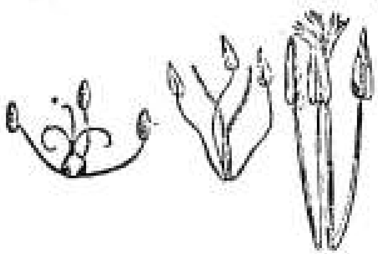
Flowers with two stamens, and with one, two, or three pistils; thus constituting three orders, of which there are upwards of sixty genera. The first order, MONOGYNIA, contains by far the greater number of the genera. Here we find the useful olive, the fragrant jasmine, the lilac, the fringe-tree, the catalpa, and many evergreen shrubs. Nor are the herbaceous members of the order less prized: the wild and cultivated speedwells, the delicate schizanthus, the showy justilias, and the elegant slipperwort, are some of the choicest gifts of Flora. The rosemary, and the numerous species of sage, are ranked in this order, though some botanists have suggested the removal of the latter plant to the class Didynamia, because, in addition to the two perfect stamens, there are the rudiments of two others in the flower. The second order, Digynia, which contains only three genera, are properly grasses—as the *Anthoxanthum odoratum*, which so greatly assists in giving hay its agreeable scent. In the third order, Trigynia, there are only two nearly allied genera—namely, *piper* and *peperomia*. The first is universally used as a spice, and is extensively cultivated in the East Indies as a most important article of commerce.



Trigynia. Digynia. Monogynia.

III.—TRIANDRIA.

Flowers with three stamens, and with one, two, or three pistils; thus constituting three orders, which embrace considerably more than two hundred genera. Almost all the grasses, as well as the grain-bearing *cereals*, are found in this class. Nor are the other genera less remarkable for the beauty of their flowers, than are the grasses and cereals for their usefulness. The well-known crocus, the corn-flag, and iris, and many allied foreign genera, are among the chief ornaments of our gardens, and which compensates in some measure for their want of usefulness when compared

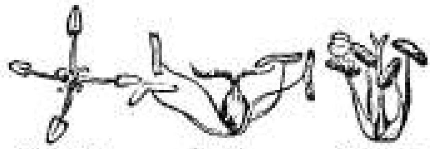


Trigynia. Digynia. Monogynia.

with their associates the cereals. No class shows more decidedly the artificial character of the Linnæan system than this; for assuredly the iris and wheat can claim no congeniality with each other, either in external structure or constitutional properties; but these having each three stamens, compelled the author to place them together. The second order, Digynia, contains most of our common grasses—as millet, panic grass, bent grass, fox and cat's-tail, oat and cock's-foot grasses, besides wheat, barley, &c. together with the far-famed sugar-cane, that source of wealth to the tropical planter, and indispensable condiment in the diet of all nations. The third order, Trigynia, contains only twelve genera, most of which are aquatic annual weeds; some are curious or pretty, but none are cultivated out of botanical collections.

IV.—TETRANDRIA.

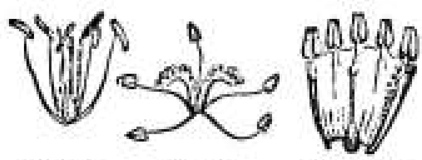
Flowers with four stamens *of equal length*, and with one, two, or three pistils, thus forming three orders, in which there are upwards of one hundred and thirty genera. The equal length of the stamens should be specially kept in mind, because the fourteenth class (*Didynamia*) has also four stamens, but of these two are longer than the others. Many of the genera in the order Monogynia are beautiful shrubs and trees, chiefly natives of the Cape of Good Hope and New Holland—as the *Proteas*, *Hakias*, *Banksias*, and the splendid waratah or *Telopia speciosissima*. Several fine ornamental Chinese shrubs—as the *Ixoras*, for instance—belong to this class, as well as many hardy plants, both shrubs and herbs, natives of Europe. The second, Digynia, contains only four genera, one of which is a British annual, *Buffonia tenuifolia*; named after the celebrated naturalist Count de Buffon. The witch-hazel, a hardy North American tree, is also placed in this order. The third order, Tetragynia, is also small, containing only eleven genera. Among these we find the well-known holly, which as a hedge plant and ornamental evergreen is unrivalled. Its timber, when it has attained full size, is solid, white, and of remarkably fine grain, and much used by musical instrument-makers and other artists. The common pond-weed, *Potamogeton natans*, so frequent in our slow-running rivers, also belongs to this order.



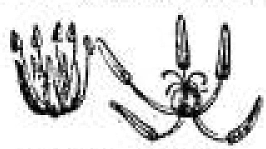
Tetragynia. Digynia. Monogynia.

V.—PENTANDRIA.

Flowers with five stamens, and with one, two, three, four, five, or many pistils; thus forming one of the most extensive of the Linnæan classes. The first order, Monogynia, is particularly abundant both in genera and species. Every description of flowering plant is found here—trees, shrubs, and herbs, terrestrial and aquatic; trailers, creepers, and climbers; annuals, biennials, and perennials; deciduous and evergreen. The second, Digynia, is also a large order, and comprises many beautiful and useful plants. Here we find the *Asclepias*, with its curiously constructed flowers, and the no less remarkable *Stapelia*, a family of leafless plants, but bearing flowers of uncommon character both in shape and colour, and, moreover, diffusing a scent so loathsome, that blowflies lay their eggs on the petals! Here also we find the remarkable English parasitical plant, the dodder, *Cuscuta Europæa*, and the stately elm-tree, so useful both for ornament and timber. The third order, Trigynia, embraces the ornamental laurustine, the elder, and other well-known plants. The sumach family, so variously useful in the arts, is also ranked here, with several other genera of inferior note. The fourth, Tetragynia, contains one genus only, and which happens to be a British plant, a beautiful inhabitant of our bogs and marshy ground, known by the name of Grass of Parnassus. There are four species of this plant already described; three of which are natives of North America. The fifth order, Pentagynia, contains nineteen genera, among which we find the highly ornamental family of *Crassula*, a tribe of succulents chiefly from the Cape of Good Hope. Here also we find the superlatively useful flax, the neat thrift, used for the edgings of walks in gardens, and the showy sea-lavender. The last, Polygynia, contains only three genera, two of which are exotics, and the other a native of Britain, common in corn-fields, called *Myosurus minimus*, or mouse-tail.



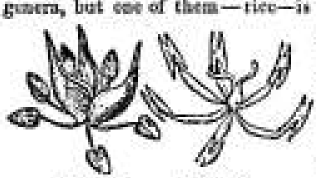
Trigynia. Digynia. Monogynia.



Pentagynia. Tetragynia.

VI.—HEXANDRIA.

Flowers with six stamens *of equal length*, and with one, two, three, or many pistils; thus constituting four orders, which embrace as many as two hundred genera. The fifteenth, *Tetradynamia*, has also six stamens; but four of them are longer than the other two. Besides this, the flowers of the two classes are obviously different. By far the greater number of our bulbous flowering and culinary plants—as the narcissus, the lilies, the long-lived American aloe, the magnificent crinums and pancratiums, the unequalled fruit of the pine-apple, and the equally useful onion, asparagus, &c.—belong to this class. The plants are chiefly herbaceous, and found in every clime from the torrid to the arctic zone, in the burning sands of Africa, and amid the snows of Siberia. The first is by far the largest order, containing nine-tenths of the whole class. The second order, DIGYNIA, contains only three genera, but one of them—rice—is most important to the inhabitants of tropical countries, and to those of the warmer parts of the temperate zones. It is the staff of life in India, and is cultivated on every spot of level ground where there is a command of water for irrigation. This plant is a true cereal, and has been properly placed by Jussieu among the grasses. The only British plant in this order is the *Oxalis reniformis*, or mountain sorrel. The third order, TRIGYNIA, comprehends a few bulbous and tuberous stemmed plants—as the bird's-tongue, the elegant trillium, and the meadow saffron, a common English plant, as also the well-known dock. The fourth order, POLYGYNIA, comprises only four genera, among which we find one of the most beautiful British genera—namely, the water plantain. It is only found in pools or turfy bogs; and if cultivated, it must have a place in the aquarium.



Trigynia. Digynia.

VII.—HEPTANDRIA.

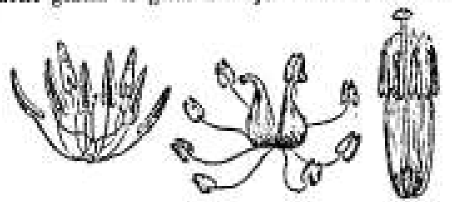
Flowers with seven stamens, and having one, two, four, or seven pistils; thus forming four orders, which comprise fifteen genera. The first order, MONOGYNIA, contains two nearly allied genera of trees—namely, the *Æsculus* and *Pavia*, better known by the name horse-chestnuts. They are among the most ornamental of our forest trees, though they are not natives. The flowers of the common sort are well known; one or two of the pavias have bright red flowers, and are most striking objects in ornamental scenery. The common horse-chestnut yields great crops of nuts; but except the deer, no other domestic animal will touch them. The second order, DIGYNIA, contains only one genus—namely, the *Limeum Africanum*, a perennial herb from the Cape of Good Hope. The third, TETRAGYNIA, comprises two genera—*Saururus*, lizard's-tail and *Astranthus*, a new genus lately introduced from China. The fourth order is HEPTAGYNIA. It is remarkable that among above three thousand genera, only one should occur with seven stamens and seven styles; indeed, as Rousseau remarks, nature has neglected the number seven in her arrangement of vegetable structure.

Digynia. Monogynia.

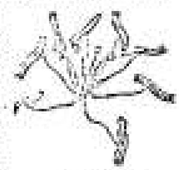
Heptagynia. Tetragynia.

VIII.—OCTANDRIA.

Flowers with eight stamens, and with one, two, three, or four pistils; thus constituting four orders, which include about eighty genera. The first order, MONOGYNIA, contains many genera, of which the heaths are the most conspicuous and numerous. Of this family alone there are five hundred and forty-three species already described, chiefly natives of the southern parts of Africa. A few are found in Britain, and several in other parts of Europe. The curious *rhexia*, the day and night-flowering *anothera*, and the elegant *fuchsia*, are found in this class; so also is the well-known mezereon, and many exotic genera of great beauty. The order DIGYNIA contains only five genera, all exotics, Weinmannia being the chief. The order TRIGYNIA comprises nine genera, among which the sea-side grape, and soapberry of the West Indies, are the most remarkable. The last order, TETRAGYNIA, contains six genera, having four pistils, among which is the curiously organised *Bryophyllum*, which bears viviparous progeny on the edges of its leaves. This is a remarkable departure from the usual way in which plants produce viviparous offspring. Bulbs send forth offsets from the radical plate or collet; some few from the axils of the leaves on the stem, as exemplified in the tiger lily; others, again, eject *living* seeds from their spathes, as some of the onion tribe; many trees and shrubs send up suckers from their roots, which become perfect plants; but in the case of the *bryophyllum*, young plants are produced from the vascular parts of the edges of the leaves, in addition to those which are yielded by the perfect seeds.



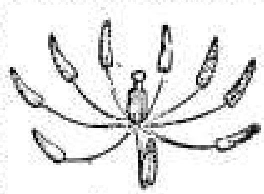
Trigynia. Digynia. Monogynia.



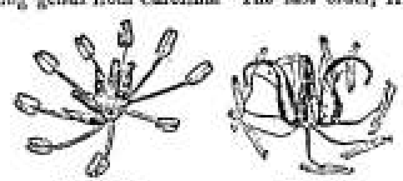
Tetragynia.

IX.—ENNEANDRIA.

Flowers with nine stamens, and with one, three, or six pistils; thus forming three orders, under which are ranked about a dozen genera. In the first, MONOGYNIA, we find the useful and fragrant cinnamon, and the famous laurel, whence so many medicinal oils and other useful substances are extracted. In the second, TRIGYNIA, there are the excellent medical and now culinary rhubarb, with only one other congener, the *Pleea*, a rush-looking genus from Carolina. The last order, HEXAGYNIA, contains but one genus, of which there are only two species—the flowering rush of Britain, and the broad-leaved rush from Nepaul. The flowering



Monogynia.

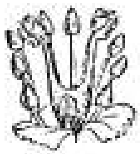


Hexagynia. Trigynia.

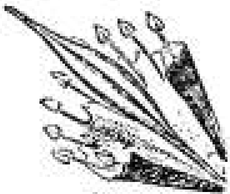
rush of Britain, *Butomus umbellatus*, is common in little ponds and ditches in many parts of this country, and is one of our most showy wild plants. The leaves are partly under and partly above water. The flower-stalk is elevated a foot or two in the air, and bears an umbel or tuft of very beautiful white flowers, often tinged with pink or blush-colour, and frequently entirely purple.

X.—DECANDRIA.

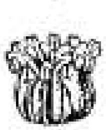
Flowers with ten stamens, and with one, two, three, five, or ten pistils; thus constituting five orders, and about ninety genera, many of the species of which are brilliantly flowering shrubs. In the first order, MONOGYNIA, we have the *Kalmias*, *Ledums*, *Rhododendrons*, *Andromedas*, &c. plants as generally admired as they are universally cultivated: we have also the arbutus, clethra, the fine aromatic scented storax tree, and many other exotics of the greatest beauty. In the order DIGYNIA we find the well-known *Hydrangea*, the extensive genus *Saxifrage*, and the equally extensive family of *Dianthus*, which include the carnation, pink, sweet-william, and other species and varieties of that favourite tribe. The order TRIGYNIA contains a great many plants which are allied to the *Dianthus* family. They are mostly slender annual weeds, though many are pretty, and a few ornamental. The catchflies, stitchworts, and sandworts, are all found here, and constitute the majority of the order. The fourth order, PENTAGYNIA, contains a good many plants, both native and foreign. The *Cotyledons* and *Oxalises* of the Cape of Good Hope, and the *Sedums* of Europe, are most numerous. The lychnis, mouse-ear, chickweed, and the common spurrey, are also placed here. The last order, DECAGYNIA, contains only one genus, and that a foreigner—namely, *Phytolacca*, of which there are nine or ten species.



Digynia.

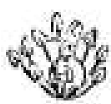


Monogynia.



Decagynia.

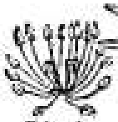
Pentagynia.



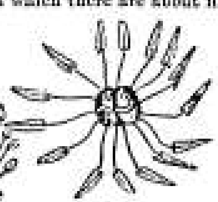
Trigynia.

XI.—DODECANDRIA.

There is no plant yet discovered with eleven stamens, and all those of this class have the number varying from twelve to nineteen. The pistils are either one, two, three, four, five, six, or twelve; thus constituting seven orders, in which there are about fifty genera.



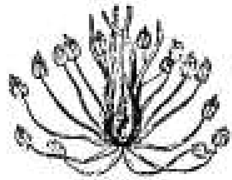
Trigynia.



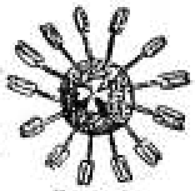
Digynia.

Monogynia.

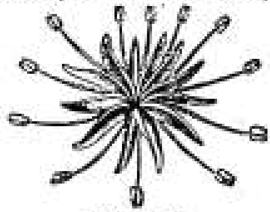
The first order, MONOGYNIA, among many fine tropical plants, includes the celebrated mangosteen, said to be the most delicious and wholesome fruit in the world. The garlic-pear, and the showy British plant which ornaments the banks of our rivers during summer, the *Lythrum salicaria*, also belong to this order. The second order, DIGYNIA, contains only two genera, of which the British plant agrimony, common on road-sides, is one. The third order, TRIGYNIA, contains the genus *Reseda*, some species of which (weld) are used by the dyer for producing a yellow colour; another species is the universal favourite, mignionette, *R. odorata*, cultivated entirely for its scent. The extensive *Euphorbia* or *Spurge* family also belongs to this order. The fourth, TETRAGYNIA, has only one genus—namely, the *Calligonum pallasia*, a native of the Caspian. The fifth order, PENTAGYNIA, contains three genera, of which the *Blackwellias* are the principal. They are all, except one, tropical shrubs. The order HEXAGYNIA contains a single genus—namely, *Cephalotus*—but that a very curious one; its leaves being formed into elegant pitchers, furnished with lids, like those of the *Nepenthes* or pitcher-plant. The last order, DODECAGYNIA, contains two nearly allied genera, one of which is the *Sempervivum* or house-leek, common on old walls and thatched cottages.



Pentagynia.



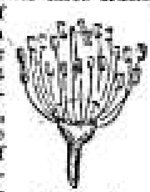
Tetragynia.



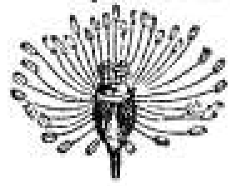
Dodecagynia.

XII.—ICOSANDRIA.

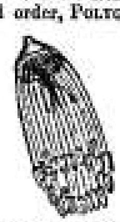
Flowers having twenty or more stamens seated upon the corolla or calyx. The situation, and not the number of the stamens, furnishes the characters of the class; they are also remarkable for rising directly from the calyx along with the corolla; the calyx is of one leaf, and hollow. The class is divided into three orders, comprising sixty genera, and is one of the most important of the Linnæan classes, as containing many of our most useful fruits, as well as most esteemed flowers. In the order MONOGYNIA we have the gorgeous *cacti*, *cereus*, *epiphyllum*, and *opuntias*; the myrtle, *eugenia*, and *eucalyptus*. Of fruits we have the guava, pomegranate, and several others. In the second order, DI-PENTAGYNIA—that is, plants having from two to five pistils—we have the pear, apple, quince, &c.; likewise the extensive genus *Mesembryanthemum*, of which there are three hundred and thirteen species. In the third order, POLYGYNIA, we have the rose, the strawberry, raspberry, and many others of great worth and beauty.



Monogynia.



Polygynia.

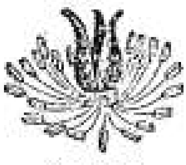


Di-Pentagynia.

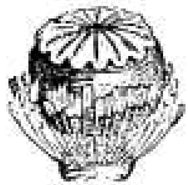
XIII.—POLYANDRIA.

Flowers having an unlimited number of stamens, distinct from each other, and seated on the receptacle.

There are six orders in the class, and one hundred and seven genera. The order MONOGYNIA comprises, among many others, the caper-tree, the well-known poppy, the curious sarracenia, and the magnificent water-lily. To this order also belongs the *Bixa orellana*, the red pulp of which is extensively used by dyers under the name

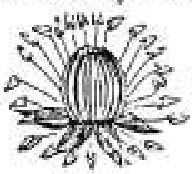


Di-Trigynia.

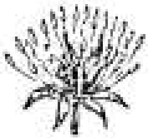


Monogynia.

of arnotta. The second order, DIGYNIA, is well typified in the splendid peony, a genus which has been lately much increased by new varieties, received from China and Siberia. The plants of this order have two pistils. The third order, TRIGYNIA, contains the beautiful larkspurs, the dangerous aconite, and the strong-scented *Hibbertia*. The fourth, TETRAGYNIA, contains only two genera—the butter-nut, a tropical fruit; and the *Drimys Winteri*, a tree allied to the magnolia. The fifth order, PENTAGYNIA, contains ten genera, of which the well-known columbine may be taken as a type. The last



Polygynia.

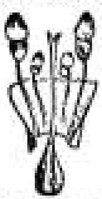


Pentagynia.

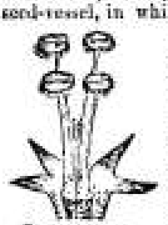
order, POLYGYNIA, includes a great many fine flowering plants, both shrubs and herbs; among the former, the magnolia is most conspicuous; among the latter, the anemone and ranunculus are confessedly beautiful. Of early or winter flowering plants, the aconite and hellebore are examples, and the globe-flower and marsh-marigold are showy plants.

XIV.—DIDYNAMIA.

The flowers of this class are generally ringent; they have four stamens, *two of which are superior;* and constitute two orders, under which are ranked one hundred and seventy genera. The flowers of the fourth class have also four stamens, but these are of equal lengths; while in this two are long and two short. The calyx also is of one leaf, and tubular, divided into five or two-lipped segments, which are unequal and persisting. The corolla is of one petal; the upper lip concave, and sometimes bifid, the lower lip trifid. In the first order, GYMNOSPERMA, the calyx is persisting, and becomes the seed-vessel, in which the seeds lie naked. In this order we find the germander, lavender, mint, and dead-nettle, and many others of similar character: several of them are useful in cookery. The order ANGIOSPERMA, so called because, though the stamens are the same in number and position, the seeds are differently disposed, being contained in a capsule. Many of the plants in this order are very beautiful; for instance, the bignonia, volkameria, antirrhinum, mimulus, &c. The common foxglove, *Digitalis purpurea*, so conspicuous in our hedge-banks, also belongs to this order, and is a good type of the whole. The seeds in the first order are four, situate at the bottom of the persisting calyx; in the second order they are numerous, and fastened to a filiform receptacle.



Angiosperma.



Gymnosperma.

XV.—TETRADYNAMIA.

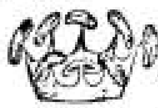
Flowers with six stamens, four of which are longer than the other two. Linnæus divided this class into two orders—SILICULOSA and SILIQUOSA; the former being a short roundish pod, and the latter a long one; but modern writers have discontinued this distinction, which is specific rather than generic. Many of the plants are dietetic—as the cabbage, turnip, radish, &c.; and some are finely scented and favourite flowers—as the wallflower, stock, arabis, rocket, &c. The seeds of several cruciferous plants yield oil of excellent quality. This is a truly natural class of plants, forming the *Cruciferæ* of Jussieu; great similarity of the flowers, seeds, &c. being observable throughout the whole of the

Stamens and Seed-vessels.

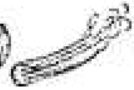
genera. The calyx is a four-leaved perianth, sepals concave, equal, and deciduous; corolla of four petals, claws inserted into the receptacle, limbs widening outwards, and assuming a cruciform direction; stamens six; filaments awl-shaped, the opposite ones shorter than the other four; anthers acuminate, often arrow-head shaped, diverging; pistillum germen superior, style short or wanting; stigma obtuse; seed vessel is a siliqua or silicula, of two valves opening at the base. The stigma is commonly persisting, and forms the apex of the dissepiment, which is prominent beyond the margins of the valves.

XVI.—MONADELPHIA.

The stamens are united into one set in this class, which is divided into eight orders, founded on the number of the stamens, not on that of the pistils, as in other classes; the whole containing one hundred and thirty-nine genera.



Octandria.



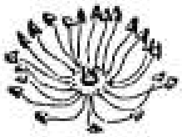
Heptandria.

Pentandria.

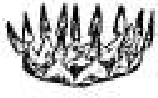
Triandria.

In the first order, TRIANDRIA, we find several beautiful Cape bulbs—as the *Ferraria*, *Tigridia*, *Herbertia*, &c. The flowers are not only of uncommon forms, but curiously spotted or streaked with dark colours. Of the second order, PENTANDRIA, the passion-flower is the most remarkable type. There is also the *Erodium* or heron's-bill, a section of plants formerly united with the geraniums. The third order, HEXANDRIA, contains but one genus, and is so distinct in itself, that it forms an order in the natural system. It is a bulbous-rooted plant, called *Gilliesia graminea*, having grass-like leaves and curious flowers. The fourth order, HEPTANDRIA, contains the pelargoniums, commonly called geraniums—a genus of plants unequalled for immense variety of forms and colours. Of pelargoniums there are above two hundred and thirty-eight species, and between three and four hundred varieties already enrolled in books. They are chiefly natives of the Cape of Good Hope, and have long held a distinguished place among our greenhouse plants. The fifth order, OCTANDRIA, contains only two genera, which have eight stamens, united in one set or brotherhood. The first genus is *Aitonia*, named by Linnæus in honour of the late William Aiton, Esq. royal gardener at Kew.

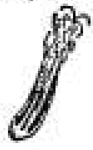
The second is *Conospermum*, hairy-seeded shrubs from New Holland. In the sixth order, DECANDRIA, we find



Polyandria.



Dodecandria.

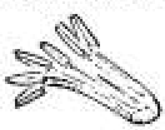


Decandria.

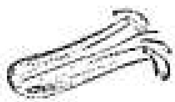
the true geraniums or crane's-bill. These are chiefly herbaceous plants, and found in many parts of the temperate latitudes. The herb-Robert is a common British plant, and is a good type of the genus. This order is, however, rich in showy plants of very differently-constructed flowers, called *papilionaceous*, or butterfly-shaped; their seed-vessels being pods. Hence we find here the crotalarias, the common furze, broom, genista, laburnum, rest-harrow, lupine, and many other beautiful plants, as well as trees, shrubs, and herbs. The seventh order, DODECANDRIA, comprises twelve genera, some of them highly ornamental, but they are all tropical plants. In the eighth order, POLYANDRIA, many of our gayest flowering plants are arranged—as the althea, lavatera, hibiscus, sida, silk-cotton-tree, the tea-tree, and its magnificent congener the camelia, now so common an ornamental favourite in British gardens. All the orders of this class are rich in fine flowering plants; and as a great majority of them were easily transported from the countries in which they were natives, a chief part of them has been long in cultivation in European collections.

XVII.—DIADELPHIA.

Flowers having two sets or brotherhoods of stamens. In general nine are united together, with a single one by itself, which is accounted the second brotherhood. The class contains one



Hexandria.



Pentandria.

hundred and twenty-nine genera, the flowers of which are chiefly butterfly-shaped. The first order, PENTANDRIA, contains only a single genus—namely, the *Monniera trifolia*, an African annual of no great beauty. The second, HEXANDRIA, contains six genera, of which the common weed fumitory is a good example. The third order, OCTANDRIA, comprises only four genera, of which the beautiful milkwort is the most numerous and conspicuous. The common one of this country is among the most interesting, and is found on chalk hills or other dry situations. The fourth

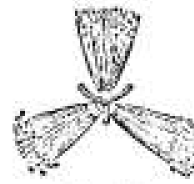
Decandria.

Octandria.

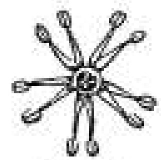
order, DECANDRIA, contains the greater number of the leguminous plants, or such as bear pods. They have all butterfly-shaped flowers, and comprise almost all our most useful kinds of pulse, forage plants, dyes, and many beautiful and valuable shrubs and trees. The pea, bean, tare, indigo, are examples of the order.

XVIII.—POLYADELPHIA.

This class contains all plants whose flowers have their stamens arranged in many brotherhoods. It is divided into two orders, embracing about twenty genera. The first order, DECANDRIA, has the flowers with ten stamens in several distinct bundles or sets. Here are only four genera, all tropical plants; among them we find the *theobroma*, which yields the useful chocolate nut. The second, POLYANDRIA, comprises plants whose flowers have many stamens in many distinct sets. This disposition of the parts on which



Polyandria.



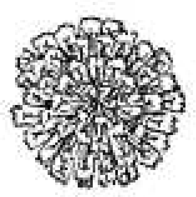
Decandria.

the order is founded, is exemplified in the St John's wort, a plant common in our fields as well as gardens; and in greenhouses the useful and beautiful fruit tree, the orange, affords a ready example.

XIX.—SYNGENESIA.

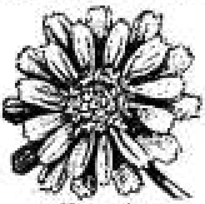
This class contains all the compound or composite flowers which form the natural order *Compositæ*. The meaning of the term *Syngenesia* signifies to generate together, the seed-bearing florets being all crowded together on the same base or receptacle; or, more probably, from the circumstance of the stamens being united in a cylinder, and surrounding the style near its apex. The peculiar arrangement by which syngenesious flowers are distinguished from all others is this, that besides the union of the anthers, the flowers or florets, instead of standing singly, are here congregated; instead of each having a calyx and receptacle, one calyx and one receptacle is common to the whole, whatever that number may be. The whole together is called the *flower*, as that of a daisy: the separate parts composing the disk of it are called *florets*. The flower is supported on its exterior by a number of scale-like leaves, by some called *calyx*, but by others *anthodium*, and mostly attached to the outer rim of the receptacle, which bears the florets on its upper surface. The florets, however, are not always perfect in themselves; some of them are of two sexes, others male, or female, or neuter. On the difference of these in position and character, the orders of the class are founded. The florets have a calyx which is superior, and becomes the crown of the seed; a corolla which is of one petal and superior; the limb campanulate or ligulate; stamens five, filaments inserted into the tube of the floret; anthers united by their margins in all bisexual florets; germen inferior, being a naked seed crowned with the other parts; style erect; stigma in two parts, each revolute and divergent; seed single, either naked or crowned with the calyx, or with a pappus to assist the dispersion. The dandelion and thistle are familiar examples. This class contains two hundred and seventy-seven genera, and upwards of two thousand six hundred and fifty species.

Superflua.

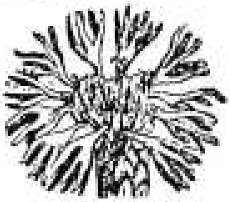


Æqualis.

The first order is ÆQUALIS, in which all the florets are of two sexes. It is very extensive, and contains many very common plants, as the sowthistle, lettuce, hawkweed, burdock, artichoke, &c. The majority of them are herbs, and many are annuals. The second order is SUPERFLUA; here we find plants, the flowers of which have the florets of the disk bisexual, and those forming the rays female, but which are impregnated by the anthers of the disk. This circumstance was considered by Linnæus as superfluous; hence the title. This is also a very large order, and contains many useful as well as beautiful plants. Of the first, tansy and chamomile are examples; of the second, the helichrisums, xeranthemums, and dahlias. The third order is FRUSTRANEA, so called because the florets of the disk are bisexual, and those in the ray or margin neuter. These last, having sometimes the rudiments of a pistil, but no other sexual organ, are said to be ineffectual or frustrated polygamy. The type of the order is the splendid sunflower, with which many of the same style of flowering plants are arranged, such as the rudbeckia, coreopsis, &c. The fourth

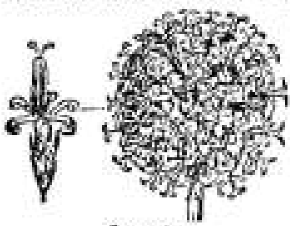


Necessaria.



Frustranea.

order is called NECESSARIA, because the florets of the disk, or centre of the flower, being all male, it is necessary that those of the ray or margin should be female, in order that there may be perfect seed. Calendula and arctotis, exotics chiefly from the Cape of Good Hope, are two of the most conspicuous genera. The fifth order is called SEGREGATA, because the florets have each its proper calyx (different from the perianthe of the floret), besides the common anthodium or exterior calyx; or there are several florets contained in each calyculus. All the plants in this order are exotic herbs and under shrubs, the globe-thistle being the most common in British gardens.



Segregata.

To the above five orders Linnæus added a sixth, called MONOGAMIA, in contradistinction to the others, which are polygamous. The plants which stood in this were such as had their stamens united, as in the other orders of the class, but had simple flowers, not aggregated florets. The genus *Lobelia* was one, but which is, as well as all the others (except one), now placed in the class *Pentandria Monogynia*.

XX.—GYNANDRIA.

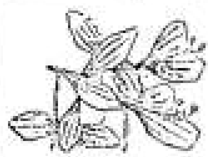
This class contains plants which have their stamens seated upon the pistillum, and comprises one hundred and ten genera. The species are generally herbaceous, with tuberous roots, curious gouty or climbing stems; many are epiphytes growing on trees, or flourishing in rotten vegetable matter in moist places. Some of their flowers are splendid, many highly fragrant, and all of remarkable conformation. The class is divided into

Hexandria. Diandria. Monandria.

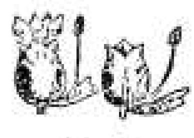
three orders. The first, MONANDRIA, contains plants having one anther seated on the pistillum, and comprises some of the most attractive wild British plants—as the orchis, ophrys, epipactis, &c. These, however beautiful, are excelled by those of the same tribe from America and other parts of the world. In the second order, DIANDRIA, which has flowers having two anthers seated on the pistillum, we find one of the greatest British beauties—namely, the ladies'-slipper, found in damp woods, particularly in the north of England. The third order, HEXANDRIA, containing plants which have six stamens seated in the pistil, has only one genus—namely, the *Aristolochia*, or birthwort, a very curious family of climbing exotics; one only being found in Britain—namely, the *A. clematis*.

XXI.—MONŒCIA.

This class consists of plants which have male and female flowers separate but on the same root, and contains ten orders, and one hundred and forty-seven genera. It may here be observed, that in syngenesious flowers the unisexual florets stand separately, but are included in the same cover; here they also are separate, but in distinct covers. The first order, MONANDRIA—that is, separate male flowers bearing one stamen—comprises five genera, one of which is the celebrated bread-fruit, tree, a native of the South Sea Islands. The only British genus arranged here is the *Zannichellia palustris*, the common pond-weed. The second order, DIANDRIA, having distinct male flowers bearing two stamens, contains only four genera, three of them exotic, and one British—namely, the common

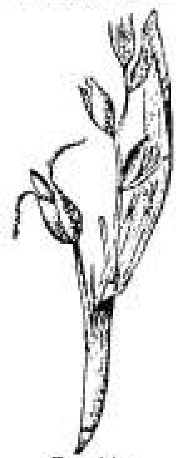


Diandria.

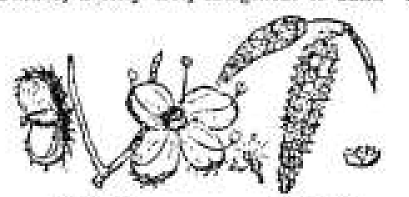


Monandria.

duckweed. The third, TRIANDRIA, consisting of plants having separate male flowers bearing three stamens, embraces a few tropical trees, and a great many coarse European grass-like plants. The cat's-tail and bur-reed are common aquatics, found in many parts of Britain. The maize, or Indian corn (*Zea*), also ranks in this order. The fourth, TETRANDRIA, includes all plants whose separate male flowers have four stamens—as the alder and birch; the box and mulberry; the common nettle; and the well-known foreigner *Aucuba japonica*. The fifth, PENTANDRIA, contains all monœcious plants whose male flowers bear five stamens. The amaranthus is most conspicuous here. The sixth, HEXANDRIA, has separate male flowers, furnished with six stamens. Its members are chiefly palms, or allied to that tribe—as the cocoa-nut, sago palm, and acrocomia. The seventh order, OCTANDRIA, has separate male flowers, bearing eight stamens, and contains only one genus, the *Dacrium*, a lofty tree, indigenous to Chili. The



Triandria.

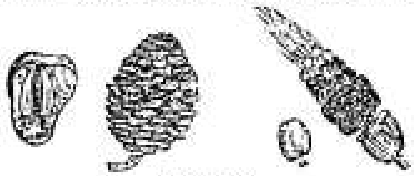


Pentandria. Tetrandria.

eighth order is ICOSANDRIA, containing plants which have male flowers separate, and bearing many stamens inserted into the calyx. Botanists have as yet discovered only one genus which can with propriety be placed here, and this is a tree from New Holland,

Polyandria. Hexandria.

called *Atherosperma moschata*. The ninth order, Polyandria, contains plants whose male flowers are separate, and which bear many stamens seated on the receptacle. It is a large order, and comprises the beautiful *Begonia*, the chestnut, beech, hazel, walnut, and, above all, the

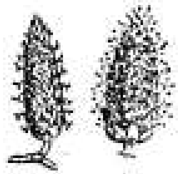


Monadelphia.

oak. The tenth, Monadelphia—plants having male flowers distinct, and whose stamens are united at the base into one brotherhood—is the most extensive, and contains some of the most magnificent forest trees—as the pines and firs, larch, cedar, cypress, &c. Here are also the gourd, melon, and cucumber, the poisonous janipha manihot, and the medicinal palma Christi.

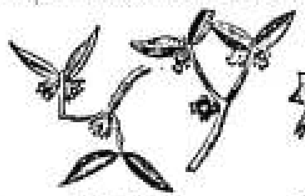
XXII.—DIŒCIA.

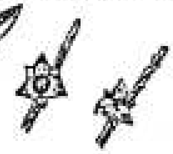
This class is composed of plants which have unisexual flowers, not on the same but on different roots. It is divided into as many as thirteen orders, and embraces upwards of one hundred genera. The first order, Monandria, consists of plants bearing unisexual flowers on different roots, those of the male plant having but one stamen. It contains only two genera, one being the remarkable screw-pine: so called because the leaves resemble those of the pine-apple, only much larger, and they issue from the stem in a very different manner; that is, neither opposite nor alternately, but the last always a little to the left of the former, so that they are expanded spirally like the worm of a screw.



Diandria. Monandria.

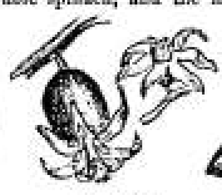
The second order, Diandria, contains plants having unisexual flowers on different roots, the males bearing two stamens, and comprises four genera, of which the common willow is the principal; there being of this genus no less than 167 species already described. The third, Triandria—having male flowers on one plant, and females on another, the former being furnished with three stamens in each—contains twelve genera, among which one is a common trailing plant, found on our moist moors—namely, the crow-berry. The date-palm, so useful to the people in Persia, and other countries where it grows naturally, belongs to this order. The fourth, Tetrandria, consists of plants having flowers of one sex, but on distinct roots. The male plants have four stamens in each flower. This order contains fifteen genera, among which we find the candle-berry myrtle, one species of which is found wild in Britain—namely, the sweet-gale. It includes the mistletoe, common in England on oak-trees, white-thorn, and particularly in apple orchards. The fifth





Tetrandria. Triandria.

order is Pentandria, the male plants of which bear flowers having five stamens. It contains thirteen genera, among which are the well-known culinary vegetable spinach, and the no less valuable hop. The

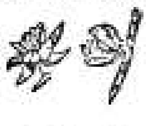


Hexandria. Pentandria.

sixth order, Hexandria, bearing male flowers, having six stamens, comprises seventeen genera, among which are six palms, some of them of stately growth, and highly ornamental in their native countries. The genus *Smilax* is also here, some of the species of which yield medical drugs. The only British genus is the

Enneandria. Octandria.

black bryony. Order seven is Octandria, the males of which have flowers furnished with eight stamens. The only genus is the poplar, four species of which are natives of Britain. The eighth, Enneandria, the male plants of which bear flowers having nine stamens, contains only three genera, two of which, the mercury and frog-bit, are British. The third, triplaris, is an American tree, useful for its timber. The ninth order,



Dodecandria. Decandria.

Decandria, the male plants of which have ten stamens, contains five genera, all of which are exotics. One of the principal is the papaw, a large tree-like herb, bearing bunches of fruit resembling melons, much used in India. The tenth order, Dodecandria, the male plants of which are furnished with twelve stamens, contains six genera; among them we find only one British, an aquatic, called the water-soldier (*Stratiotes*). Another is the menispermum, or moon-seed, which, with all the others, is exotic. The eleventh order is Icosandria, the male plants of which bear flowers having above twelve stamens inserted in the calyx. There are only three genera, none of which are British. Order twelve is Polyandria, the male plants of which are furnished with many stamens, fixed on the receptacle. It contains seven genera, all of which are exotics. Here we find *Cliffortia*, a genus common in our green-houses. Also *Cycas* and *Zamia*, plants of a singular character, to be met with in most

Polyandria. Icosandria.

collections. The last order of the class is MONADELPHIA, the male plants of which bear flowers, in which the stamens are united in one brotherhood. It comprises fifteen genera, of very various bulk and manner of growth. Here are the magnificent Bourbon palm, the lofty and symmetrical araucaria, the humble butcher's-broom, the juniper, the yew, the nutmeg, and the curious pitcher-plant.

Monadelphia.

XXIII.—POLYGAMIA.

The class POLYGAMIA (a word signifying many marriages) is composed of plants having both unisexual and bisexual flowers on the same or on different roots. There is considerable uncertainty about the arrangement of this division, because some of the genera are not always constant in their modes of flowering; and even single plants will occasionally exhibit all the characters by which the different orders are distinguished. The class is now divided into two orders, and contains about seventy genera.

The first order, MONŒCIA, comprises plants in which the polygamy is complete on one root—that is, where there are male flowers having stamens only, female flowers having pistils only, and flowers in which the stamens and pistils are united. This is a very extensive order, and contains many highly beautiful as well as useful plants. Here are the mimosas, the acacias, the maples, the beautiful ailantus, and the mango. There are also a good many of the grasses in this order.

Diœcia.

The second order, DIŒCIA, contains plants which have the polygamy complete on two different roots. There are eighteen genera, among which are the ash, so useful for its timber, the bread nut, the anacardium, and the numerous family of the fig.

XXIV.—CRYPTOGAMIA.

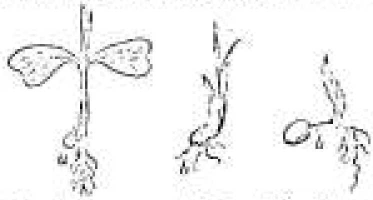
The class *Cryptogamia* (a term signifying hidden marriages) is divided into nine orders, and contains nearly four hundred genera. It is sometimes called *Agamia*, a term implying the absence of the usual organs of fructification which distinguish the flowering or Phænogamous classes. The orders are—FILICES, ferns; EQUISETACEÆ, horse-tails; LYCOPODIACEÆ, club-mosses; MUSCI, the true mosses; MARSILIACEÆ, pillworts; HEPATICÆ, liverworts; LICHENES, lichens; FUNGI, mushrooms; ALGÆ, sea-weeds—all of which form very natural and well-defined families under the Jussieuan arrangement, and whose structural peculiarities have already been adverted to under the head of VEGETABLE PHYSIOLOGY.

THE NATURAL SYSTEM.

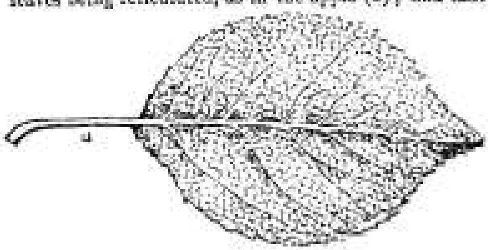
"The Natural System of Botany," says Dr Lindley, "being founded on these principles—that all points of resemblance between the various parts, properties, and qualities of plants shall be taken into consideration; that thence an arrangement shall be deduced in which plants must be placed next each other which have the greatest degree of similarity in these respects; and that, consequently, the quality of an imperfectly-known plant may be judged of by that of another which is well known—it must be obvious that such a method possesses great superiority over artificial systems, like that of Linnæus, in which there is no combination of ideas, but which are mere collections of isolated facts, having no distinct relation to each other. The advantages of the Natural System, in applying botany to useful purposes, are immense, especially to medical men, who depend so much upon the vegetable kingdom for their remedial agents. A knowledge of the properties of one plant enables the practitioner to judge scientifically of the qualities of other plants naturally allied to it; and therefore the physician acquainted with the natural system of botany, may direct his inquiries, when on foreign stations, not empirically, but upon fixed principles, into the qualities of the medicinal plants which have been provided in every region for the alleviation of the maladies peculiar to it. He is thus enabled to read the hidden characters with which Nature has labelled all the hosts of species which spring from her teeming bosom. Every one of these bears inscribed upon it the uses to which it may be applied, the dangers to be apprehended from it, or the virtues with which it has been endowed. The language in which they are written is not indeed human: it is in the living hieroglyphics of the Almighty, which the skill of man is permitted to interpret. The key to their meaning lies enveloped in the folds of the natural system, and is to be found in no other place." Such a system as is here eloquently delineated, we aim at rather than possess. All the modifications—and they are neither few nor unimportant—of Jussieu's original plan which have been promulgated, are merely contributions to one great end; and years of patient research, crowned by the most extensive powers of generalisation, must elapse before botany can boast of a perfect system. Passing, then, numerous recent suggestions, British and continental, we shall adhere in our brief exposition to that modification of the natural system which seems most applicable to botanical works now in current circulation; and which perhaps is better adapted than any unestablished innovations to convey to the reader a general idea of its principles of classification.

According to the original system of Jussieu, all the known plants were arranged into a hundred Orders, beginning with the *Fungi*, and mounting upwards to the *Coniferæ*; and these Orders were divided into three great Classes—namely, the ACOTYLEDONS, or plants without any cotyledon in the seed; the MONOCOTYLEDONS, plants with one cotyledon; and the DICOTYLEDONS, those with two or more cotyledons. The Acotyledonous plants were not subdivided; but the Monocotyledons were arranged into sub-classes, according as the stamens were *hypogynous*, or growing from under the pistil; *perigynous*, or growing away from the pistil; and *epigynous*, or growing on the pistil. The Dicotyledons were divided into the *apetalous*, or those without petals; the *monopetalous*, those with one petal; and the *polypetalous*, those with several petals: and these again were subdivided, according to the position of the stamens with regard to the pistil, in the same manner as the Monocotyledonous plants. To these were added what Jussieu called *Diclines*, or separated unisexual flowers, which included plants some of the flowers of which had only pistils, and others only stamens. The fault of this system, like that of Linnæus, was that it associated individuals dissimilar in their nature; the classification depending on one peculiar feature more than on the general appearance, qualities, and habits of the plant.

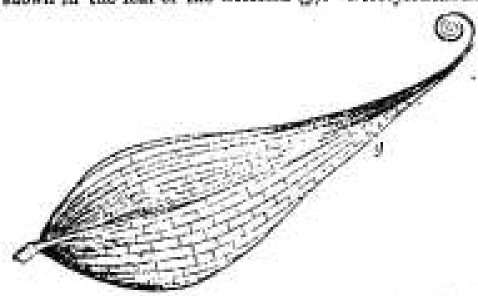
The system of Jussieu, as improved by Decandolle, cannot strictly lay claim to the term natural, as it depends principally on the number of cotyledons in the seed, and on the position of the stamens with regard to the pistil. Decandolle at first made 161 Orders; but these were afterwards greatly increased, and now some botanists enumerate as many as between 270 and 280. The first grand division of Decandolle, like that of Linnæus, is into the Flowering and Flowerless plants, which he designates respectively the *Vasculares* and the *Cellulares*. This division, however, is not absolutely correct; for although all the flowering plants contain vascular tissue, and the flowerless consist principally of cellular tissue, yet spiral vessels and ducts have been found in the ferns and club-mosses, and may possibly exist in others. The *vasculares* and *cellulares* of Decandolle may be considered as equivalent to the *Phænogamia* and *Cryptogamia* of the older botanists. His second division depends upon the cotyledons in the embryo; and, like Jussieu, he divides the flowering plants into DICOTYLEDONS, or those with two or more cotyledons or seed leaves, as *a*; MONOCOTYLEDONS, those which have only one seed leaf (*b b*); and ACOTYLE-



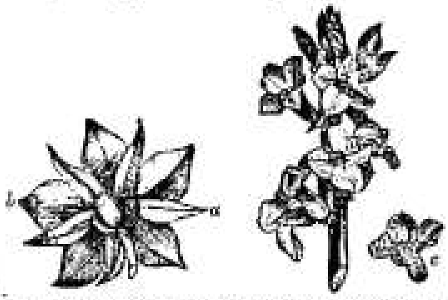
DONS, those having no seed leaf, and, in fact, no seeds—such as the Cryptogamia. The differences between these three divisions are very great, and spread through every part of the plant; but they are particularly conspicuous in the leaves—the venation of Dicotyledonous leaves being reticulated, as in the apple (*a*); and that



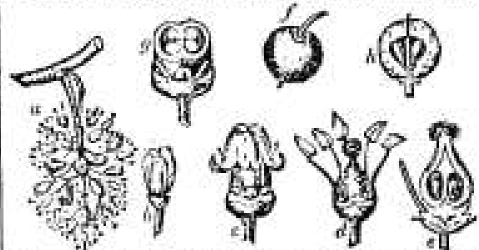
of Monocotyledonous being chiefly in parallel lines, as shown in the leaf of the Gloriosa (*g*). Dicotyledonous



trees are said to be *Exogenous*, from the fact of their trunks increasing by external layers; Monocotyledonous ones, *Endogenous*, on account of the enlargement taking place from within; and Acotyledonous trees, *Acrogenous*, because the increase takes place only at the top or growing-point. Dicotyledonous plants are again divided into the *Dichlamydeæ*, or those with two floral envelopes—that is, having a separate calyx (*a*) and corolla (*b*); and the *Monochlamydeæ*, or those having only one floral envelope, which is always called the calyx, as in the detached floret of the evergreen (*c*). These distinctions, however, are of comparatively little value, as many plants in the first division have no corolla, but simply a coloured calyx.

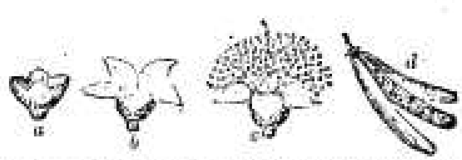


The *Dichlamydeæ* are farther divided into three subclasses:—I. *Thalamifloræ*, in which the stamens and petals are all inserted in the receptacle, as represented in the accompanying dissection of the common vine.



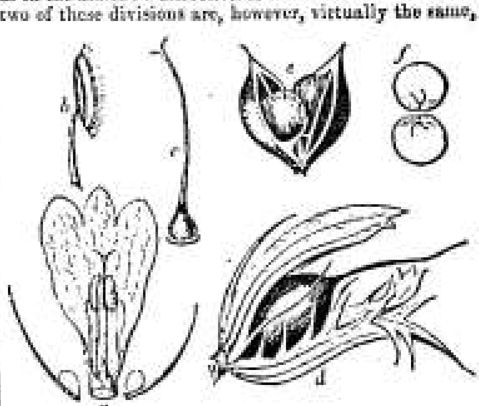
Vine.—*a*, bunch of flowers; *b*, flower before expansion; *c*, flower expanding; *d*, stamens, pistil, and germ; *e*, vertical section of the pistil and germ; *f*, fruit; *g*, horizontal section of the ovary; *h*, vertical section of the fruit, showing the position of the seed.

II. *Calycifloræ*, in which the stamens and petals are said to be inserted in the calyx, as shown in the subjoined dissection of one of the acacias. III. *Corolli-*



Acacia.—*a*, calyx; *b*, corolla; *c*, full flower; *d*, seed-pod open.

floræ, in which the stamens are inserted in the petals, as in the annexed dissection of the acanthus. The first two of these divisions are, however, virtually the same,

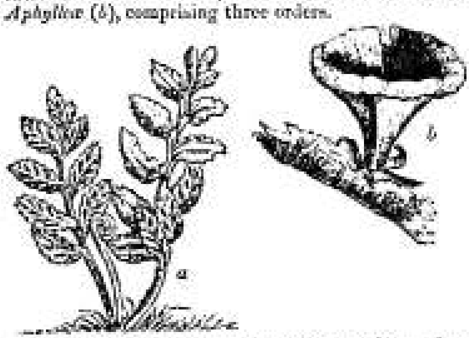


Acanthus.—*a*, corolla opened, showing the stamens and pistil; *b*, one stamen; *c*, pistil; *d*, ripe seed-vessel, covered with its calyx and bracts; *e*, seed-vessel burst previously to shedding its seeds; *f*, seed opened, showing the radicle and plume.

as in the second the stamens are inserted not in the calyx itself, but in the dilated receptacle which lines the calyx. The third division is, on the other hand, quite distinct, as the plants belonging to it have their petals united at the base, below the ovary, and the stamens are really inserted in the fleshy part of the petals. The first two of these sub-classes contain about sixty orders each, while in the third there are only about thirty orders. The *Monochlamydeæ* are those having only one floral envelope; they consist of about thirty orders, and are not subdivided.

Monocotyledonous plants are divided into those with petals, called *Petaloideæ*, which consist of about thirty orders; and those with glumes like the oat, *Glumaceæ*, which contain only two orders. The *Flowering*, or *Phanerogamous* orders, now generally admitted, amount therefore to about two hundred and twelve.

Flowerless, or *Cryptogamous* plants, are divided into two classes—those with leaves, *Foliaceæ* (*a*), of which there are seven orders; and those without leaves, *Aphyllæ* (*b*), comprising three orders.



The distinctions between the orders are drawn from the number of petals, sepals, and stamens, whether the stamens are hypogynous, epigynous or perigynous; the construction of the anthers, and the manner in which they burst; the construction of the seed-vessel and of the seeds with the position of the embryo; the position of the leaves, whether alternate or opposite, or with or without stipules; and the general habits and properties of the plants.

Having thus explained the basis of arrangement, we shall now proceed to consider the orders—premising that while the whole are tabulated, our space will only permit us to detail a few of the more interesting and important. This, however, we shall endeavour to do in such a manner as may at once present an outline of the System, and render the reader familiar with the phraseology and plan of procedure.

§ THALAMIFLORÆ.

Ranunculaceæ—Crowfoots
Dilleniaceæ—Dilleniads
Magnoliaceæ—Magnoliads
Anonaceæ—Anonads
Menispermaceæ—Menispermads
Berberidaceæ—Berberids
Cabombaceæ—Water-shields
Nymphæaceæ—Water-lilies
Sarraceniaceæ—Sarraceniads
Papaveraceæ—Poppyworts
Fumariaceæ—Fumeworts
Cruciferæ—Crucifers
Resedaceæ—Weldworts
Datiscaceæ—Datiscads
Capparidaceæ—Capparids
Flacourtiaceæ—Bixads
Cistaceæ—Rock-roses
Violaceæ—Violetworts
Droseraceæ—Sun-dews
Polygalaceæ—Milkworts
Tremandraceæ—Poreworts
Pittosporaceæ—Pittosporads
Frankeniaceæ—Frankeniads
Caryophyllaceæ—Cloveworts
Linaceæ—Flaxworts
Malvaceæ—Mallowworts
Bombaceæ—Silk-cottons
Byttneriaceæ—Byttneriads
Tiliaceæ—Lindenblooms
Elæocarpeæ—Elæocarps
Dipteraceæ—Dipterads
Chlænaceæ—Chlænads
Ternstrœmiaceæ—Theads
Olacaceæ—Olacads
Aurantiaceæ—Citronworts
Hypericaceæ—Tutsans
Guttiferæ—Guttifers
Hippocrateaceæ—Hippocrateads
Marcgraviaceæ—Marcgraviads
Erythroxyleæ—Redwoods
Malpighiaceæ—Malpighiads
Aceraceæ—Maples
Hippocastanaceæ—Horse-chestnuts
Rhizobolaceæ—Rhizobols
Sapindaceæ—Soapworts
Meliaceæ—Meliads
Cedrelaceæ—Cedrelads
Vitaceæ—Vineworts
Geraniaceæ—Cranesbills
Tropæolaceæ—Indian Cresses
Limnantheæ—Limnanths
Balsaminaceæ—Balsams
Oxalidaceæ—Oxalids
Zygophyllaceæ—Bean-capers
Rutaceæ—Rueworts
Simarubaceæ—Quassiads
Ochnaceæ—Ochnads
Coriariaceæ—Coriariads

RANUNCULACEÆ—CROWFOOTS.

The plants constituting this order are herbs, or rarely shrubs, with deeply-cut leaves and stem-clasping petioles. The majority of the species are hardy, and all abound in an acrid poisonous juice, as is well exemplified in the common buttercup of the meadows—*Ranunculus acris*—from which the order takes its name. They are very irregular in their flowers; many of them having merely one floral envelope, and others having a coloured calyx, with only very small and inconspicuous petals. When the flowers are regular—that is, when they have both a calyx and a corolla—the latter has generally five petals, and the calyx five sepals, though the number of the petals sometimes varies from three to fifteen. There are numerous stamens which grow from beneath the pistil, and are always separate, having their anthers bursting outwardly. The seeds are for the most part contained in several carpels which grow close together, but are either quite distinct or so slightly united as to be easily separated with a pin. The embryo is very small, and placed at the base of the albumen, which is either fleshy or bony. In consequence of the irregularity of their flowers, the Ranunculaceæ are somewhat perplexing to the learner, though they may be generally known by their numerous distinct stamens springing from below the pistil, and by their distinct carpels, which frequently grow in several whorls round an elevated receptacle, as in the crowfoot and *Flos Adonis*. The calyx generally falls off with the petals, but in the peony it remains till the seed is ripe. The carpels are in many cases only one-seeded, and are sometimes winged, as in the anemone and clematis, in order to scatter the seeds, as the carpels in this case do not open naturally, but fall with the seed. It is owing to this circumstance that the seeds of many of the members are so retentive of their vitality, and lie so long in the ground before germinating, as may be remarked of the *Flos Adonis*. Sometimes, however, the carpels are many-seeded, and open naturally when ripe, as in the peony, the larkspur, the columbine, &c.

The principal genera—and which lie within the examination of every one—are the Ranunculus and Peony, having regular flowers and two floral envelopes; the Anemone, the Hepatica, the Christmas Rose, and the winter Aconite, which have regular flowers, but generally only one floral envelope; and the Larkspur, Monkshood, and Columbine, which have irregular flowers. The Clematis is one of the few shrubby plants belonging to the order; it has regular flowers, and generally only one floral envelope.

The Ranunculaceæ are of little economical importance, in consequence of their usually poisonous qualities, as evinced by the aconite and hellebore in particular; though a few are simply astringent, as the Coptis trifolia, or gold-thread, of North America. The juice of the whole order is acrid, the roots of many intensely bitter, and the bark of a few tonic and bitter. The seeds of the Nigella are aromatic, and were formerly used as pepper; but those of all the other genera are poisonous, unless husked. The flowers of some are objects of great beauty—as the larkspurs, ranunculuses, anemones, peony, and columbine.

PAPAVERACEÆ—POPPYWORTS.

This order consists of very handsome herbaceous plants, annual and perennial, and a few under shrubs, most of which are natives of the temperate parts of Europe and Asia. The leaves are alternate, sometimes deeply cut, and without stipules. The flowers are solitary, elevated on long peduncles, showy, and usually white, yellow, or red; and the bud in all, except the large scarlet Eastern poppies, is shrouded in only two sepals, which fall off as soon as the flower expands. The Oriental species have three sepals, and one of them (*Papaver bracteatum*) has two large bracts which remain after the flower has expanded, and form a kind of calyx, though the real calyx has dropped off. There are generally four petals, or a multiple of four, which are crumpled in the bud, and soon fall off. The stamens are very numerous, inserted in four or more parcels beneath the pistil (*a*). The ovary is solitary, forming, when green, a capsule which consists of several carpels grown together and enclosed in the dilated fleshy receptacle which rises round them; stigmas generally stellate on the flat apex of the ovary. Notwithstanding the fleshy ovary, the fruit is a dry capsule, with only one cell, the divisions between the carpels having disappeared. The seeds are numerous, have a minute straight embryo, imbedded in albumen between fleshy and oily, and become loose in the capsule when they are ripe. Before the seeds are ripe, the walls of the capsules become as hard as a shell; and the stigmas, which have grown together, and become equally hard, form a star-shaped lid for the capsule (*b*). Under this there are a set of valves that open for the discharge of the seed.

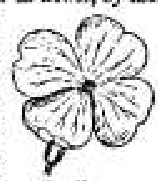
P. somniferum.

The genera most common in Britain are—*Papaver*, the poppy, of which there are twenty-five species; *Argemone*, the prickly poppy; *Meconopsis*, the Welsh poppy; *Sanguinaria*, blood-root; *Glaucium*, horned poppy; *Chelidonium*, greater celandine or swallow wort; *Eschscholtzia*; *Hunnemania*; *Romeria*; *Hypecoum*; *Platystemon*; and *Platystigma*. In the horned poppy, which is common on the south-east coast of England, the seed-vessel is formed of only two carpels grown together, which look like a pod; and when ripe, from their length and stiffness, bear a considerable resemblance to horns; hence the name. The botanical term *glaucium* alludes to the extreme glaucous hue of the plant. The greater celandine has a seed-vessel like a pod; and its juice, as well as that of the prickly poppy, is yellow—the juice of the others being white. In the Eschscholtzias the sepals do not separate; but becoming detached at the base, they retain the shape of a hood or extinguisher, till pushed off by the expansion of the corolla. The capsules of the Eschscholtzias are elongated, and are easily known by the large fleshy projection at their base. Though treated as annuals, they have large flesh roots, which render them difficult to be removed unless when quite young. The plants of the order are easily detected by their general resemblance to each other, especially in their flowers, with the exception perhaps of the celandine, the flowers of which are small.

All the Poppyworts abound in a thick glutinous juice, which poisons by stupifying. All parts of the plant furnish more or less this milky sap, but the main supply is derived from the unripe seed-vessels. When in a green state, those of the large white poppy (*P. somniferum*) are slightly wounded with a knife, which causes the juice to exude freely; and on exposure to the air, it concretes or becomes inspissated. In this state it forms crude or lump opium, which, dissolved in spirit of wine and filtered, produces the laudanum of the shops. Chemically, opium consists of an insoluble gum, a small quantity of resin, and caoutchouc. Its effects on the animal system depend upon two alkaline principles which it contains—namely, morphia and narcotine; the former producing a sedative, and the latter a stimulating effect. It is curious that the seeds possess none of the stupifying properties of the plant, but is mucilaginous and oily, and may be eaten with impunity. The seeds of one species, however (*Argemone Mexicana*), are said to be narcotic, especially when smoked; but it is probable that in this case the opiate resides in the coating of the seed rather than in the albumen.

CRUCIFERÆ—CRUCIFERS.

This is one of the most extensive and important of the natural orders. Most of the genera are herbaceous annuals and perennials, only a few are shrubby. The leaves are alternate, and the flowers are produced in corymbs or racemes. The flowers are regular, with a calyx of four sepals, and a corolla of four petals, disposed in the form of a Maltese cross: hence the name *Cruciferæ*, or cross-bearing. There are six stamens, two much shorter than the others, as shown under the Linnæan class, *Tetradynamia*. The pods open naturally when ripe, the valves curling outwards. The seeds have no albumen, and the cotyledons are curiously folded down on the radicle. There can be no difficulty in recognising a cruciferous plant when it is in flower, by the cross-form of its corolla, as in the adjoining figure, and its six stamens, two of which are shorter than the others; besides, it has a permanent distinction, in having the pods equally divided. Even when it has neither flowers nor seeds, a plant of this order may be known by its straggling habit of growth and its pungent taste.



Crucifer.

Among the more common genera may be mentioned *Brassica*, including all the cabbages; *Cheiranthus*, the wall-flower; *Mathiola*, the stocks; *Iberis*, the candytuft; *Isatis*, the woad; *Cochlearia*, the horse-radish; *Sinapis*, the mustard; and many other well-known plants. Most of them are natives of Europe; but plants of the order, which contains about 170 genera, are found in every part of the world.

The properties of the Crucifers are antiscorbutic and stimulant, combined with an acrid flavour, and the seeds of many abound in a fixed oil: properties of which the common cress, mustard, and rape may be taken as examples. Most of them form articles of human food, and are valuable not only for their antiscorbutic properties, but from the fact that they contain a large amount of nitrogen, and therefore supply the place of butcher-meat better than any other vegetable. It is this gas that occasions them to have so unpleasant a smell when decaying, as may be experienced in the case of the common cabbage. The flowers of the order are most commonly yellow or white, though some, as the Virginian stock (*Malcomia maritima*), have pink and reddish colours.

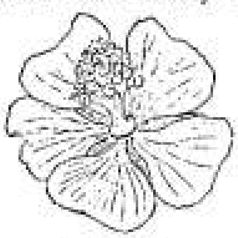
LINACEÆ—FLAXWORTS.

A very small order, formerly included in *Caryophyllaceæ*, but differing in the stems not being swollen at the joints, in the leaves being not usually opposite, in their being void of stipules, and in their presenting no traces of volatile secretion. The flowers are in five parts, like those of the cloveworts; but the sepals of the calyx are always distinct, and instead of being arranged in a regular whorl, two are placed a little lower than the others, as in the *Cistaceæ*. The stamens are united at the base into a cup, which has five little teeth peeping up between the stamens. The ovary has five styles and stigmas; but the seed-vessel splits into ten valves, each carpel containing two seeds, separated by an obscure partition, which gives the carpels the appearance of being only one-seeded. The seeds are flat and shining, with a large embryo.

The only genera are Linum and Radiola; the former comprehending many species, of which the common flax (*L. usitatissimum*) is the most important and best known. Flax will grow in almost any part of the world; and though but an annual, its stem contains so much woody fibre that it is exceedingly tough and durable. This external coating of tough fibre, and the peculiar construction of the flower, are amongst the most obvious distinctions of the tribe, though only one or two of the members yield fibre sufficiently strong for economical purposes. This fibre, separated from the stem by maceration and bleaching, produces the flax of commerce, so extensively used in the manufacture of linen, thread, and cordage. The seeds contain a great quantity of oil—*linseed oil*—which is obtained from them by pressure, and the refuse forms *oil-cake*, employed by farmers in feeding cattle. The seeds also abound in mucilaginous matter, and are thus made use of medicinally, for coughs, &c.; or, when ground into meal, for poultices. Though at one time pretty extensively grown in Britain, our manufacturers now derive the greater part of their supplies from the countries adjoining the Baltic, from which, in one year, not less than 70,000 tons of flax, and about 2,000,000 bushels of linseed, have been imported. The valley of the Nile, anciently celebrated for its fine linen, now yields but an inconsiderable quantity, in consequence of the present barbarous condition of the inhabitants.

MALVACEÆ—MALLOWWORTS.

This is a very marked and natural order, all the plants belonging to it bearing a striking resemblance to each other, and remarkable for their large showy flowers. The petals and sepals are both five in number, but the calyx has three bracts on the outside, which are frequently so near to it as to have the appearance of a second calyx below the true one. Estivation twisted. The most remarkable part of the flower is the central column, and this is so decided, that a botanist is always able to recognise one of the Malvaceæ at first sight. This column is formed by the filaments of the stamens growing together, so as to leave only a small portion just below the anthers free, as is seen in the flower of the marsh-mallow—the lower portion forming a tube round the pistil. The anthers themselves are also peculiar: they are one-celled, kidney-shaped, and burst transversely. This peculiar construction of the stamens may be observed distinctly in the common mallows, the Lavateras, the hollyhocks, and, in short, in all the genera belonging to the order; and thus no malvaceous plant can ever be mistaken by any one in the least acquainted with botany. The styles also grow together, as may be seen when the stamens are removed; and the carpels, which are of the same number with the styles, form what children call "mallow cheeses." The carpels are one or many seeded, sometimes closely united, sometimes separated or separable; fruit capsular or baccate. Most of the species are herbaceous plants; several, trees or shrubs. Leaves alternate, more or less divided, and stipulate.



Marsh-mallow.

This order consists of twenty-two genera, which are sometimes subdivided into those having the calyx double—as *Malva*, *Althæa*, *Lavatera*, *Hibiscus*, *Gossypium*, &c.; and those having it single—as *Palavia*, *Cristaria*, *Sida*, &c. All of them possess showy flowers, abound in mucilage, and are destitute of unwholesome qualities. It will be seen that there is a considerable resemblance between the flax and the mallow tribes. Both possess mucilaginous qualities; in both the parts of the flower are in fives; and in both the filaments of the stamens are partially united; though in the flax the union is only at the base, whereas in the mallows it is carried up so as to form the central column, which is so marked a feature of the order. The herbaceous species of the Malvaceæ have woody fibre in their stems, but not in such abundance as in the common flax. The one-celled anther of the mallows, and the central column, are, however, the striking marks of distinction. Plants belonging to the order are found in almost every part of the world, but the cotton plants (*Gossypium*) will only thrive in hot climates.

The economical uses of the order are highly important. Cotton, on which so much of British commerce depends, is obtained from several species of gossypium, and is the downy covering which envelopes the seeds. The quantity of cotton imported into Great Britain is enormous—being in some years upwards of five hundred millions of pounds. There is only one species of cotton-tree in the West Indies from whence we obtain our principal supply of the raw material; several in the East Indies, and another in China, which has its cotton naturally of a buff colour. It is from the latter that the Chinese manufacture the stuff called *nankeen*, which is cotton cloth in its natural dye. Many of the Malvaceæ are also medicinal and dietetic. The *pâté de Guimauve*, which is made from a species of marsh-mallow, is much used on the continent in all disorders of the lungs; from the *Althæa officinalis* is prepared, in France, the vegetable tracing paper known by the name of *papier végétal*; and a blue matter, not inferior to indigo, is said to be obtained from the leaves of the hollyhock, *A. rosea*.

TERNSTRŒMIACEÆ—THEADS.

This is one of the most interesting natural orders, as, besides other fine plants, it contains the camelias and tea-trees. All the members are trees or shrubs, with very handsome flowers. The leaves are alternate, and without stipules; they are frequently leathery, and are sometimes marked with pellucid dots. The flowers have generally five sepals and five petals; sometimes there are two additional sepals a little below the others. The stamens are numerous, and either grow together into a central column, or are in five distinct bundles. The seeds are contained either in five distinct carpels, or in a capsule with five cells. There are but few seeds, which are large, and entirely filled with an embryo having thick cotyledons like the bean, and no albumen.

Only a very few genera belonging to this order have been introduced into this country; but there are a number of equally beautiful species said to be found in the East Indies and South America. Those best known in Britain are the genera *Gordonia*, *Stuartia*, *Malachodendron*, *Camelia*, and the *Tea-tree*. The camelia—for example, *C. Japonica*—is too well known to need any description, and its beautiful flowers and thick leathery leaves must be familiar to every one who takes any interest in plants. The tea-tree (*Thea viridis*) is very nearly allied to the camelia, but its flowers are smaller, and its leaves of a thinner texture. The outside of the capsule, which is furrowed in the camelia, is smooth in the tea-tree. Two kinds of tea-tree have been introduced into this country, the green and the black (*Thea Bohea*); but it is frequently asserted that the greater part of the dried leaves sent to this country is gathered from the green tea-tree, and that the difference in colour depends solely on the manner of drying the leaves, and on the time of gathering them. Be this as it may, *T. Bohea* has smaller leaves, and is a more tender and less vigorous-growing plant than *T. viridis*. The young leaves of *Camelia Sasanqua*, and some of the other camelias, are also dried and mixed with the tea. All these plants are natives of China and Japan; seem to thrive well in northern India; and require a slight protection in England during winter.

The properties of most of the species are as yet but little understood. An excellent table oil is obtained from the seeds of *Camelia oleifera*. The tea of commerce is produced by several species of Thea and Camelia; and this is well known for its astringent and stimulating qualities. About fifty millions of pounds is said to be annually exported from China, which furnishes almost the sole supply of the world. The tea plant is cultivated by the Chinese as the coffee-tree is in the West Indies, and as vines are in France; that is, it is planted in rows at regular intervals, and the leaves are gathered regularly at particular seasons. It is stated by those who are best informed on the subject, that no leaves are gathered till the trees are three years old, or after they are seven, and that a young plantation is formed every year, in order to have a constant supply at the proper age. Three several gatherings take place during the year—the leaves of the earliest being esteemed the strongest and best.

AURANTIACEÆ—CITRONWORTS.

The golden fruit of the orange and lemon, so characteristic of this order (*Aurum*, gold), is so beautiful, that it is supposed to have been typified by the celebrated apples of the Hesperides. The order comprises fourteen genera, generally elegant and fragrant trees. The leaves, though apparently entire, are called compound by some botanists, because they are articulated with the petiole, which in the orange, and some other species, is winged. The calyx is tubular, with five short teeth, and this small calyx remains on the front till it is ripe. The petals of the corolla are five in number, thick and fleshy, and when held up to the light, they appear full of pellucid dots, which are receptacles of secretion filled with fragrant oil. There are generally twenty stamens, which are divided into five bundles, the filaments in each bundle adhering together. The fruit is a kind of berry, divided into numerous cells by dissepiments, and having a central placenta of pith, to which the ovules are attached in the ovary; but as the fruit swells, the seeds become detached, and the cells fill gradually with cellular tissue, till at last they become replete with an acid and bitter pulp, in which the seeds are immersed. The seeds are marked conspicuously with a chalaza and raphe, the vessels of which are spread beautifully over the testa.

Lemon.

The most familiar genus is Citrus, the species of which are trees or shrubs, chiefly natives of the tropics—most of them being found in a wild state exclusively in the East Indies. The orange, however, appears to have an extraordinary facility of adapting itself to any country the climate of which is dry and sunny; and thus have arisen the orange groves of St Michael's and of Florida, besides those of Malta, and various parts of Europe and North Africa. All the kinds of orange, lemon, shaddock, citron, &c. belong to the genus *Citrus*—as *C. aurantium*, the sweet orange; *C. vulgaris*, the bitter or Seville orange; *C. nobilis*, the Mandarin orange; *C. medica*, the citron; *C. limonium*, the lemon; *C. limetta*, the sweet lime; *C. Paradisii*, the forbidden fruit; and *C. Decumana*, the shaddock. The Wampee, the fruit of *Cookia punctata*, is much admired in India, but does not appear to have been introduced into Europe.

All the Aurantiaceæ abound in a fragrant oily matter, which is contained in the receptacles of secretion, in the rind of the fruit, and in the leaves of the tree. This oil is volatile, fragrant, bitter, and exciting. The pulp of the fruit is more or less acid, and is used either in its natural state, or medicinally in the form of salts, essence, or other extract. About 272,000,000 of oranges are said to be annually imported into Great Britain. The productiveness of the common orange is enormous: a single tree at St Michael's has been known to produce 20,000 oranges fit for packing, exclusively of the damaged fruit and the waste, which may be calculated at one-third more.

ACERACEÆ—MAPLES.

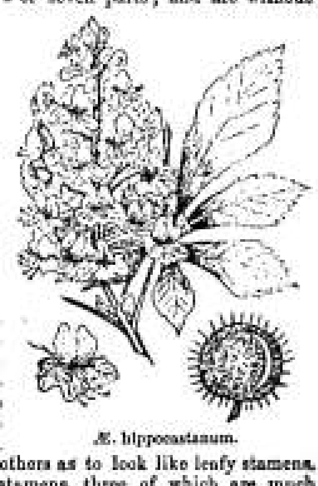
This order consists of three genera, and of fourteen or sixteen species, all of which are trees natives of temperate climates. The leaves are opposite, and without stipules; they are generally large and handsome, with five or seven lobes, though the *Negundo*, or box-elder, has the leaves pinnate. The flowers are small, but pretty, being in long drooping racemes or corymbs. The male and female flowers are distinct. The stamens, which are eight in number, are the only conspicuous part of the flower, as the petals are frequently wanting. The bracts are large and leathery, and generally roll back when the flowers expand. Most people have seen the fruit, or *keys*, as they are called, of the sycamore and maples, the botanical term for which is *samara*. This kind of fruit consists of two cells joined together on one side, each having a long membrane-like wing. There is usually only one seed in each cell; the embryo has two, and sometimes three, large thin cotyledons, which are curiously folded up, and fill the whole seed. This is rather a remarkable construction, as where there is no albumen, the cotyledons are for the most part fleshy.

The genera are *Acer*, *Negundo*, and *Dobinea*; of which only the two former are common in Britain. The genus *Acer* comprehends all the maples, and the sycamore. *Negundo* is easily distinguished from the maples by its compound leaves, which resemble those of the ash, and by its long pea-green shoots, which have very few buds. The male and female flowers of this genus are on different trees, and very inconspicuous. The common maple, *A. campestre*, and the sycamore, *A. pseudo-platanus*, are the only members of the order natives of Britain, though a number of other species have been introduced by culture. The Negundo belongs to America, and the other genus to Nepaul.

The ascending sap of all the maples is remarkably sweet, and sugar is frequently made in America from that of *A. saccharinum*. Indeed the sugar-maple may be said to be a rival of the sugar-cane, the United States alone producing not less than 10,000,000 pounds per annum. The timber of the maples and sycamore is remarkably light and close-grained, and therefore much used in veneering and inlaying. The beautiful veneers called *bird's-eye maple* are obtained from the cuts of *A. saccharinum*. The bark is astringent, and yields the dyer reddish-brown and yellow colours.

HIPPOCASTANACEÆ.—HORSE-CHESTNUTS.

This order contains only two genera—namely, *Æsculus*, the horse-chestnut; and *Pavia*, the scarlet-flowering chestnut. The species are all trees and shrubs, natives of temperate climates. The leaves are palmate—that is, divided into five or seven parts; and are without stipules. The flowers are produced in large panicles or racemes; and though they are very handsome, they are extremely irregular in their construction. There are five petals, two of which are smaller than the others, and all of which have very small claws. In the scarlet horse-chestnut, and some other kinds, there are only four petals; and in the *Pavia*, two of the petals are so much smaller than the others as to look like leafy stamens. There are seven stamens, three of which are much



Æ. hippocastanum.

shorter than the others. The fruit of the horse-chestnut consists of a leathery husk, which opens when it is ripe into three valves. The ovary is usually only one-celled, with two ovules, of which seldom more than one ripens. The husk of the pavia is smooth. The scar of the hilum is very strongly marked on the testa of the nuts of both genera; and in the pavia it is so conspicuous, as to give rise to the American name of the genus, which is called *Buck's-eye*, from the resemblance of the hilum to the pupil of an eye. When the seed is put into the ground, the cotyledons only open sufficiently to allow the escape of the plumule and the radicle. The plumule is very large, and has two leaves in the seed; and the radicle is close to the hilum, where of course is also the foramen. There is no albumen, the nourishment for the young plant being laid up in the thick fleshy cotyledons.

The horse-chestnuts are supposed to belong originally to the north of India; but they have been so long cultivated in Europe, as now to spring up like natives of the soil. The pavias are all natives of North America. Both of the genera are amongst the finest of our flowering trees, and on this account are common in park scenery. The seeds of the order abound in starchy matter, which renders them nutritious; they also contain much potash, and are bitter. The bark of the common *Æsculus hippocastanum* is bitter, astringent, and has been recommended as a valuable febrifuge in intermittent and other fevers.

VITACEÆ—VINES.

This order comprises four genera, and fifty-three species, natives of temperate climates. Their prevailing habit is a long dangling growth of stem, thyrsus of simple colourless flowers, or tendrils opposite the leaves, and yielding bunches of berried fruit. The stem and branches are furnished with tumid articulated nodes; the leaves are lobed or compound, generally alternate with stipules. The flowers are small, often with the male and female distinct; calyx very small; sepals and petals four or five, the latter sometimes cohering and falling off before the bursting of the anthers; stamens equal in number to the petals, and opposite to them; ovary two-celled; fruit, a berry, with the seeds immersed in pulp; seeds with a bony testa; albumen hard; embryo small. The curious formation of the flower and berry is well illustrated by the dissection of the common vine, as shown in page 91.

The genera are—*Ampelopsis*, the vine-leafed ivy; *Vitis*, the grape vine; *Leea*, and *Cissus*. With the exception of the vine, the other genera are of little interest, being employed only as ornamental creepers; as *A. hederacea*, which grows with amazing rapidity, and soon covers any straggling fence or unsightly wall. *Leea* is nearly allied to the Meliaceæ, and forms, as it were, a connecting link between the two orders.

The properties of the grape, either in its fresh state, or dried to form raisins and currants (Corinths), or expressed and fermented to form wine, &c. are too well known to require description. The berries of the Virginian creeper (*A. hederacea*) are small and unpalatable, but might be eaten with perfect safety. According to Von Martius, the leaves and fruit of *C. tinctoria* abound in green colouring matter, which soon becomes blue, and is highly esteemed by the natives of Brazil as a dye for cotton fabrics. Acid leaves, and a fruit like that of the common grape, are the usual characters of the order.

GERANIACEÆ—GERANIUMS.

This *Geraniaceæ* comprise only five genera, but above four hundred species. They are herbs or shrubs, with stems which are tumid and articulated at the joints. The leaves are generally lobed, and furnished with small stipules. Calyx persistent in five-ribbed sepals. Corolla generally five-petalled, with strongly-marked veins. Stamens twice as many as the petals, usually half of them abortive; filaments united at the base. Fruit consists of five elastic one-seeded carpels, called *cocci*, adhering to a central axis, or gyno-base, from which they part with an elastic jerk when ripe. Seeds without albumen; cotyledons rolled up or folded.

The chief genera are *Geranium*, *Pelargonium*, and *Erodium*, respectively crane's-bill, stork's-bill, and heron's-bill, from the fancied resemblance of the ripe seed-vessel to these objects. Many of the species, which are very widely distributed, are natives of Europe; but the majority of our greenhouse favourites are from the Cape of Good Hope. The herb Robert (*G. Robertianum*), and the meadow crane's-bill (*G. pratense*), are common British weeds, as are also *E. cicutarium* and *moschatum*. All the pelargoniums have their flowers in heads, or umbels, and the calyx remains till the seeds are ripe. Their leaves vary very much, some being round—as the horse-shoe geranium—and marked with a dark stripe; and others are deeply lobed, as the rose-scented varieties. Many are shrubby; some are herbaceous; the stems of some are warty, and the roots of others are tuberous. In the Erodiums, the filaments are less united at the base, and five of the stamens are always sterile. The Geraniums have all the stamens perfect, but are alternately long and short, and have a gland at the base of each.

The Geraniaceæ are all innocuous plants, being generally slightly acid, and sometimes astringent. They are all more or less fragrant, secreting oils and resins; and in some, these secretions are so abundant—*Sarcocaulon L'Heritieri*—that the stems burn like torches, and emit an agreeable odour during combustion. In America, the roots of *G. maculatum* are used as a remedy for diarrhœa; the British Erodiums are sometimes employed as aromatic bitters; from *P. odoratissimum* a fragrant oil has been distilled, resembling the attar of roses; the underground tubercles of *P. hirsutum* are esculent, and prized by the Arabs as food; and Mr Backhouse, in his recent travels, mentions that the tubers of *G. parviflorum* are eaten by the natives of Van Diemen's Land, where it is called the Native Carrot. Notwithstanding these uses, the members of the order are chiefly esteemed for the beauty of their flowers, and have long continued among the most admired favourites of the conservatory.

These and the other orders tabulated in page 92 comprise all the plants belonging to the sub-class Thalamifloræ. They include several interesting members, some of which are of the greatest importance to man. By far the greater part of the genera contain only herbaceous plants; and the few timber trees that are among them have all very light wood, though it is generally fine-grained, and in some—as the mahogany, satin, maple, and partridge woods—extremely beautiful. Flax and cotton, both belonging to this division, are also of the greatest economical importance. The contrast between the durability of these two kinds of thread is very striking, and of peculiar interest to the student of vegetable physiology. Linen thread, being the *woody fibre* of the flax plant, is much stronger than cotton thread, which is composed entirely of *cellular tissue*. The particles of cotton, however, adhere together more firmly than any other kind of cellular tissue; and though several seeds are also abundantly enveloped in down, that of the cotton is the only one capable of being spun into thread. The bombax, or silk-cotton-tree, forms no exception to this statement, because though the silky hairs that surround the seeds are used to stuff cushions and beds, and though a sort of felt has been made of them, yet they cannot be spun into threads of sufficient tenacity to endure weaving. Ropes and other fabrics are manufactured from the barks of many of the trees included in this division, but none of these is in very general use except the bast mats, made from the macerated bark of the lime-tree. Cocoa and chocolate, tea, wine, oranges, lemons, maple-sugar, opium, several fruits, drugs, dyes, and oils, are the produce of plants belonging to this division; and to these may be added cabbages, mustard, horse-radish, turnip, and other esculents.

§ CALYCIFLORÆ.

Of the plants comprised in this sub-class, the greater number have their petals and stamens inserted in the calyx, or rather in the mouth of the dilated disk which lines the tube of the calyx and surrounds the ovary. The sepals of the calyx are always united, so as to form a tube in the lower part, with the upper part divided into a lobed limb; and this, in fact, constitutes the principal difference between the plants of this and the previous section. Another distinction consists in the stamens of the Thalamifloræ being *hypogynous*—that is, inserted in the disk at the base of the ovary; whereas in the Calycifloræ they are generally inserted in an elevated part of the disk, so as to appear placed upon the ovary, *epigynous*; or they grow out of the calyx at a distance from the ovary, when they are termed *perigynous*. Of the orders comprised in this section, about forty have their stamens attached to the disk which lines the tube of the calyx, and seventeen have their stamens attached to the corolla: the latter being sometimes arranged under the sub-class Corollifloræ. The reason why Decandolle placed these doubtful members in the present section, appears to be that the petals do not unite beneath the ovary, as they do in the other genera of Corollifloræ. Subjoined are the usually admitted Orders:—

Celastraceæ—Spindle-trees	Turneraceæ—Turnerads
Rhamnaceæ—Rhamnads	Portulaceæ—Purslanes
Bruniaceæ—Bruniads	Illecebraceæ—Knotworts
Samydaceæ—Samyds	Crassulaceæ—House-leeks
Homaliaceæ—Homaliads	Cactaceæ—Indian figs
Chailletiaceæ—Chailletiads	Grossulariaceæ—Currantworts
Aquilariaceæ—Aquilariads	Escalloniaceæ—Escalloniads
Terebintaceæ—Terebinths	Saxifragaceæ—Saxifrages
Leguminosæ—Leguminous [plants]	Cunoniaceæ—Cunoniads
Rosaceæ—Roseworts	Umbelliferæ—Umbellifers
Calycanthaceæ—Calycanths	Araliaceæ—Ivyworts
Memecylaceæ—Memecyls	Hamamelidaceæ—Witch-hazels
Combretaceæ—Myrobalans	Caprifoliaceæ—Caprifoils
Vochysiaceæ—Vochyads	Loranthaceæ—Loranths
Rhizophoraceæ—Mangroves	Chloranthaceæ—Chloranths
Onagraceæ—Onagrads	Rubiaceæ—Madderworts
Haloragaceæ—Hippurids	Valerianaceæ—Valerianworts
Ceratophyllaceæ—Hornworts	Dipsaceæ—Teaselworts
Lythraceæ—Loosestrifes	Calyceraceæ—Calyceres
Tamaricaceæ—Tamarisks	Compositæ—Composites
Melastomaceæ—Melastomads	Lobeliaceæ—Lobeliads
Alangiaceæ—Alangiads	Stylidiaceæ—Styleworts
Philadelphaceæ—Syringas	Goodeniaceæ—Goodeniads
Myrtaceæ—Myrtle-blooms	Campanulaceæ—Bellworts
Cucurbitaceæ—Gourds	Gesneraceæ—Gesnerworts
Passifloraceæ—Passionworts	Vacciniaceæ—Cranberries
Malesherbiaceæ—Crownworts	Ericaceæ—Heathworts
Loasaceæ—Loasads	Penæaceæ—Penæads

TEREBINTACEÆ—TEREBINTHS.

An extensive order, containing sixty-seven genera and about one hundred and eighty species of trees and shrubs, which vary much in their character and qualities. The order was originally constituted by Jussieu, but modern botanists have found it necessary to subdivide it into seven tribes, and even with respect to these they are far from being agreed. It is more than likely, therefore, that as the species become better known, these tribes will be recognised as independent orders. The general characters of the order, as it now stands, may be described as follows:—Trees or shrubs abounding in a resinous, gummy, caustic, poisonous, and sometimes milky juice; leaves alternate and simple, ternate or pinnate, for the most part without stipules, and dotted. Flowers terminal or axillary, mostly unisexual; calyx two, four, or five cleft, usually the latter number; petals equal in number to the segments of the calyx; stamens as many as the petals, sometimes twice the number; disk fleshy; ovary simple; fruit indehiscent, with a solitary ex-albuminous seed.

The following are the seven sections or tribes into which Brown and others have divided the order:—1. ANACARDIACEÆ, including the cashew-nut (*Anacardium occidentale*), the mango (*Mangifera indica*), and the turpentine-trees (*Pistacia*). In these the leaves are alternate, and not dotted; the parts of the flower in fives; the fruit drupaceous; and the species trees or shrubs with resinous, gummy, caustic, or milky juice. 2. SUMACHINEÆ, which contains the genera *Rhus*, *Schinus*, and *Duvaua*, all nearly allied to the preceding tribe. The species are trees with unequally pinnate leaves, but otherwise agree with the general character of the order. In the Venetian sumach (*R. cotinus*), the flower-stalks which do not bear fruit dilate after the fall of the flower, and become covered with white cottony hair; hence the French name of the tree—*Arbre à perruque*. 3. SPONDIACEÆ, containing the hog-plum of the West Indies (*Spondias mombin*). The leaves are without dots, unequally pinnate, and the juice is non-resinous. 4. BURSERIDEÆ, including the Jamaica birch (*Bursera*), and the balm-of-Gilead-tree (*Balsamodendron*). Trees or shrubs abounding in balsam, gum, or resin; leaves alternate, usually without dots; fruit compound, in which respect it differs from the first and fifth tribe. 5. AMYRIDEÆ, represented by the West Indian *Amyris*. In this tribe the species are resinous trees and shrubs, with opposite, compound, and dotted leaves; the parts of the flower are in fours; fruit somewhat drupaceous. 6. SPATHELIACEÆ, the West Indian sumach (*Spathelia*). 7. CONNARACEÆ, including *Connarus*, *Omphalobium* and *Cnestis*, which are trees and shrubs with compound alternate leaves, without dots or stipules, without resinous juices, and with capsular fruit. The Connards are now generally treated as an independent order.

It will be seen, from what has been stated, that this order contains many plants of considerable economical importance. Among the edible fruits may be mentioned the cashew and pistacia nuts, the spondias, and the esteemed mangoes of India. Many of them also are plants yielding gums, resins, &c. useful in the arts, besides spices and balsams—as frankincense, myrrh, obilanum, balsam of Mecca, mastich, and the like. The bark of most of the genera is aromatic, bitter, and astringent, employed medicinally against diarrhœa, and in some instances (*Rhus coriaria*) used by tanners. The beautiful zebra-wood of the cabinetmakers, according to Sir Robert Schomburgk, is produced by *Omphalobium Lamberti*, a large tree common in the forests of Guiana; where also abounds the *Icica altissima*, whose gigantic trunk furnishes the light, easily-worked, and highly-aromatic cedar-wood of Guiana.

LEGUMINOSÆ—LEGUMINOUS PLANTS.

This is one of the most extensive and best defined orders in the vegetable kingdom, containing upwards of four hundred and forty genera, and nearly six thousand species. It embraces all the plants bearing butterfly-shaped (papilionaceous) flowers, and podlike seed-vessels, among which may be mentioned, as familiar examples, the pea, vetch, bean, lupine, restharrow, broom, furze, and laburnum. In an order so extensive, it may be expected that there will be many minor differences requiring subdivision into tribes; but without adverting to these in the meantime, the following may be stated as the general characteristics of the *Leguminosæ*:—Herbs, shrubs, or trees; leaves alternate, generally compound, and frequently have the common petiole tumid; usually two stipules at the base of the petiole, and also two to each leaflet in the pinnate leaves; the pedicles are generally articulated, and the flowers are furnished with small bracts; calyx five-parted, the segments being sometimes unequal and variously combined; petals never more than five, but often less, and sometimes wanting, inserted into the base of the calyx, and variously arranged, being usually papilionaceous, and sometimes spreading, the odd petal being always superior; stamens definite or indefinite, inserted with the petals, or sometimes hypogynous, dis-

Papilionaceous.

tinct, or in one, two, or three bundles; ovary superior, for the most part one-celled; ovules one or many; style and stigma simple; fruit a true legume, a modified form of legume or loment, or when containing only one seed, drupelike; seeds one or several, sometimes furnished with an arillus; albumen none; embryo straight, with the radicle in some instances bent along the edge of the cotyledons.

This order has sometimes been divided into two sub-orders—namely, *Papilionaceæ*, or those genera which have butterfly-shaped flowers and true legumes; and *Lomentaceæ*, those in which the corolla is regular and somewhat rosaceous, and the fruit a loment or modified form of legume. This division, though sufficiently distinct, serves little purpose in detail; and therefore that of Decandolle, which arranges the order into the following tribes or sections, is now generally received:—1. *Sophoreæ*, the sophora tribe, handsome flowering plants; 2. *Loteæ*, the lotus tribe, several species of which are found in Britain, and known as the bird's-foot trefoil; 3. *Hedysareæ*, the sainfoin tribe; 4. *Vicieæ*, the vetch tribe, including the pea and bean; 5. *Phaseoleæ*, the kidney-bean tribe; 6. *Dalbergieæ*, the gum-dragon, a group of stately trees and twining shrubs; 7. *Swartzieæ*, a tribe of evergreen shrubs; 8. *Mimoseæ*, including the well-known mimosas of our conservatories; 9. *Geoffrieæ*, the earthnut tribe, including the earthnut (*Arachis*), and the tonquin bean (*Dipteris*); 10. *Cassieæ*, the cassia tribe; and 11. *Detarieæ*. Some botanists exclude *Moringa*, the horse-radish tree, in the Leguminosæ, while others make it a separate order, under the name of *Moringaceæ*. The main point of distinction consists in the fruit, which is a three-valved podlike capsule; but as others of the Leguminosæ have their carpels similarly united, the Moringas may be regarded as the twelfth tribe of the Leguminous order.

This family, says a recent writer, is amongst the most important to man, whether as affording objects of beauty, of utility, or of nutriment. The bean, the pea, the vetch, and the clover tribe belong to it; as do the logwood, the laburnum, indigo, the tamarind, liquorice, senna, and the acacias. Its general property is to be wholesome, but there are several exceptions. Thus the seeds of laburnum, and the juice of *Coronilla varia*, are poisonous. Senna obtained from various species of cassia is purgative, and several others of the order possess a similar property. The pericarp of some contains much tannin; dyes are obtained from others; and many yield gums and balsams. But it would consume pages to enumerate all the uses to which this, one of the most extensive orders in the vegetable kingdom, has been applied.

ROSACEÆ—ROSEWORTS.

Like the preceding, this is one of the most extensive natural orders, comprehending upwards of seventy genera, and about nine hundred described species. The genera are herbs, shrubs, and trees, often of very dissimilar habits and appearance, but all bearing a striking resemblance in their inflorescence to the single or wild rose of our woods and hedges, which has been taken as the type of the order. Among the trees may be mentioned, as familiar examples, the almond (*Amygdalus*), the pear and apple (*Pyrus*), the sloe and plum (*Prunus*), the peach and nectarine (*Persica*), the cherries and laurels (*Cerasus*), and the japonicas (*Eriobotrya*); among the shrubs, the rose (*Rosa*), the hawthorn (*Cratægus*), the bramble and raspberry (*Rubus*), and the quince (*Cydonia*); among the herbs, the common yellow *Potentilla* of the roadsides, the *Geum*, the *Tormentilla* of our woods and commons, and the delicious strawberry (*Fragraria*). From the mention of these plants, the reader will be enabled to form some

Rosaceous.

idea of the order, and to perceive that the varied nature of its genera requires a subdivision into several tribes for the purposes of detailed description. Before mentioning the different sections into which the *Rosaceæ* have been arranged, the following may be taken as their general characteristics:—Herbs, shrubs, and trees; leaves alternate, generally compound, and always furnished with stipules; calyx five-lobed, united below, but separate and expanding above; corolla four or five petals, for the most part five. The ovary is one-celled, and there is seldom more than one seed, scarcely ever more than two in each cell. Carpels numerous, and generally enclosed in the fleshy tube of the calyx.

The order is usually divided into the following tribes:—1. CHRYSOBALANEÆ, or cocoa-plum family, represented by *C. icaco*, an irregular shrub, eight or ten feet high, found in South America and the West Indies, where its fruit, which is about the size of a plum, of a whitish-yellow, and possessing a sweetish taste, is brought to the markets. There are nine genera belonging to this tribe, all of which are trees or shrubs, with simple alternate stipulate leaves, and flowers in racemes or panicles. They are natives of the warmer parts of Africa and America, and differ from the almond tribe in having irregular petals and stamens, and in the style arising from the base of the ovary. 2. AMYGDALEÆ or almond family, represented by the common almond (*A. communis*), and embracing the peach, apricot, nectarine, plum, cherry, &c. well known for their delicious fruits, and a few bushes remarkable for their gay appearance during the flowering season. The fruits of this tribe are for the most part edible; and though the leaves and bark possess medicinal properties, yet one of the most subtile poisons—prussic acid—can be extracted both from the fruit and leaves of the almond. 3. SPIRÆEÆ, deciduous shrubs and perennial herbs, represented by *Spiræa salicifolia*, or bride's-wort. In this section the five-cleft calyx is lined with the dilated receptacle, which forms a sort of cup for the carpels; the petals are small and round, overset by from twenty to fifty stamens, which project far beyond them. The carpels are follicles, and from two to five in number, opening at the tops to discharge the seeds when ripe. 4. DRYADEÆ, embracing all those plants which agree with the common *Potentilla* in the construction of their flowers—that is, in having a calyx of ten sepals, a cup-shaped corolla of five petals, and the stamens, which are numerous, forming a ring round an elevated receptacle, on which are placed numerous carpels. By this test the student will find that the section comprises not only herbs, such as the potentilla, geum, tormentilla, and strawberry, &c. but also erect and trailing shrubs, as the raspberry and bramble. These genera, though alike in their flowers and in many of their habits, are otherwise very dissimilar. In the potentilla, for example, the carpels form the prominent part of the so-called fruit, while in the strawberry it is the receptacle which dilates and becomes edible. Again, in the raspberry the receptacle is a torus surrounded by the carpels, which swell out and soften, forming the edible portion, while the receptacle constitutes the core or torus. The leaves and stems of these genera are also very dissimilar, but the habit of increasing by suckers or runners is very prevalent in all. 5. SANGUISORBEÆ, a section of herbaceous perennials, illustrated by *S. officinalis*, or the weed burnet of our pastures. The flowers have no petals, but the clefts of the calyx are coloured instead, besides being generally furnished with glossy coloured bracts. 6. ROSEÆ, or roses proper, the type of which is the single wild-rose, or dog-rose of the hedges. The characters of this section are too well known to require much description. They have all a cup-shaped corolla of five equal slightly indented petals, capable of being increased indefinitely by cultivation; numerous yellow stamens; a five-cleft calyx, the throat of which is filled with the receptacle. The pitcher-shaped portion of the calyx becomes the hip as the seeds ripen, and forms a false pericarp, enclosing the numerous bony carpels. They are all shrubs, with pinnate leaves and prickly stems—the prickles differing from thorns in being articulated to the stem—that is, of being separated without tearing the bark. Most of them are fragrant, and the leaves of some, as the sweetbrier, are replete with a fragrant volatile oil. 7. POMEÆ, an extensive and varied section, the type of which is the common apple (*Pyrus malus*). It comprehends the apple, pear (*Pyrus communis*), the mountain-ash (*P. aucuparia*), the wild service (*P. torminalis*), the quince (*Cydonia*), and the hawthorn (*Cratægus*). In all of these genera, which are trees and shrubs, the flowers are remarkably similar; but the habits of the plants, the leaves, and the fruit, present numerous differences. These, however, are too well known, or at least can be so easily ascertained, that it is needless to describe them.

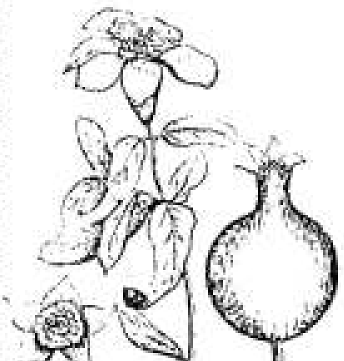
The properties of the order have already been so far noticed in the preceding detail, that it may be stated of them generally as follows:—The fruit of some of the *Chrysobalaneæ* are eaten under the name of the cocoa-plum. The *Amygdaleæ*, including the almond, plum, cherry, sloe, &c. are well known; the leaves and kernels contain prussic acid, which, in a concentrated form, is one of the subtlest poisons; but being generally diluted in a natural state with gum, sugar, &c. it is harmless, and serves to give an agreeable flavour to the fruits containing it. Of the *Potentilleæ*, the roots of several are astringent and febrifugal, and the fruits of such as the raspberry and strawberry are delicious and wholesome. The *Roseæ* are chiefly valued for their ornamental flowers, but they also yield valuable extracts—as attar of roses, rose-water, conserve of roses, &c. The *Pomeæ*, under cultivation, supply wholesome and delicious fruits, of which the apple, pear, quince, and serviceberry, are familiar examples.

MYRTACEÆ—MYRTLE-BLOOMS.

This important order consists of upwards of sixty genera, and about thirteen hundred species. They are all trees or shrubs, often with angled branches, with simple exstipulate leaves, which are for the most part opposite, full of transparent dots, and with a transparent line round the edge—rarely alternate or without dots. The substance of the leaf is coriaceous, and the dots are glands, or cysts, full of a fragrant volatile oil. The inflorescence is both terminal and axillary, variable in its form, but generally aggregate—the flowers being regular and united, of a white, red, or sometimes yellow colour, but never blue. The tube of the calyx adheres to the germen; the limb from four to eight cleft, persistent and deciduous. The petals, which are rarely wanting, are equal in number to, and alternate with, the segments of the calyx; the stamens are inserted with the petals, and are twice as many, or (usually) indefinite, and then arranged in several series; the anthers are oval, two-celled, and burst longitudinally. Ovary cohering with the tube of the calyx, and from one to six celled; style and stigma simple. The fruit is various, being either dry or fleshy, capsular, baccate, or drupaceous; many-celled, or one-celled by the obliteration of the dissepiments of the carpels. Seeds generally indefinite, seldom few, and without albumen.

In an order so extensive, strict uniformity of character is scarcely to be expected; hence the variations which occur in the fruit, manner of flowering, and arrangement of the leaves, have induced botanists to suggest various subdivisions. For example, a twofold division has been proposed; namely, those genera which have a dry capsule for the fruit—as *Melaleuca*, *Eucalyptus*, &c.; and those with berry-like fruit, like the myrtle (*Myrtus*), the guava (*Psidium*). This division, however, gives little aid to discrimination: and perhaps the best arrangement is that given by Decandolle; 1. CHAMÆLAUCIEÆ, having a one-celled ovary and capsule, with leaves opposite and dotted; 2. LEPTOSPERMEÆ, having a many-celled capsule, with opposite or alternate leaves, which are usually dotted; 3. MYRTEÆ, having a berry, distinct stamens, opposite leaves, which are always dotted; 4. BARRINGTONIEÆ, having a fleshy, one-celled fruit, monadelphous stamens, and opposite or whorled leaves without dots; 5. LECYTHIDEÆ, having a many-celled woody capsule, that opens with a lid or remains closed, monadelphous stamens, leaves alternate and without dots. All the species are natives of mild and warm climates; the most northerly situation in which they are known to grow to perfection being the southern latitudes of Europe.

The myrtle-blooms are possessed of many useful as well as ornamental properties. Among the edible fruits may be mentioned the guava, yielded by several species of *Psidium*; the rose-apple and jamrosade, produced by *Eugenia* and *Jambosa*; the Brazil nut, which is the seed of the *Bertholletia excelsa*, there being from sixteen to twenty of these seeds in the larger woody capsule. Of spices yielded by the order, which are all more or less aromatic, we have the clove, being the unexpanded flower-bud of the *Caryophyllus aromaticus*; all-spice, the dried berries of *Eugenia pimento*; and also the dried berries of the common myrtle. It is the volatile oil which is found in the dots of the leaves, the unexpanded petals, and in almost all the parts of the plant, that gives to them their fine aromatic fragrance. The pomegranate, *Punica granatum*—now ranked under this order—forms a delicious fruit in warm countries; the pericarp or rind is used in the East as an astringent; and the bark of the root is esteemed an efficient anthelminthic. The name pomegranate—*pomum - granatum*—is derived from the resemblance of the fruit to an apple filled with grains or seeds; and the term *punica*, either from its being obtained from the Punic or Carthage shores of the Mediterranean, or from its bright scarlet colour (*punicus*).



Pomegranate.

CUCURBITACEÆ—GOURDS.

This is a large and interesting family of herbaceous plants, containing fifty-six known genera, and about three hundred species. The roots are annual or perennial, fibrous or tuberous; the stems succulent, climbing by means of lateral tendrils formed of the abortive stipules, and furnished with alternate, palmated, rough leaves. The flowers are usually unisexual, solitary, or panicled; and of a white, red, or yellow colour. The calyx is five-toothed, sometimes obsolete; petals five, more or less united, sometimes scarcely distinguishable from the calyx, strongly marked with reticulated veins, sometimes fringed; stamens five, distinct, or in three bundles; anthers two-celled, long, and sinuous; ovary inferior, one-celled, and adhering to the calyx; style short; stigmas five, two-celled, velvety or fringed. Fruit a peponida (as illustrated by the cucumber and melon); seed usually ovate and flat, enveloped in a juicy or dry and membranous arillus; testa leathery, often thick at the margin; embryo without albumen; cotyledons leafy.

The Cucurbits are natives of all hot climates, but are most abundant in India; a few exist in the northern parts of Europe and America, and some are found at the Cape of Good Hope. Decandolle divided the order into two sections—NHANDIROBEÆ and the true CUCURBITACEÆ: the former including the genera *Nhandiroba* and *Zanonia*, &c.; and the latter the well-known gourds and pumpkins (*Cucurbita*), the cucumbers and melons (*Cucumis*), the white bryony (*Bryonia*), the spirting cucumber (*Momordica*), the bottle gourd (*Lagenaria*), and the snake gourd (*Trichosanthes*). Some botanists include the papaw-tree (*Carica papaya*) under this family; but it is better to consider it as a separate order.

In an economical point of view, the order is of considerable importance, furnishing the well-known esculents—the cucumber, melon, gourd, pumpkin, and calabash; and the purgatives colocynth and elaterium. The general properties of the gourd family may be regarded as bitter and purgative—these qualities pervading more or less all the species, and rendering their fruit either esculent or purgative. The seeds of all are sweet and oily, and from some a considerable quantity of fine-flavoured oil may be expressed. The roots and leaves are sometimes replete with a bitter drastic juice. The fruit of many of the members grow to an enormous size; the calabash, for example, being sometimes found six feet long and eighteen inches in circumference. *Gerkins* are the fruit of the common cucumber pickled when in a young state.

CACTACEÆ—INDIAN FIGS.

The Indian Figs or Cactuses constitute one of the most singular and interesting orders in the vegetable kingdom. They are unique in their forms and habits, and meet with but very distant allies in the other fleshy-leafed orders. They are perennial succulent shrubs, some having tall angular stems, and others rounded spiny ones, not above a few inches in height. In general, the stems and branches are jointed; the leaves are either very minute, or altogether wanting, their place being supplied by spines, either solitary, or growing in bunches. The flowers are sessile, usually white, scarlet, or purple, in many cases showy and attractive, and frequently ephemeral; the sepals are numerous, either crowning the ovary, or covering its surface; petals numerous, arising from the mouth of the calyx, and more or less combined; stamens also numerous, in many rows, and more or less cohering with the petals and sepals; filaments long and slender; anthers ovate; ovary one-celled; style filiform; stigmas many and clustered; fruit a fleshy berry, smooth, scaly, or tuberculated; seeds enveloped in pulp.

The order is usually divided into the OPUNTIACEÆ and RHIPSALIDEÆ; the former including the genera *Cactus*, *Melocactus*, *Opuntia*, *Cereus*, *Mamillaria*, *Echinocactus*, *Epiphyllum*, and *Pereskia*—in which the ovules and seeds are fixed to the parietes of the fruit—the latter the solitary genus *Rhipsalis*, in which they are attached to a central axis. All the genera have leaves only when very young; and as soon as the plant begins to grow, the leaves either fall off, or their place is taken by prickles. They are all natives of tropical America, but thrive well in all hot, dry, and exposed places. Of the more common genera we may mention the following:—*Mamillaria*, so called from the pap-like tubercles which cover its sub-cylindrical stem. Each tubercle is crowned with a little tuft of radiating spines; and the flowers, which are sessile, are ranged in a kind of zone round the plant. The melon cactus (*Melocactus communis*), which has a globose stem, with alternate furrows and ridges, the latter being armed with tufts of spines. The stem is crowned by a woolly tuft, from which spring the flowers. The hedgehog thistle (*Echinocactus*) has also a globose stem, but wants the woolly head, and has its flowers springing from the tufts of spines which arm the ridges. The torch thistle (*Cereus*) has the stem angular, the projecting angles being armed with spiny tufts, from which the flowers generally spring. The old man cactus (*Pilocereus*) is so called from its resemblance, when of small size, to an old man's head, being covered with long white hairs. In our hothouses it is generally of small size; but in its native country it is said to attain the height of twelve or fifteen feet. The Peruvian torch thistles (*C. peruvianus* and *hexagonus*) are still more gigantic plants, often attaining a height of forty feet, though their stems be not thicker than a man's arm. The creeping cereus (*C. flagelliformis*) is well known from its long whip-like stems, which hang down from the sides of the suspended pots in which it is usually grown. The night-flowering cereus (*C. grandiflorus*), so called from its blossoms opening during night, and fading before morning, has an angular, branched, and climbing stem, throwing out roots at every point. The rays of the calyx are of a bright yellow when open, and the petals are of the most delicate white. The genus *Rhipsalis* has slender jointed stems, which look like samphire; and the opuntias, which are numerous and useful, are distinguished by their round, flat, leaf-like bodies, united together by joints, and for the most part covered with spines.

The fruit of many of the cactaceæ are esculent, but are rather insipid, having little of that acidulous flavour which characterises the Currantworts, to which they are allied. It is upon the cactus and opuntias that the cochineal insect, so valuable in the arts, chiefly feeds. It is stated that not less than 300,000 lbs. of cochineal is annually brought to Europe, one-fourth of which is consumed in Britain alone, at the cost of £300,000 sterling: so valuable to man is an insect which ignorance would be apt to regard as mean and insignificant. In the south of Europe, the prickly pear (*O. communis*) is reared as a hedge, and also for its fruit, which is edible, and yields a rich carmine pigment; and the Indian fig (*O. tuna*) is grown for similar purposes in Brazil. In our conservatories, the cactuses are cultivated as ornamental plants alone, either for the beauty of their flowers or the singularity of their structure.

GROSSULARIACEÆ—CURRANTWORTS.

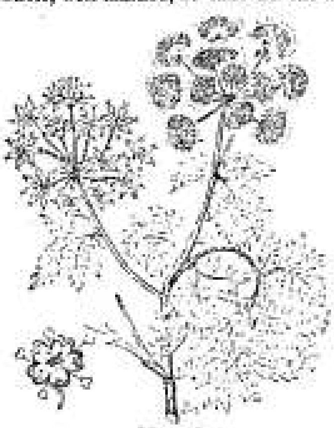
This is a well-known order, consisting of two genera, one of which, *Ribes*, includes all the gooseberries and currants of our gardens. The species, of which there are upwards of eighty, are unarmed or thorny shrubs, with round or irregularly-angled stems and branches; simple, lobed, alternate leaves, destitute of stipules and tendrils. The inflorescence is axillary and in racemes; the pedicle is furnished with two bracteoles, and a large deeply-cut bract at its base. The calyx, which is coloured, is four or five cleft; petals perigynous, equal in number to, and alternate with, the segments of the calyx; stamens of the same number, alternate, and inserted with the petals; filaments distinct; anthers two-celled, bursting longitudinally; ovary one-celled, cohering with the tube of the calyx; ovules indefinite; style several cleft; placentas two, parietal and opposite; fruit a berry, crowned with the remains of the flower, one-celled, filled with pulp; seeds numerous, suspended among the pulp by filiform funicles; testa externally gelatinous; albumen horny.

By Jussieu and other French botanists, this order, on account of its perigynous stamens, is considered as allied to the cactuses and saxifrages; but Dr Lindley considers it as allied to the vine in its succulent fruit-lobed leaves and racemose inflorescence. It, however, differs very essentially in having a superior calyx—into the sides of which the stamens are inserted—and in its fruit containing but one cell with parietal placentation. The order is very conveniently grouped into two sections—namely, the gooseberries, which have prickly stems, and the flowers either singly, or in clusters of not more than two or three; and the currants, which are entirely without spines, and the flowers in racemes. There are a few species, such as *R. diacantha* and *saxatile*, which may be considered as intermediate, these having the spines and habit of growth of the one and the racemose inflorescence of the other. The common gooseberry (*R. grossularia*), the red currant (*R. rubrum*), the black currant (*R. nigrum*), and the flowering currant (*R. sanguineum*), are familiar examples of the order, and all too well known to require any detailed description. The gooseberry is found wild in many parts of Britain; and is reared in England to greater perfection than in any other country, Lancashire prize specimens having been known to weigh an ounce and a half.

Gooseberries and currants are well known as agreeable acid fruits, their acidity or sweetness depending upon the relative quantities of malic acid and sugar which they contain. They are used both as dessert and kitchen fruits; preserved with sugar, they make the best jams and jellies; and when fermented, produce wines little inferior to that of the grape. The blackberry has tonic and astringent properties, infusions of the leaves being used for this purpose.

UMBELLIFERÆ—UMBELLIFEROUS PLANTS.

This is one of the most extensive and important of the natural orders, comprising nearly three hundred genera, and above fifteen hundred species. The genera, though presenting many minor differences, are, on the whole, well-marked, so that no one who has seen the flower of the parsley and common hemlock, can have any difficulty in detecting an umbelliferous plant. The species are for the most part herbs, seldom shrubs, with fistular, furrowed stems, loving damp waste places, and varying much in their properties, according to the climate under which they are grown. The leaves are generally divided, sometimes simple; are alternate, and clasp the stem by a sheathing petiole. The flowers are white, pink, yellow, or blue, and in umbels, which are simple or compound, and these are with or without bracts at their base; when seated at the base of the umbel, the bract is called an involucre, when at the base of the umbellules in the compound head, an involucellum. The calyx is superior and five-toothed; petals five, and inserted on the outside of a fleshy disk, which is placed on the top of the ovary; stamens five, and inserted alternately with the petals; ovary inferior, and two-celled, with pendulous ovules; styles two, distinct; stigmas simple. The fruit consists of two carpels, united by a common axis, from which they separate when ripe; the external part of the carpels is traversed by linear ridges, which are divided into primary and secondary, there being five of the latter, and four of the former, between them. The ridges are separated by channels, below which are often placed, in the covering of the seed, receptacles or vittæ of an oily matter. The seed is pendulous, usually cohering with the carpel, rarely loose. The fruit and seed are often confounded in common language, but this arises from their peculiar position, as a little inspection will show.



Hemlock.

Among the more familiar genera may be mentioned the parsnip (*Pastinaca*), the cow parsnip (*Heracleum*), the celery (*Apium*), the carrot (*Daucus*), the hemlock (*Conium*), the cow-bane (*Cicuta*), and the coriander (*Coriandrum*). Several relations have been pointed out between the Umbelliferæ and other orders; such as their agreement with the Crowfoots in the sheathing leaves, the acrid juice, and large albumen; with some of the Geraniums in their habit, form of leaves, and poisonous properties; and with Ivyworts, from which they differ little, except in the parts of the flower. Decandolle has arranged the genera into three sub-orders—namely, 1. ORTHOSPERMÆ, having the albumen of the seed flat on the inner surface, neither involute nor convolute; 2. CAMPYLOSPERMÆ, having the albumen rolled inward at the edge; and 3. CŒLOSPERMÆ, having the albumen curved inwards from the base to the apex. The first of these sub-orders comprises eleven tribes—as Hydrocotylidæ, Mulinidæ, &c.; the second four tribes, as Elæoselinidæ, &c.; and the third only one tribe—namely, the Coriandridæ.

The properties of this order are very variable and important. Generally speaking, all the genera are characterised by an acrid principle, which finds its full development in the hemlock, rendering the roots of that plant virulently poisonous. This principle is more or less diffused through the whole order, but is often enfeebled by change of situation, or altogether destroyed by cultivation. It is this principle which gives the peculiar flavour to celery, parsley, and samphire. Another important secretion is the aromatic oil contained in the vittæ of the pericarps, which is used in diet as a condiment, and in medicine as an aromatic and carminative. It is found abundantly in the anise, caraway, dill, cumin, and coriander. A gum-resinous exudation characterises others of the genera, which yield the valuable medicines assafœtida, galbanum, opopanax, sagapenum, &c. The roots of many of the Umbelliferæ, when cultivated and properly treated, are replete with starch and sugar—as the common carrot, the parsnip, the skirret, and the arracacha of the South Americans.

CAPRIFOLIACEÆ—CAPRIFOILS.

A well-known order, consisting of twelve or fourteen genera, and upwards of two hundred and ten species. They are shrubs, rarely trees, having opposite, simple, or pinnated leaves, without stipules; and flowers terminal, in corymbs, or axillary. The flowers are white, scarlet, or yellow, and often sweet-scented, as in the common honeysuckle. The essential characters of the reproductive organs are—calyx superior, with its limb five-lobed; corolla inserted on the calyx in one piece, with its margin lobed, sometimes irregular, the divisions alternate with those of the calyx; stamens equal in number to the segments of the corolla, alternate with them, and inserted on the calyx; filaments awl-shaped; anthers ovate, two-celled; ovary cohering with the calyx, from one to five-celled, with a few pendulous ovules in each cell; style exserted; stigmas as many as the cells, either distinct, or combining into one capitate stigma; fruit one or more celled, either dry, fleshy, or succulent, and crowned by the persistent limb of the calyx; seeds generally solitary, pendulous; embryo straight; albumen fleshy.

The order has been divided into two sections—namely, the SAMBUCEÆ or elder tribe, and the LONICEREÆ or true honeysuckle tribe. In the former, the corolla is regular and rotate, seldom tubular; ovary three or four-celled; style none; stigmas three, sessile; raphe on the inner side of the ovule. It includes the genera *Sambucus* and *Viburnum*. In the latter, the corolla is tubular, often irregular; style one; berry from two to four-celled, each cell containing one or many seeds; raphe on the outer side of the ovule. It embraces the genera *Caprifolium*, *Lonicera*, *Triosteum*, *Diervilla*, *Abelia*, *Symphoricarpus*, *Linnæa*, &c. As examples of the first tribe, may be mentioned the common elder (*Sambucus nigra*)—well known by its pinnate leaves and terminal cymes of white flowers, which blow in June; by its dark purple pulpy berries, which ripen in September; and by its yellow wood, which is full of a light white pith—also the dwarf elder or Danewort (*S. ebulus*), the red-berried elder (*S. racemosa*), and the white-berried, which is only a variety of the common kind. The Laurestinus (*Viburnum tinus*) is a well-known evergreen, whose showy white flowers appear during winter; and the Gueldres rose (*V. opulus*) is common in gardens under the name of the 'snowball-tree.' In the Viburnums the leaves are not pinnate, and the wood is hard, and without the spongy pith of the elders. As examples of the second, may be mentioned the climbing honeysuckles (*Caprifolium*); the upright species or fly honeysuckles (*Lonicera*); the snow berry (*Symphoria*); and the little graceful *Linnæa borealis*, called in honour of the immortal botanist. The Caprifoils grow chiefly in the temperate regions of the northern hemisphere, and delight in cool shady places.

The properties of the order are varied, and of considerable utility. The berries of the elder are fragrant and sudorific; they contain malic acid, and a wine is often made from them, which is drunk warm with spices and sugar. The leaves are emetic and purgative; and the berries, in a green state, are poisonous to some animals. The wood, which is hard and yellow, is used by turners, and the pith is often employed in electrical experiments. The fruit of Viburnum has an austere astringent pulp, but becomes eatable after fermentation. The wood of the wayfaring tree is in great repute for the tubes of tobacco-pipes in some parts of Turkey; and the bark yields a viscous substance, used as birdlime. The roots of *Triosteum* and *Diervilla* are used in America instead of ipecacuanha; and the berries of *T. perfoliatum* are said to form no bad substitute for coffee. The honeysuckle is a purgative, but is employed principally as a handsome and fragrant climber. Indeed the whole genera are grown more for their beauty than economical uses—the climbing species for adorning old walls and trunks of trees, and the upright sorts for their shelter and covert; the elder, for example, growing in exposed places by the seaside, where any other plant would perish.

RUBIACEÆ—MADDERWORTS.

This is a large, and in many respects not a well-defined order, composed of small trees, shrubs, and herbs. It has been proposed to separate it into two orders—CINCHONACEÆ, containing those plants most resembling cinchona; and GALIACEÆ, those most resembling the galiums or bedstraws. Decandolle has proposed a further subdivision into thirteen sub-tribes, taking the genera *Cinchona*, *Gardenia*, *Hedyotis*, *Isertia*, *Hamelia*, *Cordiera*, *Guettarda*, *Pæderia*, *Coffea*, *Spermacoce*, *Anthospermum*, *Rubia*, and *Operculuria*, as the types. Without following these details, it may be stated that, collectively, the Rubiaceæ are described as herbaceous plants, with square or angular stems, and whorled and exstipulate leaves; the verticilli being formed of two opposite gemmiferous leaflets, with a variable number of intermediate ones, not differing in appearance from the general foliage, but destitute of buds. The inflorescence is in panicles; the florets small, and in general united; the calyx is superior, the tube joined to the germen, and the limb from four to six cleft; the corolla is synpetalous, rotate, or funnel-shaped, regular, with its petals equal to the sepals, and exserted from the calyx; the stamens are as many as the lobes of the corolla, and exserted alternately with them; the filaments are free, the anthers incumbent, two-celled, and open longitudinally. The germen consists of two connected carpels, invested by the adherent tube of the calyx; the styles two, and the stigma headed.

By far the greater number of the species are tropical plants, though many are amongst the most common and neglected British weeds. Madder (*Rubia tinctorum*) is common in gardens, and is much cultivated in Belgium and Holland for its roots, which yield a rich brownish-red dye. The *Galiums* or bedstraws are familiar plants, growing on hedges, on dry banks, or sides of old ditches, and known by the common names of cleavers, ladies' bedstraw, crosswort, and the like. *Asperula odorata*, another of the order, is the well-known woodruff, which acquires, when dried, a most delicate fragrance. The coffee-tree (*Coffea*), Jesuit's bark (*Cinchona*), the Cape jasmine (*Gardenia*), and ipecacuanha (*Cephäelis*), are also well-known members.

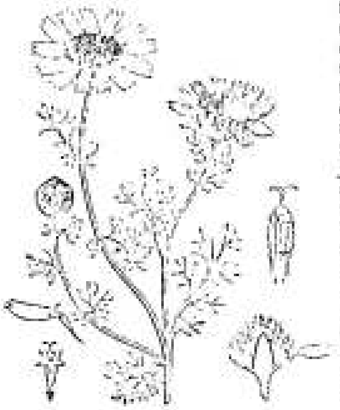
As might be expected, the properties of such an indefinite order are very varied. The roots of many, as the madders and bedstraws, contain a large quantity of colouring matter; in others they are acrid, emetic, purgative, or diuretic. The bark (as that of the Cinchonia or Peruvian bark) is sometimes bitter, tonic, and astringent, and highly prized in intermittent fevers. The value of the roasted albumen of the coffee-berry is too well known to require allusion; and perhaps, if trial were made, the fruit of others of the order might answer the same purpose. The fruit of the genipa and sarcocephalus are eaten in their native countries; and the fragrance and beauty of some, as the Gardenias, Hindsias, and Ixoras, are unsurpassed in the vegetable kingdom. Among our ancestors, the dried soft haulm of the galliums was much used for beds; hence the term 'bedstraws' for the plants of this sub-tribe.

COMPOSITÆ—COMPOSITES.

This is one of the most extensive of the natural orders, containing not fewer than nine hundred genera, and upwards of eight thousand species. The members are herbaceous plants or shrubs, with leaves alternate or opposite, without stipules, and usually simple. What is called the flower is an aggregation of unisexual or hermaphrodite *florets*, collected in dense heads upon a common receptacle, surrounded by an involucre, as exemplified in the common daisy, marigold, and dandelion. As the compound leaf is composed of a number of leaflets, so is the composite flower made up of a number of florets arranged on one receptacle, which is furnished with a calyx-like involucre. Each floret is complete in itself, having all the appendages of bracts, calyx, corolla, stamens, and pistil. The bracts may be either present or absent; when present, they are stationed at the base of the florets, and designated the *paleæ* of the receptacle. The calyx is superior, and united with the ovary, so that the tube is rarely sufficiently distinct to be perceptible; the limb is either wanting, or membranous, and cut into long feathery segments called pappus. The corolla is monopetalous, and either ligulate, tubular, or bilabiate—that is, has two equal lips cut into several lobes. The stamens are equal in number to the teeth of the corolla, and alternate with them; the anthers grow together, so as to form a kind of cylinder, through which passes the style, ending in a two-lobed stigma. The ovary is inferior, one-celled, with a single erect ovule. The fruit is an achenium, which retains the pappus when ripe, and falls without opening; the adherence of this pappus or down is familiarly illustrated in the head of the ripe dandelion.

The term COMPOSITÆ is employed in consequence of the crowding together of the florets into *heads*. The term SYNANTHEREÆ has been also proposed, on account of the cohesion of the anthers; and from the star-like arrangement of the florets, some have applied the word ASTERACEÆ. Retaining, however, the original Jussieuan term, the Composite order has been divided into three sections:—1. *Cichoraceæ*, in which all the florets are ligulate; 2. *Corymbiferæ*, most of the florets tubular, involucre soft and unarmed, style not jointed; 3. *Cynarocæ*, most of the florets tubular, involucre hard or spiny, style jointed at the end. To these Decandolle has added a fourth section—*Labiatifloræ*—in which the florets are bilabiate; a distinction either overlooked or unknown to the founder of the Natural System. The Composite plants are widely scattered over the globe, forming, according to some authorities, one-twelfth of its vegetable productions. Humboldt states that they constitute one-seventh of the flowering plants of France, one-eighth of those of Germany, one-fifteenth of those of Lapland, a sixteenth of those of New Holland, a sixth of the North American Flora, and one-half of that of America within the tropics. Though their increase and decrease do not follow any law of climate, it may be stated generally that the Chicoraceæ are chiefly found in cold, and the Corymbiferæ in warm regions. The Composites are herbaceous in the colder quarters of the globe, and become shrubby as we approach the equator.

The Chichoraceæ are well illustrated by the common lettuce (*Lactuca*), the dandelion (*Taraxacum*), the succory (*Chicorium*), and the sow thistle (*Sonchus*), which are common and familiar British plants. All the members of this section yield a milky juice, which is bitter, astringent, and slightly narcotic. Many of them are used in medicine—as the lettuce, from which the narcotic and diuretic *Lactucarium* is obtained. Many are also used as articles of food; thus endive (*C. endivia*) is employed as a salad, so is the garden lettuce when young, the root of the sonchus, and perhaps more than all, the root of (*C. intybus*) or wild succory, which is roasted and largely mingled with coffee under the name of chicory. The Corumbiferæ, which have the central florets tubular, and the outer ones generally ligulate, are illustrated by the tussilago or colt-foot (*T. farfara*), by the daisy (*Bellis perennis*), the chamomile (*Anthemis nobilis*), the groundsel (*Senecio*), the tansy (*Tanacetum vulgare*), the dahlia, marigold, &c. The juice of this section is watery; sometimes bitter and tonic, and sometimes acrid. Many of them, either in their seeds, or in the whole substance, contain volatile oils, which are used for various purposes; and some yield yellow and other dyes. Among the most useful of the section may be mentioned the Jerusalem artichoke, wormwood, chamomile, tansy, arnica, and ragwort; indeed most of the corymbifers are of medicinal value. The Cynaraceæ embrace all those which bear an affinity to the common cardoon (*Cynara cardunculus*). Their juice is watery, bitter, and tonic. By cultivation this bitterness is lessened, and the plants, or portions of them, become edible. The section may be illustrated by the cardoon and common artichoke, all the thistles (*Carduus*), the burdock (*Arctium*), the corn blue-bottles (*Centaurea*), the safflower (*Carthamus*). The properties of the artichoke are well known, as are also those of the carthamus, which is used in dyeing as well as in medicine. The Labiatifloræ are less known, being rarely seen in British gardens. *Mutisia* and *Triptilion* are examples of this section, which possess to a certain extent the bitter and tonic properties of the order.



Chamomile.

ERICACEÆ—HEATHWORTS.

This is an extensive order of shrubs or undershrubs, with leaves evergreen, rigid, entire, whorled, or opposite, and without stipules. 'The name of the heath family,' as it has been very appropriately remarked, 'conjures up immediately the image of a number of narrow-leaved plants, with globular, ventricose, or bell-shaped flowers; and we are apt at first to think that the family is so natural a one, as to require very little explanation.' Did the order include only the heaths, this would be the case, for all the heaths, differing as they do in some particulars, may be recognised at a glance; but as the order includes the Rhododendra, the Azaleas, and Kalmias, besides several other plants which have not so strong a family likeness to each other as the heaths, it becomes necessary to say a few words on the botanical resemblances which connect them together. The first and most striking of these is the shape of the anthers, each of which appears like two anthers stuck together; and the manner of their opening, which is always by a pore or round hole in the upper extremity of each cell. The filaments also in all the genera, except Vaccinium and Oxycoccus, grow from beneath the seed-vessel, being generally slightly attached to the base of the corolla. There is always a single style with an undivided stigma, though the capsule has generally four cells, each containing several of the seeds, which are small and numerous. The calyx is four or five cleft, and the corolla is tubular, with a larger or smaller limb, which is also four or five cleft. The above are the connecting points between the various genera which compose the family; but the differences are such as, according to most botanists, to require a subdivision of the Ericaceæ into four sub-orders, or even into four distinct and independent orders. Adopting the former idea, we shall consider the heath family under the following subdivisions:—1. *Ericeæ*, or those most closely resembling the true heaths; 2. *Rhodoreæ*, those allied to the Rhododendra; 3. *Vaccinieæ*, those associated with the common bilberry; and 4. *Pyroleæ*, those allied to the winter-green and fir-rape of our woods and commons.

1. *Ericeæ.*—This sub-order may be arranged into two sections—namely, the true heaths (*Ericidæ*), having bracteal pedicles of flowers, the corolla of each flower being more or less bell-shaped or globose, with a four-cleft limb, a four-lobed calyx, and eight stamens; and the *Andromedidæ*, which have the corolla more globose, the limb five-cleft, the calyx five-lobed, and ten stamens. In other respects, both sections are nearly alike: both have a honey-bearing disk under the ovary; and both have the leaves, which are narrow and leathery, slightly rolled in at the margin. The stamens appear differently in the several genera, some being capitate, others ending in awn-shaped horns; in some they are concealed by the corolla, in others they are exposed. The style, in some of the genera, projects considerably beyond the corolla, in others it is rather contracted. The more familiar genera are the besom-heath of our moors (*E. tetralix*), the Cape heath (*E. hispida*), common ling or heather (*Calluna vulgaris*), the moor heaths (*Gypsocallis*), and those Cape heaths with shiny, glutinous, cylindrical corollas (*Callista*). All of these are true heaths, and bear so striking a resemblance to the common ling of our moors, as to be at once recognised. The genera *Andromeda*, *Zenobia*, the strawberry-tree (*Arbutus*), the bearberry of our Highlands (*Arctostaphylos uva-ursi*), and *Gaultheria*, frequent in gardens, are illustrations of the second section. The heaths cover large tracts of our own country, are common in North and South America, and abound at the Cape of Good Hope, which has supplied our gardens with hundreds of the most beautiful species. All of them possess bitter, astringent, and diuretic properties; and the berries of some, as well as the flowers, have been used in dyeing. The Arbutus is a very ornamental shrub, the berries of which are edible, and may be used in the preparation of a wine. The Picts are said to have derived a wholesome beverage from the heath; and the bearberry plant is used in some parts of Russia for tanning. The Highland heaths furnish excellent pasture for bees, and its seeds furnish the principal food of the grouse.

2. *Rhodoreæ.*—The plants in this sub-order have all less or more a resemblance to the well-known genus *Rhododendron*—the species of which have generally evergreen leaves, and large showy flowers produced in terminal corymbs. The calyx is small; the corolla large in proportion, bell-shaped, and deeply five-cleft; the stamens five or ten; the capsule five-celled, and five-valved. The flowers are generally purple or whitish, though in some they are yellow, pink, or bright-scarlet, as in the Nepaul tree-rhododendron. The genus *Azalea* is very nearly allied to the Rhododendra; but its species—the Indian and American—differ considerably in their inflorescence and leaves; the latter in some species being deciduous. *Kalmia* and *Menziesia* are familiar garden genera: *Ledum palustre*, or wild rosemary, and the Labrador tea-plant (*L. latifolium*), also rank

under this section. The members of this sub-order have an extensive range, being found abundantly in Europe, Asia, and North America. They are chiefly inhabitants of high cold regions, and in this particular agree with the general habit of the order. The Rhododendra possess soporific properties—*R. crysanthum* being used in gout and acute rheumatism. The Azaleas are astringent, and some, as *A. pontica*, is said to be poisonous. The same may be said of the Kalmias; and indeed the whole of this section require to be used with caution. The intoxicating effect of liquors is increased by an infusion of any of the species.

3. *Vaccinieæ.* — This section, which we have tabulated as a separate order, contains two well-known genera—*Vaccinium*, the bilberries and whortle-berries; and *Oxycoccus*, the cranberries. They are shrubs with alternate, leathery leaves, and of a close-growing bushy habit, with round or angled stems. The flowers are solitary, or in racemes, and in their general structure differ little from the heaths, except in the ovary being inferior. In Vaccinium, the stamens are eight or ten, and the anthers horned or spurred; in Oxycoccus, the stamens are eight, and the anthers without spurs. The members are natives of Europe and America; the former genus delighting in high dry situations, and the latter in marshes and swamps. Both yield edible berries, which have austere antiscorbutic properties. The bilberry or blaeberry (*V. myrtillus*) of our woods and hills is familiar to every one, as also the whortleberry (*V. vitis-idæa*). In North America there are many species—as *V. angustifolium* (bluets); *V. stamineum* (deerberries); and *V. frondosum* (blue tangles). Of the cranberry there are generally reckoned two species—*O. palustris*, the common cranberry of European morasses; and *O. macrocarpa*, the American cranberry, which has a larger and more oblong fruit. The berry of both is extensively collected, and used for tarts and other conserves.

4. *Pyroleæ.*—The main distinction of this sub-order is the long arillus or skin which encloses the seeds, and gives them the appearance of being winged. It is well illustrated by the winter-green (*Pyrola*), which is common in British woods; and by the fir-rape (*Monotropa*), a rather rare parasite, which attacks roots of the beech and pine. The species of Pyrola are described as 'pretty little evergreen plants, with white flowers, the corollas consisting of five distinct petals, and which have ten stamens, the anthers of which are two-celled, each cell opening by a pore: the style is single, ending in a capitate stigma cut in five lobes; the fruit a five-celled capsule.' The yellow fir-rape has a coloured stem, furnished with scales instead of leaves. The flowers, which are drooping, have a four or five parted calyx, and a four or five petalled corolla.

§ COROLLIFLORÆ.

The plants belonging to this subdivision have the stamens inserted in the fleshy part of the petals, which are joined together so as to form a monopetalous corolla. This corolla furnishes, as it were, a cup for the stamens and pistil, quite distinct from the calyx. The Orders exhibiting these distinctive characteristics are as follow:—

Epacridaceæ—Epacrids	Convolvulaceæ—Bindweeds
Styracaceæ—Storaxworts	Boraginaceæ—Borageworts
Myrsinaceæ—Ardisiads	Cordiaceæ—Sebestens
Sapotaceæ—Sapotads	Solanaceæ—Nightshades
Ebenaceæ—Ebenads	Scrophulariaceæ—Figworts
Brexiaceæ—Brexiads	Lamiaceæ } —Labiates
Oleaceæ—Oliveworts	Labiatæ }
Jasminaceæ—Jasminworts	Verbenaceæ—Verbenes
Strychnaceæ—Strychnads	Myoporaceæ—Myoporads
Apocynaceæ—Dogbanes	Acanthaceæ—Acanthads
Asclepiadaceæ—Asclepiads	Orobanchaceæ—Broomrapes
Gentianaceæ—Gentianworts	Lentibulariaceæ—Butterworts
Bignoniaceæ—Bignoniads	Primulaceæ—Primworts
Pedaliaceæ—Pedaliads	Globulariaceæ—Globulariads
Polemoniaceæ—Phloxworts	Plumbaginaceæ—Leadworts
Hydrophyllaceæ—Hydrophyls	Plantaginaceæ—Ribworts

OLEACEÆ—OLIVEWORTS.

Under this order is reckoned upwards of twenty genera, and about one hundred and thirty species. They are trees and shrubs with erect or climbing stems, and with leaves opposite, petiolate, simple, seldom ternate or pinnate, and destitute of stipules. The inflorescence is in panicles; the flowers regular and united, or sometimes, by abortion, polygamous; calyx free, divided, and persistent; corolla hypogynous, four-cleft, and rarely wanting; stamens two, hypogynous when the corolla is absent, alternating with its lateral lobes when present, or when there are four petals connecting the lateral petals in pairs; filaments free; anthers two-celled, bursting longitudinally; ovary free, two-celled; ovules pendulous and in pairs; style sometimes wanting; stigma entire or bifid; fruit drupaceous, baccate, or samaroid. According to the character of the fruit, the order is sometimes subdivided into the OLEÆ, having it a drupe or berry, and the FRAXINEÆ, having it samaroid.

The principal genera are *Olea*, the olive; *Fraxinus*, the ash; *Ornus*, the manna-ash; *Ligustrum*, the privet; *Syringa*, the lilac; *Chionanthus*, the fringe-tree; *Phillyrea*, *Millingtonia*, *Linociera*, *Fontanesia*, and *Notelæa*. The olive (*O. sativa*) is a well-known tree, with small white flowers, and a fleshy drupe like a sloe, from which is expressed the oil of commerce. The ash (*F. excelsior*) is a common British tree, with pinnate leaves, the flowers without a corolla, and the fruit a winged samara or key, resembling a dry leaf, with one or two seeds. The manna-ash (*O. Europæus*), though closely resembling the common ash in its leaves and samara, has loose panicles of white flowers, the corollas of which are divided into four long narrow segments. The privet (*L. vulgare*), the lilac (*S. vulgaris*), and Phillyrea, are too common ornamental shrubs to require particular notice.

Economically, the oliveworts are of great importance. Besides the oil of the olive, so universally used in Europe, the unripe berries are pickled and eaten on the continent to provoke an appetite; and the bark, which is bitter and astringent, is used as a substitute for cinchona. The bark of the common ash, as well as that of several members, is astringent and febrifugal, while the wood of the former is easily worked, and exceedingly tough and durable. Manna, which is a saccharine cathartic, is procured by wounding the bark of the Ornus, &c. The sweetness of this substance is not due to the presence of sugar, but to a distinct principle called Mannite, which differs from cane-sugar in not fermenting with water and yeast. The lilac, like the ash and others, is held in great repute, in some of the marshy districts of France, as a febrifuge; being indeed the only remedy ever employed for the marsh or intermittent fever which prevails there. The flowers of *O. fragrans* are said to be employed by the Chinese to impart a delicate flavour to some of their teas.

CONVOLVULACEÆ—BINDWEEDS.

A well-defined order, containing above forty genera, and between six and seven hundred species. The members are herbaceous plants or shrubs, with stems usually twining, smooth, or pubescent, and with leaves alternate, undivided or lobed, and exstipulate. The inflorescence is axillary or terminal; peduncles one or many flowered, the partial ones generally with two bracts. The essential characters are—calyx persistent in five divisions, and imbricated as if in more whorls than one—often very unequal; corolla monopetalous, hypogynous, regular, deciduous; the limb five-lobed, and plaited; stamens five, inserted into the base of the corolla, and alternate with its segments; ovary simple, with two or four cells, few-seeded, the ovules definite and erect; style one, usually divided at the top; stigmas obtuse or acute; capsule with the valves fitting at their edges to the angles of a loose dissepiment, bearing the seeds at its base.

The more familiar genera are—*Convolvulus*, *Caly-*

stegia, *Ipomæa*, *Falkia*, *Cuscuta*, and *Batatas*. All these genera have the corollas marked with a decided fold or plait, have the peculiarly imbricated calyx, are climbing plants, and not to be easily confounded with any other family. The *Convolvulus arvensis* is the wild climber of our hedges; and *C. tricolor*, so common in gardens, is a native of Sicily. The bindweed, *Calystegia sepum*, is another of our hedge natives, and is the well-known pest of the farmer. The *Cuscutas*, or dodders, often arranged into an independent order, are extremely destructive parasites, originally springing from the ground, but decaying at the root as soon as they are established on the plants they attack. The other genera are chiefly natives of warmer regions; none have yet been discovered in the coldest climates.

The roots of the order abound in an acrid, purgative, milky juice, exemplified in *jalap*, which is obtained from *Ipomæa Xalapa* (from Xalapa in Mexico); and in *scammony*, the concrete juice of the root of *Convol. scammonia*, found principally in Asiatic Turkey. Excellent jalap is also obtained from *Exogonum purga*, a beautiful climber with crimson flowers; and indeed more or less from almost the whole of the order. Notwithstanding, the roots or tubers of *Batatas edulis*, the common sweet potato, is edible, as is also that of *Ip. macrorhiza*, whose insipid farinaceous tubers are found in the sandy soil of Georgia and Carolina, weighing as much as forty or fifty pounds. The majority of the members have fine showy flowers, which add greatly to their importance.

SOLANACEÆ—NIGHTSHADES.

An extensive and somewhat varied order, of between fifty and sixty genera, and nearly nine hundred species. They are herbaceous plants or shrubs, with alternate leaves, and with angular or rounded stems. The essential characters are—calyx five (rarely four), plaited and persistent; corolla with the limb having the same number of lobes as the calyx, somewhat unequal, and deciduous; æstivation folded or imbricate; stamens alternating with the segments of the corolla, sometimes one abortive; anthers bursting longitudinally, or by terminal pores; ovary two or more celled, rarely one-celled; ovules usually indefinite; style continuous; stigma obtuse, very rarely lobed; fruit either a capsule opening variously, a berry with the placenta adhering to the dissepiment, or a nuculanium, with five spurious-celled nucules, which have one seed in each; seeds sessile. Though agreeing in most of the above characteristics, the various members have differences sufficient to require a division into four sub-orders—namely, *Soleneæ*, *Nicotianeæ*, *Verbasceæ*, and *Nolaneæ*.

1. The *Solaneæ* closely resemble each other in their flowers, of which those of the garden night-shade and potato may be taken as examples; and also in their berry-like fruit, which is always crowned by the persistent calyx. The genus *Solanum*, to which belongs the bitter-sweet (*S. dulcamara*), the garden nightshade (*S. nigrum*), and the potato (*S. tuberosum*), has the anthers opening by two pores like the heaths, whereas all the other members of the order have a slit down each cell. The tomato, or love-apple (*Lycopersicum esculentum*), with its edible fruit; the capsicum (*C. frutescens*), whose dry inflated berry yields the cayenne pepper of commerce; the winter cherry (*Physalis Alkekengi*), also with edible berry-like fruit; the deadly nightshade (*Atropa belladona*), which furnishes the deadly poison of that name; and the Barbary or box-thorn (*Lycium barbarum*), all belong to this sub-tribe. The Solaneæ are rather dangerous in their qualities, the leaves and flowers being an acrid or narcotic poison, and the fruit and tubers only becoming wholesome and nutritious when cooked. 2. The *Nicotianeæ* closely resemble the preceding sub-tribe in their folded-like corolla, but differ in having capsular fruit; that is, in having the seed-vessel dry and hard when ripe, and not soft and pulpy like a berry. The flowers are also more funnel shaped, with a longish tube and spreading limb. The principal genera are *Nicotiana* (*N. tabacum*), being the Virginian tobacco of commerce; *Petunia*, which furnishes some of our best-known garden favourites; *Nierembergia*, a genera of ornamental green-house plants; *Hyoscyamus*, the poisonous henbane; *Datura*, *D. stramonium*, being the common thorn-apple; and *Brugmansia*, *Salpiglossis*, and *Schizanthus*, all more or less prized for their showy funnel-shaped flowers, some of which are highly fragrant. The members of this sub-order also require to be used with caution, on account of their acrid and narcotic properties, which are well illustrated by the henbane and tobacco. 3. The *Verbasceæ* have not the corolla plaited in the bud, and possess only one-celled anthers. The genera *Verbascum*, *Celsia*, and *Anamonda*, illustrate this sub-tribe. *V. thapsus* is the common weed shepherd's club, so called from the club-like raceme of its flowers; it has mucilaginous and emulcent properties. 4. *Nolaneæ*. 'This tribe,' says Mrs Loudon, 'is principally known by the genus *Nolana*, the species of which are annual plants, natives of Chili and Peru, which have of late been much cultivated in British gardens. The flowers of *N. atriplicifolia*, one of the commonest kind, very much resemble those of the convolvulus tricolor, and the leaves are large and juicy like those of the spinach. On opening the corolla there will be found five stamens, surrounding four or five ovaries, which are crowded together on a fleshy ring-like disk. These ovaries, when ripe, become as many drupes, enclosing each a three or four celled nut or bony putamen, which is marked with three or more grooves on the outside, and has three or more little holes beneath. All the species of Nolana have the same peculiarities in their seed-vessels, though they differ in many other respects.' In this sub-tribe there is also the genus *Grabowskya*, the nuts of which resemble those of the coffee.

Besides the genera contained in the preceding sub-tribes, there are others, placed by some botanists under the nightshades, and by others under the figworts—such as *Anthocercis*, the species of which are evergreen shrubs from New Holland, with bell-shaped corollas; *Browallia*, containing several tender annuals; and the medicinal *Franciscea* of Brazil.

SCROPHULARIACEÆ—FIGWORTS.

The Figworts, of which the common foxglove may be taken as the type, form rather an extensive order, consisting of about one hundred and seventy genera and nearly two thousand species. The members are herbaceous, rarely shrubby plants, with round or square stems; the leaves being simple and exstipulate, opposite or whorled, seldom alternate, and either sessile or with foot-stalks. The inflorescence is very variable, being axillary or united, usually in spikes, racemes, or in panicles; calyx inferior, persistent, and often unequal; corolla tubular or inflated, with a short limb, which is flat or erect, nearly equally divided or labiate; stamens definite, two or four; filaments free; anthers two-celled; ovary two-celled and many-seeded; style simple; stigma obtuse, rarely bifid; fruit a dry capsule.

Foxglove.

The following genera may be mentioned as illustrative of the order:—*Scrophularia*, weeds common in British ditches; *Digitalis*, the foxglove of our waysides and gardens; *Antirrhinum*, the well-known snapdragon; *Linaria*, the toadflax of our hedges and banks; *Euphrasia*, the meadow eyebright; *Veronica*, including the brooklime of our ditches, and the speedwells which abound in every waste place; *Rhinanthus*, the yellow rattle; and *Calceolaria*, *Buddlea*, *Mimulus*, and others, now favourites in every flower-garden. The form of the flowers in the different genera vary considerably, as may be seen by examining the foxglove, the speedwell, and calceolaria—plants at the command of every one. The stamens also present considerable differences: in the foxglove (*D. purpurea*) there are two long and two short; in *Pentstemon* there are five, the fifth being long and slender, and without an anther; in *Calceolaria* and *Veronica* there are only two. Various attempts have been made to subdivide the order—as, for example, into two sections, the one including the genera having four anther-bearing stamens, and the other those having only two-anthered stamens. Mr Bentham divides it into three sub-orders, according to the inflorescence, each of which are again subdivided into several tribes.

In their properties the members of this family present no great uniformity. The majority, however, contain a principle more or less acrid, purgative in some, and poisonous, as in the foxglove, unless taken in small doses. The meadow eyebright (*E. officinalis*) is slightly astringent and aromatic, without the deleterious qualities of the other genera. Cows are said to be fond of *Melampyrum pratense*; and Linnæus says the best and yellowest butter is made where it abounds. One or two species of Linaria and Calceolaria are named as yielding colours for the dyer.

LABIATÆ—LABIATES.

A very large natural order, remarkable for the uniformity of structure and properties which prevails among the members. The *labiate* or lipped corolla immediately suggests the mint, sage, thyme, dead-nettle, horehound, and lavender, with which every one must be less or more familiar. They are herbs or undershrubs, with quadrangular stems, and with opposite, divided or undivided, exstipulate leaves, replete with receptacles of aromatic oil. The flowers are in opposite, nearly sessile, axillary cymes, resembling whorls, as in the dead-nettle; sometimes solitary, as if capitate; calyx tubular and persistent; corolla bilabiate, the upper lip (*a*) being entire or bifid, the lower (*b*) three-cleft, the upper in æstivation overlapping the lower; stamens four, didynamous, the upper sometimes wanting; ovary deeply four-lobed, seated on a fleshy disk, each lobe containing one erect ovule; style simple; stigma bifid; fruit from one to four small nuts, enclosed within the persistent calyx.

Labiate.

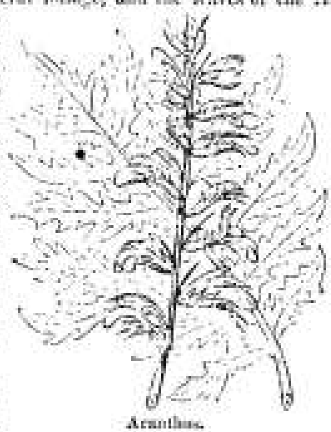
The following plants well exemplify the order:—*Lamium album*, the white dead-nettle of our wall-sides; *Salvia officinalis*, the common garden sage; *Rosmarinus officinalis*, the well-known rosemary shrub; *Thymus vulgaris*, the garden thyme; *Lavandula vera*, the sweet-scented lavender; *Mentha viridis*, spearmint, and *M. piperita*, peppermint; *Nepeta glechoma*, the ground ivy of our woods and ditches; *Marrubium vulgare*, the true medicinal horehound; *Ballota nigra*, black horehound, well known for its heavy oppressive smell; *Prunella vulgaris*, self-heal; *Ajuga reptans*, the common bugle of our woods and shady situations; with basil, marjoram, betony, hyssop, and other culinary or medicinal herbs. The order is sometimes known by the term *Menthaceæ*, taking mint as the type; and sometimes as *Lamiaceæ*, taking the dead-nettle; but we retain the older and better established one of *Labiatæ*. It is usual to divide the Labiates into twelve tribes, each embracing minor subdivisions or families.

Most of the Labiate order are medicinal, at least none of them are dangerous. The leaves are full of little pustules or receptacles of essential oil, which gives to the plants their cordial sudorific and antispasmodic properties. Many of them also possess bitter and tonic qualities in conjunction with those derived from the essential oil. The names of the genera above recited will at once recall to the mind of the reader all that is pleasant and valuable in the order.

ACANTHACEÆ—ACANTHADS.

There are nearly one hundred genera enumerated under this order, and upwards of seven hundred species of herbs and shrubs, principally inhabiting tropical regions. Leaves opposite and without stipules; inflorescence terminal or axillary; flowers in spikes with two or three bracts to each; calyx in four or five divisions and persistent—but in many of the species inconspicuous or obsolete, its place being supplied by the large bracts; corolla monopetalous and usually irregular, with the limb ringent or bilabiate, and deciduous; stamens two or four, and in the latter case didynamous; anthers one or two celled, sometimes bearded as in Acanthus, and bursting longitudinally; style simple; stigma one or two lobed; fruit a two-celled capsule, elastically two-valved; seeds supported on a filiform podosperm. The elastic dehiscent capsules, wingless seeds with hooked dissepiments, and imbricated flowers, are distinguishing features.

The genera best known are *Acanthus*, *Thunbergia*, *Ruellia*, and *Justicia*, sometimes taken as the representatives of tribes or sub-orders. The species of Acanthus are found chiefly in the south of Europe; they are plants with graceful foliage, and the leaves of the *A. mollis* is said to have furnished Callimachus with patterns for the capital of the Corinthian pillar. The corolla varies considerably in the different genera; being bilabiate in Justicia, funnel-shaped in Ruellia, and Campanulate in Thunbergia, the species of which are climbers.



Acanthus.

The properties of the order are little known. The Arabs use the leaves of an Acanthus by way of salad; *Justicia pectoralis*, boiled in sugar, yields a syrup used in the West Indies as a stomachic; and *J. paniculata* is said to be the basis of the famous French tonic *Drogue Amère*. A valuable deep blue dye is said to be obtained from one of the East Indian Ruellias.

DICOTYLEDONS.—II. MONOCHLAMYDEÆ.

The plants in this division have either no floral envelope, or have one only. In the former case, the pistil and stamens stand naked; in the latter, they are surrounded by a coloured calyx or perianth—there being no membrane corresponding to a true corolla. In treating the orders arranged under the section *Monochlamydeæ*, we shall use the term perianth, whether coloured or not, in preference to calyx, which refers more especially to an envelope which is exterior to the true corolla when present. The following are the Orders usually enumerated:—

Nyctaginaceæ—Nyctagos	Santalaceæ—Sandalworts
Amaranthaceæ—Amaranths	Elæagnaceæ—Oleasters
Phytolaccaceæ—Phytolaccads	Aristolochiaceæ—Birthworts
Chenopodiaceæ—Chenopods	Cytinaceæ—Cytinapes
Begoniaceæ—Begoniads	Euphorbiaceæ—Spurgeworts
Polygonaceæ—Buckwheats	Stackhousiaceæ—Stackhousiads
Lauraceæ—Laurels	Antidesmaceæ—Antidesmads
Myristicaceæ—Nutmegs	Urticaceæ—Nettleworts
Proteaceæ—Proteads	Ulmaceæ—Elmworts
Thymelaceæ—Daphnads	Piperaceæ—Pepperworts

Juglandaceæ—Juglands	Myricaceæ—Galeworts
Salicaceæ—Willowworts	Garryaceæ—Garryads
Betulaceæ—Birchworts	Empetraceæ—Crowberries
Corylaceæ—Mastworts	Coniferæ—Conifers
Platanaceæ—Planes	Cycadaceæ—Cycads

LAURACEÆ—LAURELS.

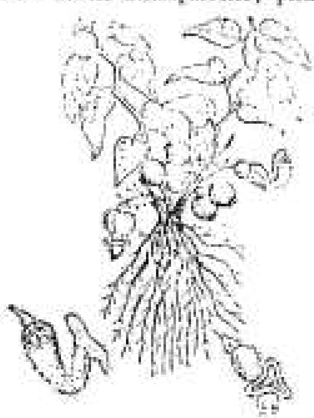
An important order, comprising above forty genera, and four hundred species. There are two sub-types—the one consisting of trees, with elegant foliage and aromatic properties; the other of herbs, which are leafless, twining in habit, and insipid. The arborescent species have exstipulate, alternate (seldom opposite) leaves, with inconspicuous flowers; the herbaceous are sometimes twining parasites. The perianth is from four to six-cleft, the limb sometimes obsolete; æstivation imbricate. The male and female flowers are distinct; the former have four, six, or eight stamens, opposite the segments of the perianth; the latter have four or more abortive stamens, furnished with glands, but without anthers, a one-celled, one-seeded ovary, with a simple style and an obtuse-crested stigma. The fruit is fleshy and indehiscent, naked, or covered by the enlarged and fleshy perianth. The two or four-celled anthers, with the valves curling upwards when ripe, like those of the berberry, and the filaments furnished with kidney-shaped glands at their base, are peculiar characteristics of the order.

The chief genera are—*Laurus*, the sweet bay; *Sassafras*, the sassafras-tree; *Persea*, the avocado pear; *Camphora*, the camphor-tree; *Cinnamomum*, the cinnamon-tree (all of which were at one time included under the genus Laurus); *Cassytha*, *Tetranthera*, and *Cryptocarya*. The true laurels have two anthers, and naked fruit; the cassia, cinnamon, and camphor have four anthers, and the fruit covered.

The arborescent Lauraceæ contain essential oil in abundance, which imparts to them a peculiar sweet, though strong penetrating odour, and a warm and pleasant taste; hence they yield some of our most grateful stimulants and spices. Cinnamon, cassia, camphor, benzoin, and sassafras, are products of the family; the roots of the red bay yield a violet dye; and a concrete oil, used in candle manufacture, is obtained from the fruit of *L. glauca*. The cogwood or Madeira mahogany is the wood of *L. chloroxylon* and *Indica*; and the Isabella wood of the cabinetmaker is the produce of *L. borbonia*, the red bay. The custom of crowning heroes and scholars with the leaves of the bay or laurel is well known to every reader of ancient history.

ARISTOLOCHIACEÆ—BIRTHWORTS.

There are only six or eight genera in this order, the members of which are herbaceous plants or shrubs, sometimes of climbing habit. The essential characters are—flowers hermaphrodite; perianth tubular, adherent with the ovary, and divided into three segments; stamens from six to ten, sometimes free and distinct, at other times adhering with the style and stigma; ovary three to six-celled; style short; stigma six-rayed; fruit capsular, dry, or succulent, three to six-celled, and many-seeded; seeds thin, flat, and of a dark-brown colour.



Aristolochia.

The chief genera are—*Aristolochia* the birthwort; and *Asarum*, the wild ginger of North America. Many of the species are natives of Europe; but they abound most in the tropical regions of America: *Arist. clematitis* and *Asar. Europæum* are the only two found in Britain. The genus *Asarum*, dividing, as it were, the representation of the order, the term *Asarineæ* is sometimes used indiscriminately with that which we have adopted.

The birthworts are heating and stimulating in their properties, and act chiefly on the skin and kidneys. The prepared root of *Arist. serpentaria* (Virginian snake-root) is used in ague, typhus fever, and in gout—being one of the ingredients of the celebrated Portland powder. The snake-root, as the name implies, is regarded as an antidote against serpent-bites; but whether it is or not, there can be no doubt that a drop or two of the juice, if introduced into the mouth of one of these reptiles, has the power of stupifying it, so that it can be handled with impunity; and a few drops swallowed, almost instantly causes death. The roots of the *Asarums* partake more of bitter and acrid properties, and have a disagreeable odour like that of the stapelias. *Asarum canadense* has an aromatic flavour, and is often used by the country people in lieu of the true ginger—*Zingiber officinale*.

URTICACEÆ—NETTLEWORTS.

This is an extensive order of plants, which, to the uninitiated, may appear very dissimilar. It is illustrated, for example, by the common nettle, the hop, the hemp, the pellitory of the wall, the bread-fruit-tree, the cow-tree, upas, mulberry, common fig, banyan, and India-rubber-tree, all of which, though exhibiting different habits and products, are not only strikingly alike in their essential characters, but also in their general properties. The order is much simplified by subdivision into two sections—namely, *Urticeæ* and *Artocarpeæ*—the former including the herbaceous species, as the nettle, hemp, and hop, with watery juice; and the latter the ligneous species, as the bread-fruit, mulberry, and fig, which have their juice milky. Bearing this distinction in mind, the following may be stated as the characteristics of the order:—Trees, shrubs, or herbs, with alternate leaves, usually covered with asperities or stinging hairs, and furnished with membranous stipules, which are deciduous or convolute in vernation; flowers usually monœcious, sometimes diœcious; perianth membranous, lobed, and persistent; stamens definite, distinct, inserted into the base of the perianth, and opposite its lobes; anthers turned backwards with elasticity when bursting; ovary superior, simple; ovule solitary, erect, or pendulous; stigma simple; fruit a simple indehiscent nut, surrounded by the membranous or fleshy calyx, as in the nettle and hemp—or a fleshy receptacle, either covered by numerous nucules lying among the persistent fleshy calyxes, as in the bread-fruit, or enclosing them within its cavity, as in the fig. 'The unisexual flowers,' says Dr Lindley, 'simple lenticular fruit, superior radicle and stipules, afford the essential characteristics of this order, which cannot well be mistaken for any except *Chenopodiaceæ*; and the plants of that order never have stipules, or rough or stinging leaves.'

The chief genera under the sub-order URTICEÆ are—*Urtica*, of which *U. dioica* is the common stinging nettle of our old wall-sides; *U. urens*, the smaller stinging nettle; and *U. pilulifera*, the Roman nettle of our gardens; *Humulus lupulus*, the cultivated hop; *Cannabis sativa*, the fibrous hemp of commerce; and *Parietaria officinalis*, the medicinal pellitory of the wall. The members of this section are widely scattered over the world, and increase apparently with the progress of civilisation. The chief genera of the sub-order ARTOCARPEÆ are—*Artocarpus*, of which *A. incisa* is the far-famed bread-fruit of the South Sea Islands; and *A. integrifolia*, the jack-tree of the East India Islands; *Galactodendron utile*, the cow-tree or palo de vacca of South America; *Antiaris toxicaria*, the upas-tree of Java, about which so many fabulous stories have been told: *Morus*, of which *M. nigra* is the common black mulberry; *M. rubra*, the red, and *M. alba*, the white mulberry, the leaves of which are so much esteemed for feeding silkworms: *Ficus*, of which *F. carica* is the common edible fig; *F. sycamorus*, the sycamore of the Scriptures; *F. Indica*, the spreading banyan; and *F. elastica*, the Indian-rubber-tree.

Hop.

The Urticeæ have watery juice, which is acrid and astringent, and the fibres of their stems are all less or more tenacious. The leaves of the hemp are narcotic; the hop has bitter, aromatic, and stomachic properties, and its effluvia are also said to be narcotic. The stinging property of the common nettle is well known, but the poisonous secretion is distinct from the juice. In the Artocarpeæ, on the other hand, the juice is milky, and on exposure to the air, becomes tough and elastic. Their fruit is edible, but their juice is generally acrid and poisonous; unless in that of the Galactodendron, which is wholesome and nutritious. The elaboration of a tough elastic product seems to be characteristic of the whole order—making its appearance in the stem of the hemp, in the inspissated juice of the Indian-rubber-tree, or in silk, the best of which is derived from silkworms which feed on the leaves of the mulberry. Hemp, hops, silk, caoutchouc, figs, mulberries, and bread-fruits, may be regarded as the most valuable products of the order.

BETULACEÆ—BIRCHWORTS.

A small order of trees and shrubs, abounding in the temperate and colder regions of the globe. They have alternate simple leaves, with the primary veins often running straight from the midrib to the margin, and deciduous stipules. The flowers are in catkins, unisexual, and monœcious; the males sometimes having a membranous lobed perianth. Stamens distinct, scarcely ever monadelphous; anthers two-celled; ovary two-celled; ovules definite, pendulous; style single or none; stigmas two; fruit membranous, indehiscent, by abortion one-celled; seeds pendulous, naked.

The chief genera are—*Betula*, the birch, and *Alnus*, the alder, the species of which abound in every northern country. The common white birch (*B. Alba*) is an elegant tree, thriving in almost any sort of soil, and becoming stunted and dwarfish only in the arctic regions, or at great elevations. The weeping-birch (*B. pendula*) is a still more graceful tree, grown in lawns and parks for its fine drooping branches and neat small foliage. *B. nana* is the dwarf birch of high and exposed situations, being found on the very limits of perpetual snow. *B. nigra* is the black birch of North America, the timber of which is used so much by cabinetmakers; and *B. papyracea* is the paper birch, whose bark is used by the Esquimaux and others in the construction of canoes. The common alder (*A. glutinosa*) is a quick-growing tree, found in swampy flats, and by the borders of streams; the hoary alder (*A. incana*) is seldom found south of the sixtieth parallel; the notch-leaved alders (*A. sinuolata* and *A. glauca*) are both American species.

The bark of the order is astringent and bitter, and has been used with effect as a febrifuge. A decoction of birch-bark is used by the Laplanders in the preparation of reindeer-skins; and the empyreumatic oil derived from it is said to be used by the Russians in tanning—hence the peculiar odour of their leather. The sweetish sap obtained by tapping the birch in spring is the chief ingredient in birch wine; the leaves, which, when young, are highly odorous, are also used in imparting dyes of various shades of yellow. The wood of several of the birches is used in furniture-making and turning, and makes no mean substitute for mahogany. The wood of the alder is soft and white, endures well under water, and is used by turners and veneerers.

CORYLACEÆ—MASTWORTS.

The Corylaceæ or Cupuliferæ are so named from the cup-like shape of the persistent involucre in which their fruit or nuts are placed—as, for example, the acorn. This cupule is called *cup* in the oak; but husk in the chestnut and filbert. It includes many genera of well-known trees and shrubs—as the oak, chestnut, beech, hazel, and hornbeam. Their leaves are alternate, simple, and stipulate; their vernation well-marked, and often rigid; flowers unisexual; the males in catkins; and the females in clusters or in catkins; the male flowers have from five to twenty stamens inserted into the base of the scales, or of a membranous perianth, generally distinct; in the females, the ovaries are crowned by the rudiments of an adherent perianth, seated within a coriaceous involucre (*cupule*) of various figure, and with several cells and several ovules, the greater part of which are abortive; ovules twin or solitary, pendulous; stigmas several, nearly sessile, and distinct; fruit a bony or leathery nut, of one cell, and less or more enclosed in the involucre.

The following are the most familiar genera:—*Quercus*, of which *Q. pedunculata* is the common British oak; *Q. sessiflora*, another British oak; *Q. suber*, the cork-tree; *Q. ilex*, the evergreen oak; *Q. rubra*, the scarlet oak of America; and *Q. phellos*, the willow oak, with long narrow entire leaves. *Fagus*, of which *F. sylvatica* is the common beech of our woods; and *F. ferruginea*, the bloody or copper-leafed beech. *Castanea*, to which belong *C. vesca*, the edible sweet chestnut; and *C. pumila*, the dwarf Virginian chestnut. *Corylus*, of which *C. avellana* is the common hazel nut or filbert; and *C. colurna*, the Constantinople nut. *Carpinus betulus*, the humble hornbeam of our hedges; and *Ostrya vulgaris*, the hop hornbeam. The hornbeams are by some botanists ranked under the Birch tribe, on account of the involucre not forming so complete a cupule as the other genera; but this seems too minute a distinction, as the involucre is not more leafy than it is in some of the filberts. The members of the family abound in Europe, Asia, and North America; more sparingly found in South America; and altogether absent from the south of Africa.

The bark in all the Mastworts is bitter and astringent, and is used for dyeing, tanning, or for medical purposes. Their timber is in general employed as a durable material for house and shipbuilding, and implement-making—as that of the oak, chestnut, and beech. In a few, the fruit is bitter and disagreeable; but in the majority it is farinaceous, and frequently contains an oily matter, used in domestic economy. Many of the lower animals derive their main subsistence from the acorns, beech-mast, chestnuts, and hazel-nuts of this order; and their fruit, as well as their bark and timber, is of the highest value to man. The gall-nut is an excrescence of the oak-leaf, caused by the puncture of an insect; it is used in medicine, and is the chief ingredient in ink and in black dyes.

CONIFERÆ—CONIFERS.

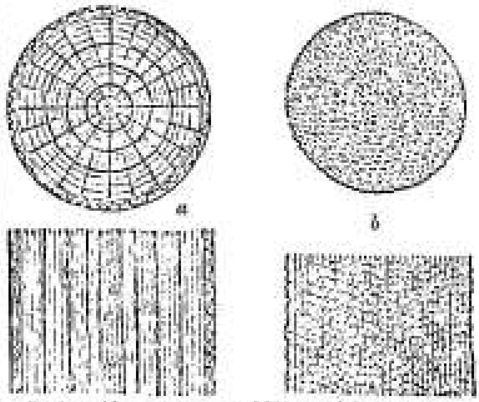
One of the most important, as it is one of the best defined, of the natural orders. Its members are trees or shrubs, with a branched trunk abounding in resin, and are familiarly illustrated by the Scotch pine, the spruce and silver firs, the larch, the cedar, the araucaria, the arbor vitæ, the cypress, the yew, and the juniper. The ligneous tissue of their wood is marked with circular disks; their leaves are linear, needle-shaped, or lanceolate, entire at the margin, and with the veins parallel to each other. The essential characters of the fructification are:—Flowers unisexual; males monandrous or monadelphous, each floret consisting of a single stamen, or of a few collected into a deciduous catkin about a common rachis; females in cones; ovary spread open, and resembling a flat scale, destitute of style or stigma, and arising from the axle of a membranous bract; ovules naked, in pairs on the face of the ovary, and consisting of one or two membranes open at the apex, and of a nucleus; fruit consisting of a cone formed of the scale-shaped ovaries, become enlarged and indurated, and occasionally of the bracts also; seed with a hard crustaceous testa. In speaking of the Coniferæ, it has been not inaptly remarked that 'the flowers are quite different from what is generally understood by that name, being in fact nothing but scales; those of the male containing the pollen in the body of the scale, and those of the female producing the ovules or incipient seeds at the base.'

Well-defined as the order obviously is, there are minor distinctions which warrant its subdivision into the following sections—namely, ABIETINEÆ, the true pines and firs; CUPRESSINEÆ, the cypresses; and TAXINEÆ, the yews. In the firs, the fruit is a cone, the scales of which open, and more or less recurve, when the seeds are ripe; in the cypresses it is also a cone, but rounder, and with fewer scales; and in the yews it is an open succulent cup, bearing the seed or nut in its centre. In other respects—as in their foliage, habit, resinous secretions, &c.—they closely resemble each other. Of the Abietineæ the following are very typical members:—The *Pinus sylvestris*, the Scotch pine; *Abies excelsa*, the spruce fir; *Picea nobilis*, the spruce fir; *Larix Europæa*, the common larch; *Cedrus Libani*, the cedar; and *Araucaria excelsa*, the Norfolk Island pine—all of which are evergreens, with the exception of the larch. The Cupressineæ are well represented by *Cupressus sempervirens*, the evergreen cypress; *Thuja occidentalis*, the American arbor vitæ; *Taxodium distichum*, the deciduous cypress; *Juniperus communis*, the juniper of our rocky glens; and *J. sabina*, the savin-tree. The Taxineæ embrace the common yew (*Taxus baccata*), the salisburias of our shrubberies, and a few others less common.

The high importance of this order is derived from its timber, which in all is straight, easily worked, and durable. It is also valuable for its resinous productions; several kinds of pitch, tar, turpentine, gums, and balsams being procured from the various species. The large seeds of some are said to be edible and wholesome; the berries of the juniper are largely used in the preparation of gin; and the main ingredient in spruce-beer is an extract from several species of Abies. Great tanning powers exist in the bark of the Larch; the savin, juniper, and others, possess stimulating and diuretic properties; and the leaves of the common yew are fœtid and poisonous, especially to cattle.

MONOCOTYLEDONS—ENDOGENS.

The Monocotyledons or Endogens include all those plants whose leaves have their veins placed parallel—as the palms, the grasses, the hyacinth, crocus, &c. Their stems have no distinction of pith, wood, bark, concentric circles, and medullary rays, like the Exogens (*a*), but is merely a confused mass of pithy matter, with intermingled bundles of ligneous fibre (*b*). Their seed contains an embryo, having only one seed-lobe or cotyledon: hence the term Monocotyledon. Their trunks increase from within, instead of by external concentric layers: hence also the term Endogen. They are divided into sections—PETALOIDEÆ and GLUMACEÆ. The former includes those having a perianth—such as the orchis, cane, lily, palm, &c.; and the latter those which are destitute of a perianth, but have a glume or husk instead, like the grasses, cereals, and sedges. The trees of this division are strictly tropical: the herbaceous species are found all over the globe.



Sections of Dicotyledonous and Monocotyledonous Stems.

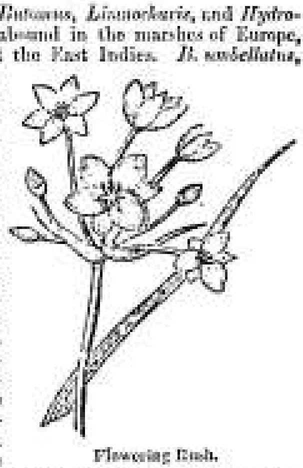
§ I.—PETALOIDEÆ.

Hydrocharidaceæ—Hydrocharads	Smilaceæ—Sarsaparillas
Alismaceæ—Alismads	Liliaceæ—Lilyworts
Butomaceæ—Butomads	Melanthaceæ—Melanths
Juncaginaceæ—Arrow-grasses	Pontederaceæ—Pontederads
Orchidaceæ—Orchids	Gilliesiaceæ—Gilliesiads
Musaceæ—Musads	Commelynaceæ—Spiderworts
Zingiberaceæ—Gingerworts	Palmaceæ—Palms
Marantaceæ—Marants	Pandanaceæ—Screwpines
Iridaceæ—Irids	Typhaceæ—Bulrushes
Hæmodoraceæ—Blood-roots	Araceæ—Arads
Hypoxidaceæ—Hypoxads	Naiadaceæ—Naiads
Amaryllidaceæ—Amaryllids	Juncaceæ—Rushes
Bromeliaceæ—Bromeliworts	Restiaceæ—Cordleafs
Dioscoreaceæ—Yams	Eriocaulaceæ—Pipeworts.

BUTOMACEÆ—BUTOMADS.

A small order of aquatic plants, having cellular leaves, furnished with parallel veins, and handsome umbellate flowers of a purple or yellow colour. Calyx three-sepalled, usually herbaceous; corolla three-petalled and coloured; stamens hypogynous, definite or indefinite; ovaries superior, three, six, or more, either distinct or united into a single mass; stigmas of the same number as the ovaries, and simple; follicles many-seeded, either distinct and rostrate, or united into a single mass; seeds minute, attached to the whole inner surface of the fruit. The order is nearly allied to the preceding, but differs in each carpel, having numerous seeds.

The genera are—*Butomus*, *Limnocharis*, and *Hydrocleis*, all of which abound in the marshes of Europe, South America, and the East Indies. *B. umbellatus*, the flowering rush, is common in our ditches and by river sides, growing from two to three feet high, with sword-shaped leaves, and umbels of a rose or purplish-white flowers. *Limnocharis plumieri*, a native of Brazil, has yellow flowers, and the apex of each leaf is furnished with a curious pore, apparently for the discharge of the superabundant moisture which constantly distils from the plant. All the members are very pretty



Flowering Rush.

plants; the common flowering rush being universally acknowledged as one of our handsomest native plants.

The order is said to possess acrid properties; and most of the species yield a milky juice. The rhizome and seeds of the flowering rush had once an officinal value as refrigerants and solvents.

LILIACEÆ—LILYWORTS.

A very extensive, and to the florist one of the most important of the natural orders. Taking the common white lily as the type, there is a great resemblance in all the Lilyworts, not only in their habits and forms, but also in their essential characters. Notwithstanding, botanists have somewhat perplexed themselves by subdivisions founded upon the minutest differences. Thus by some the order is termed *Tulipaceæ*—the tulip being taken as the type; by others it is made into three distinct orders—namely, *Asphodeleæ*, *Tulipeæ*, and *Hemerocallideæ*; while by others these are merely regarded as sub-tribes. According to the latter view, the Asphodeleæ would include the asphodel, onion, hyacinth, asparagus, &c.; the Tulipeæ—the common tulip, lily, fritillary, gloriosa, &c.; and the Hemerocallideæ—the day-lily, the aloe, and tube-rose. Sinking these distinctions in the meantime, and viewing the whole as one order, the following are the essential characteristics:—Plants with scaly or tunicated bulbs and stemless; or tuberous, creeping, erect, or arborescent; leaves not articulated with the stem, either sessile or with a narrow petiole. In some of the genera the flowers are erect and single, as in the tulip; in others they are erect but in umbels, as in the orange lily; and in others they are in racemes and drooping, as in yucca; or single and drooping, as in the fritillary; or with the segments curved back, as in the martagon lily. Perianth coloured, regular, and six-divided, occasionally tubular; stamens six, inserted into the segments of the perianth; anthers opening inwards; ovary superior, three-celled, and many-seeded; style one; stigma simple or three-lobed; fruit either a three-celled, three-valved loculicide capsule; or fleshy, and then occasionally tripartite. The seeds of the Asphodeleæ have a black, crustaceous, brittle testa; in the Tulipeæ and Hemerocallideæ the testa is brown and spongy.

Liliaceous.

The following plants may be mentioned as illustrative of the principal genera:—*Lilium candidum*, the white lily; *Tulipa sylvestris*, the wild tulip; *Allium cepa*, the onion; *Fritillaria meleagris*, the fritillary; *Hyacinthus orientalis*, the garden hyacinth; *H. nutans*, the harebell; *Asparagus officinalis*, the garden asparagus; *Muscari racemosum*, the starch hyacinth; *Erythronium dens-canis*, the dog's-tooth violet; *Phormium tenax*, the New Zealand flax; *Aloë*, the aloe; *Polianthes*, the tube rose; *Hemerocallis*, the day-lily; *Scilla*, squills; *Asphodelus*, king's spear—all of which are within the reach of every one's examination. The Lilyworts are found in every quarter of the globe, being more abundant, however, in temperate than in tropical climates, where they exist chiefly in arborescent forms.

The properties of the order, as may be expected, present considerable differences. All the Asphodeleæ contain a bitter stimulant principle in a viscid juice, as is exemplified by the onion, garlic, leek, and chives. The roots of some are purgative, as the aloe; while those of several lilies are eaten in Siberia, as potatoes. Gum-dragon is the styptic juice of *Dracæna draco*; New Zealand flax is the tough fibre of the leaf of *Phormium tenax*; squills is a well-known demulcent; and the succulent suckers of asparagus are largely eaten as a vegetable. Many of the species are cultivated solely for their fine showy flowers.

BROMELIACEÆ—BROMELWORTS.

This family consists of about a dozen genera, and more than one hundred species of plants with scarcely any stem, and sometimes parasitic in their habit. Their leaves are rigid, channelled, and often spiny or toothed at the margin. The perianth is tubular, and in two rows; the outer, or calyx, in three clefts, rigid, and persistent; the inner, petaloid and deciduous; stamens six, inserted into the base of the segments of the perianth; ovary free or cohering, and three-celled; ovules indefinite; style single; stigma three-parted, often twisted; fruit capsular or succulent, three-celled, and many-seeded.

The principal genera are—*Bromelia*, the pine-apple; *Agavé*, the American aloe; *Billbergia*, *Lyllua*, *Pitcairnia*, and the curious epiphyte *Tillandsia*, Spanish or Brazilian moss. They are natives of moist warm climates, such as Brazil, West and East Indies; but many of them, with a little care, might be cultivated in the south of Europe. All the above-named genera are common in our stoves and conservatories. The common pine-apple (*B. ananas*) was named by Linnæus after Olaus Bromel, a Swedish botanist; and it receives its English name from the circumstance of its fruit being covered on all sides with small triangular scales, resembling the cone of a pine-tree. The American aloe (*A. Americana*) is a very frequent plant in our greenhouses, remarkable for its thick leathery leaves and high flower-stalk, which sometimes reaches the height of thirty feet.

The order has several important uses. The pine-apple, so much esteemed for its fine aromatic flavour, is perhaps the most delicious fruit in the world. What is called the fruit is, in fact, the fruits of the same spike cohering into one mass, by means of their perianths becoming succulent; something similar to the cohesion which forms the strawberry. Several of the species are esteemed for their showy blossoms; the juice of others yields a vinous liquor; and the tough leaf-fibres of such as the Agave produce excellent cordage. Some of the Tillandsias, which hang their threadlike festoons from the trees of Brazil, are collected and used for stuffing mattresses, saddles, &c. making a pretty good substitute for horse-hair. Most of the genera yield a fine aromatic odour; and from their habit of retaining water in the sheathing axes of their leaves, are specially grateful to the traveller in the regions where they abound.

PALMACEÆ—THE PALM-TRIBE.

An important order of arborescent endogens, with lofty simple trunks, bearing a tuft of leaves or fronds on the summit, and only in one or two instances branched. The leaves are terminal, and large, with a plaited vernation; flowers small, with bracts, forming a mass or spadix, which is enclosed in a spathe bursting on the under side; florets bisexual or polygamous; perianth six-parted, and persistent, in a double row—the three outer segments often smaller, the three inner sometimes deeply connate; stamens inserted into the base of the perianth, usually six, seldom three, and in a few polygamous species indefinite; ovary one or three celled, or deeply three-lobed; ovules three, rarely one; fruit baccate or drupaceous, the flesh fibrous; albumen cartilaginous, either ruminate, or furnished with a central cavity.

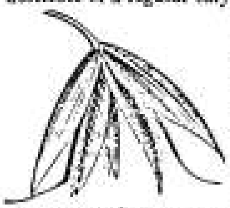
Palm.

The principal genera are—*Cocos*, the cocoa-nut; *Phœnix*, the date-palm; *Sagus*, the sago-palm; *Calamus*, the common cane; *Areca*, the areca-nut; *Borassus*, the cabbage-palm; *Ceroxylon*, the wax-palm; *Elais*; *Sabal*; and *Acrocomia*. They are strictly inhabitants of the tropics, to the natives of which they are undoubtedly the most useful order of vegetation.

The properties of the Palms are numerous and varied—wine, oil, wax, flour, sugar, salt, thread, utensils, habitations, and food, being obtained from some one or other of the species. The cocoa-nut, sago, date, areca, betel nuts, and palm-oil, are well-known products. *Coir*, which is worked into mats and cordage, is the dry fibrous pericarp of the cocoa-nut.

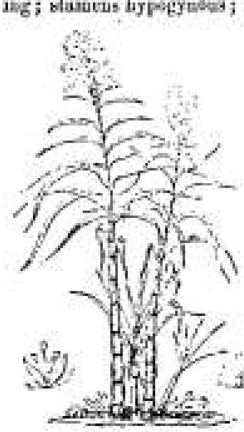
§ GLUMACEÆ.

The plants in this section of the Monocotyledons are destitute of a regular calyx and corolla, having instead green or brown scales to cover the stamens and pistil. The glume, or chaff of the oat (see fig.), is a familiar example of this kind of envelope. The Sedges (CYPERACEÆ) and the Grasses (GRAMINACEÆ) are the only Orders ranking under this sub-class. We can merely glance at the latter—naming a few of the genera which lie within the inspection of every reader.



GRAMINACEÆ—GRASSES.

One of the most important and valuable, as it is one of the most extensive, of the natural orders. According to the latest authorities, it comprehends two hundred and ninety-eight genera, and three thousand eight hundred species, familiarly illustrated by the common grasses of our pastures, by the bread-corns or cereals—wheat, barley, rye, oats, &c.—and by the sugar-cane and rice. Their rhizomes are fibrous or bulbous; their culms or stems cylindrical and hollow, except at the joints, where they become solid, the whole culm generally covered with a shining siliceous coating; leaves alternate, and though sheathing the stem, do not unite round it; flowers in spikelets or *locustæ*, and arranged in a spiked, racemed, or panicled manner. The essential characters of the fructification, according to Dr Lindley, are—flowers usually hermaphrodite, sometimes monœcious or polygamous, consisting of imbricated bracts, of which the most exterior are called *glumes*, the inferior immediately enclosing the stamens *paleæ*, and the innermost at the base of the ovarium *scales*: glumes usually two, alternate, sometimes single, most commonly unequal; paleæ two, alternate, the lower or exterior simple, the upper or interior composed of two, united by their contiguous margins, and usually with two keels, together forming a kind of dislocated calyx; scales two or three, sometimes wanting; stamens hypogynous; anthers feathery or hairy; pericarp usually undistinguishable from the seed, membranous; albumen farinaceous.



Sugar-cane.

The Grasses are scattered all over the globe, and are the most directly useful of all vegetation both to man and to the lower animals. The following well-known plants may be taken as illustrative of the order:—*Triticum vulgare*, common wheat; *Hordeum distichum*, common two-rowed barley; *Secale cereale*, rye; *Avena sativa*, common oats; *Zea mais*, maize or Indian corn; *Saccharum officinarum*, the sugar-cane; *Oryza sativa*, rice; *Bambusa*, the bamboo; *Phleum pratense*, cat's-tail grass; *Agrostis stolonifera*, fiorin grass; *Anthoxanthum odoratum*, sweet-scented vernal grass; *Dactylis glomerata*, cock's-foot grass; *Festuca pratense*, meadow fescue; *Lolium perenne*, rye-grass; *Briza media*, maiden-hair; *Alopecurus pratensis*, meadow fox-tail grass; and *Holcus lanatus*, woolly soft grass. Though allied in many respects to the Sedges, the Grass family are readily distinguished by their hollow-jointed stems, and leaves that sheathe, but do not completely surround, the stem like a tube.

As food for man and beast, the value of this order is too well known to require more than a passing notice. Wheat, barley, oats, rye, rice, guinea corn, millet, maize, and the sugar-cane belong to it, with the products of which every one is familiar. The straw or dried culms is used as fodder, litter, thatch, and as material for the manufacture of ladies' bonnets. All the Grasses—from the bamboo and sugar-cane to the common rye-grass—have a thin siliceous coating on their stems, which seems intended to furnish them with greater strength and durability than could have been procured by simple ligneous fibre.

CRYPTOGAMS, OR ACROGENS.

This class of vegetation is readily distinguished by none of its members bearing flowers—hence the term *Cryptogamia*, or *Flowerless*. They consist of cellular tissue only, and increase by simple additions of matter to the growing-point, or apex of the parts already formed—hence the term *Acrogens*. They exhibit, however, very different degrees of organisation,—the highest (*ferns*) having both stems and leaves, and peculiar sort of wood; the lowest consisting of simple-jointed threads, or even mere nucleated granules. Between these two extremes there are various conditions of stem and leaf—the two most frequently graduating into each other, and forming neither true leaf nor stem, but thin expansions, botanically termed *thalli*. The Cryptogams are divided into two sub-classes—namely, the FOLIACEÆ, or those in which the distinction of stem and leaf can be traced; and APHYLLEÆ, those which show no such distinction. None of the members have seeds like the vascular plants, but are reproduced by spores or little embryo plants, which arise from various parts of their structure. See VEGETABLE PHYSIOLOGY.

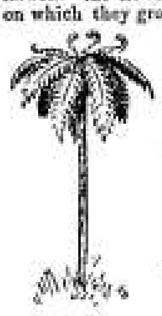
§ FOLIACEÆ.

Filices—Ferns	Characeæ—Stoneworts
Lycopodiaceæ—Club-mosses	Musci—Mosses
Marsileaceæ—Pillworts	Hepaticæ—Liverworts.
Equisetaceæ—Horsetails	

FILICES—FERNS.

In this order the different parts of the plant spring from a *rhizoma*, or root-stock; the fronds or leaves being either separate and independent, or uniting by their stalks so as to form a sort of trunk, as in the tree-ferns. The fronds are not leaves in the ordinary sense of that term; their veins are forked instead of being either reticulated or parallel. The fronds are usually pinnatifid, and more or less compound; sometimes nearly simple and entire; in their vernation they are circinate—that is, they unroll from the stem outwards. The reproductive organs or *sori* are brown membranous-looking spots, either upon the backs of the fronds, or on the margin, or wrapped up in contracted and deformed fronds. These sori either form under the cuticle near to some vein, in which case the raised portion of the skin forms what is called an *indusium*; or they are outside the cuticle, and naked; or they are arranged along the margin of the leaf, which curls over them, and supplies the place of the indusium. The sori contain a number of brownish grains, called *thecæ*, each being in reality a case containing a number of minute *sporules*, which are the true reproductive embryos.

It is usual to divide the Ferns into two sections—namely, the POLYPODIACEÆ and the OSMUNDACEÆ—the former having the sori either on the back or on the margin of the frond, and the former having apparently flowers—the flowers being merely sori with the leaves on which they grow shrivelled up around them. The former section is illustrated by the following genera:—*Polypodium*, the polypody, which has naked sori; *Aspidium*, the shield fern; *Cystopteris*, the bladder fern; *Asplenium*, spleenwort; *Pteris*, the common brake; *Nephrodium*, to which belongs the male and female ferns of our woods; *Adiantum*, maiden-hair; and *Scolopendrium*, hart's tongue, the frond of which is tongue-shaped, and simple. The latter section is represented by *Osmunda*, the flowering fern; *Botrychium*, the grape fern; *Ophioglossum*, the adder's tongue; and by the tree-ferns of Australia and New Zealand. The Filices are widely distributed, delighting in humid soil and shady situations—some growing parasitically on trees.



Tree Fern.

The fronds of the family generally contain an astringent mucilage, and are thus considered as pectoral and lenitive; the roots of some are used as anthelmintics and purgatives; and *Aspidium fragrans* has been employed as a substitute for tea. The young leaves and rhizomes of some are edible; and the fronds of the common brake, when burned, yield a considerable quantity of alkali.

§ APHYLLEÆ.

The orders under the Aphyllous, or frondless subclass of Cryptogams, are—

Lichenes—Lichens. Fungi—Mushrooms. Algæ—Seaweeds.

FUNGI—MUSHROOMS.

The Fungi, or Mushroom family, which are among the lowest forms of vegetation, are extremely diversified in their size, shape, colour, and consistence. The common field mushroom is one of the best known, and forms the type of the family; but the puff-ball, truffle, morel, as well as the mould on cheese and stale bread, the mildew on trees, the rust on corn, the substance called dry rot, and many other minute and yet unobserved appearances of a similar nature, are all fungi. They are strictly aphyllous, having neither fronds nor thalli; and their reproductive organs consist of sporules lying loose on the tissue of the plant, or collected in certain places which are distended by their aggregation. In the field mushroom (*Agaricus campestris*) the plant consists first of some filamentous thalli or spawn, which look like roots, then the stipe or stalk, surmounted by the pileus or cup. 'When the mushroom first appears, the stalk is covered by a thin membrane, called the veil, which unites the cup to the lower part; but as the mushroom grows, this veil is rent asunder, and it either entirely disappears, or only a small portion of it remains round the stalk, which is called the *annulus*, or ring. Under the cup are gills or lamellæ, which are of a dark reddish brown; and attached to these are the thecæ, containing the spawn or seed.' In some, the spawn is in the substance of the plant at the base; nor is the mode of growth the same in all. Many—as the moulds, &c.—are mere microscopic jointed filaments, or filaments surmounted by little ball-like receptacles which contain the sporules, or are mere spherical granules, which increase with astonishing rapidity, each granule containing a number of undeveloped granules.

Among the more familiar genera are—*Agaricus*, the mushroom; *Tuber*, the truffle; *Morchella*, the morel; *Boletus*, the puff-ball; *Puccinia*, the mildew; *Clavaria*, the yellow meadow fungus; *Tremella*, the jelly-looking masses found on decaying trees; and *Tubercularia*, the small, red, pimple-like fungus, also found on rotten sticks and trunks of trees. The Fungi are scattered everywhere—springing from the ground, yet without roots; under the ground, as the truffle; on all decaying organic substances; and even on living animals, as the *Achlya prolifera*, which looks like a whitish slough or slime on gold fishes, yet is a true rapidly-developing fungus, with a filamentous stipe crowned by a ball-like receptacle. Even what we call yeast is but a spherical fungus, having a nucleated development.

The plants of this order are not more diversified in form than in properties. Some are wholesome and palatable—as the mushroom, morel, truffle, &c.: others, similar to these in appearance, are deadly poisons. Many of the minuter fungi—as moulds, smuts, rusts, &c.—are noxious to the human system. Ergot forms a powerful and dangerous medicine. German tinder is prepared from a species of boletus, which, after being dried, is impregnated with nitre.

Such, according to our limits, is an outline of the Natural System of Botany; which, though as yet but partially developed, is infinitely more interesting and instructive than any artificial method, however elaborate and complete. Undeveloped as we must admit it to be, harsh and difficult as much of its nomenclature is, unnecessarily multiplied and complicated as its orders and tribes really have been, it has still the germs of truth and nature within it, and only requires a cordial and patient elaboration, on the simple principles of its great founder, to render it what it professes to be—an exposition of the system upon which Nature has proceeded in the creation of the Vegetable Kingdom. Our brief synopsis, as contained in this and the two preceding sheets, can at most but convey to the reader a very general notion of vegetable life and relationship, and only introduce him, as it were, to the technical phraseology and mode of procedure: for further acquaintance with the subject, we cannot refer to a more accessible source than the excellent suite of works recently published by Professor Lindley of London. There the inquirer will find, in a connected form, all that is necessary to be known in ordinary cases; there, if he is ambitious of proceeding further, he will find reference to the highest authorities, British and continental; and there, too, he may learn the best modes of practical investigation. To observe generally, to collect everywhere, to examine carefully, and to pronounce with caution, are the duties of the true phytologist; and the more attention to these, the sooner will the objects of a Natural System be accomplished. It is true that there are some difficulties at the outset—and where is the department of human knowledge without such obstructions!—but these overcome, and what a delightful field of intellectual enjoyment beyond! The beauty and variety of flowers, the fragrance and freshness which we are insensibly led to associate with them, have long been themes for the poet and moralist; but really not more so than the subject deserves. The endless forms in which plants appear, their adaptations to certain situations, the peculiar properties which many species possess, though all grow on the same soil, the wonderful metamorphosis which they undergo from seed to plant, and from plant and flower to seed again—not to speak of the amenity and beauty with which they invest the landscape, or of the utility they confer as articles of food, medicine, and clothing—are all subjects of never-failing interest to a cultivated mind. There is, perhaps, no pursuit which leads more directly to an appreciation of that wisdom and goodness which pervade creation, than the study of the vegetable kingdom, in which infinite variety, beauty and elegance, singularity of structure, the nicest adaptations, and the most pre-eminent utility, meet us at every step, and compel us to observe and learn, even when often the least disposed to inquiry or reflection. Take it even in the light of a mere recreation for an idle moment, it is at least an innocent and cheerful one: one that never interferes with the comfort of a neighbour, or brings to the cultivator a single feeling of mortification or regret.

ANIMAL PHYSIOLOGY—THE HUMAN BODY.

The external appearance of the human body is necessarily familiar to all. Its internal structure, however, and the manner in which its different functions are performed, are not understood as they ought to be by the generality of people. The more fully that we comprehend the structure of our frame, the more attentive shall we be to its preservation in a state of health, and the more capable of accomplishing that all-important object. The present treatise will therefore be devoted principally to a description of the human body, in language as popular as the subject will permit, and as concise, at the same time, as possible. Though chiefly directed to the structure and functions of the human body, notice will be taken, under the several sections, of the analogous structure and functions in the lower animals; so as to convey to the reader an outline of Animal Physiology in general, and thus prepare him for a more intelligent perusal of the succeeding numbers on SYSTEMATIC ZOOLOGY.

Zoological science places the human being in the class of *Mammalia*, or suck-giving animals, and in the order of *Bimana*, comprising the two-handed creatures of that class. An erect posture is the peculiar characteristic of man, and it is one which gives to his aspect that dignity becoming his high place in creation. By the adaptation of an erect structure, also, his hands are left disengaged, and ready for the numerous operations to which he is inclined by his judgment or urged by his wants. His general stature is between five and six feet. A combination of hard and soft parts forms the material of his frame, the soft portions being arranged, generally speaking, upon and around the more solid parts of the structure. These latter parts consist of a beautiful framework of bones, termed the *skeleton*, which naturally occupies the first place in our description. *Muscles* and *tendons*, which are the organs of locomotion; the *brain* and *nervous system*, or organs of sense, feeling, and intellect; the *lungs*, for respiring the air essential to the maintenance of the principle of life; the *stomach* and *digestive organs*, for the supply of nourishment; the *heart*, *blood-vessels*, and *absorbents*, for the circulation of vital fluids through the body—these and other important parts will fall to be described after the solid framework on which they rest has received its due share of our attention.

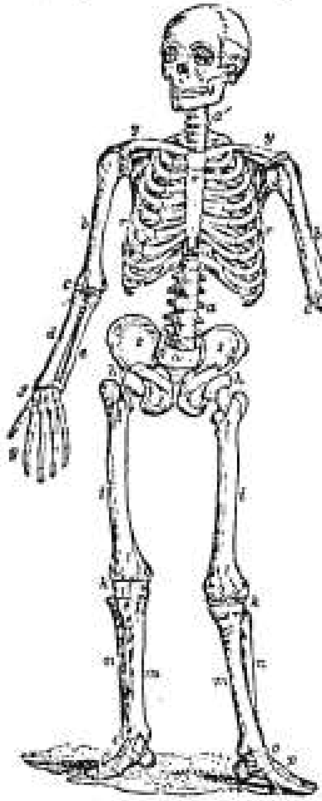
THE BONES.

The skeleton comprehends three main divisions—the head, trunk, and extremities—which consist, in all, of 251 bones, joined together in a manner combining great strength with ease and freedom of motion. The whole of the bones are composed of nearly the same materials—namely, earthy matter, chiefly lime, and gelatine or animal glue. According to Berzelius, 100 parts of human bones are composed of 51.04 phosphate of lime, 11.30 carbonate of lime, 2 fluoride of calcium, 1.20 soda and chloride of sodium, 1.16 phosphate of magnesia, and 33.30 animal matter, consisting of albumen, gelatine, and fat. This notable proportion of lime imparts to them the necessary hardness and solidity, while the animal matter cements or binds them together, and renders them not easily broken. Weighed *en masse*, a middle-sized adult skeleton ranges between 160 and 200 ounces, or from 10 to 13 pounds avoirdupois. Individually, the bones vary in solidity and weight, the heaviest in proportion to their size being those of the skull, the extremities, and the pelvis or under part of the trunk. The surface of human bone is for the most part smooth; and the interior, beneath a cake or coating of more condensed substance, is porous and spongy. The bones of the extremities are hollow, like pipes, by which arrangement they are rendered at once light and strong. The marrow is contained in the internal cavity. Compact as they are, the bones are nevertheless pervaded by blood-vessels, which, indeed, are essential to their growth and vitality.

The crown or summit of the osseous fabric is occupied by the cranium or skull, which is composed of eight bones, the *frontal*, the *occipital*, and the two *parietal*, constituting the greater part of the outward skull, before, behind, and laterally. The two *temporal* or temple bones, on the under part of each side, and the sphenoid and ethmoid bones, placed at the base of the skull internally, are the remaining bones of the head. The union of these bones is remarkably firm and strong in the adult being. In some cases, the osseous plates are joined by serrated or ragged edges, like the teeth of a saw. In other instances, they overlap each other, like the ridge of a house; the arrangement, in each case, being precisely the one best fitted to insure strength and stability in the particular part. Altogether, an arch of the most powerful kind is formed, for the safe protection of the important organ within—the *brain*. The bones of the face, situated below and before the cranium, are numerous. Among the facial bones are reckoned the two upper *maxillary* or jaw bones; two *malar* or cheek bones; two *nasal* or nose bones; two small bones, attached to the nose internally, called the *turbinated* bones; two *palate* bones; the two *lacrymal* bones, situated in the orbit; the vomer, or ploughshare bone, forming a part of the basis of the nose; and the single lower jawbone, or *maxillary* bone of the lower jaw.

The bones of the skull and face rest upon the top of the spine or backbone, which consists of twenty-four separate pieces, called *vertebræ*, firmly and curiously jointed the one into the other. The column of the spine is curved in several places, the most prominent being a curve forwards near the middle of the back. Seven of the vertebræ are called *cervical*, twelve *dorsal*, and five *lumbar*, from being situated respectively in the neck, back, and loins. Each vertebra has various projections and depressions, to admit of a firm union with those adjoining it; and, by the junction of the whole, a long hollow or canal is made, for the reception of the spinal marrow. In the annexed figure, the upper part of the vertebral column is marked *b*, and the lower *a*. The second of the vertebræ of the neck sends upwards a projecting pinion or tooth, which is received into a corresponding depression in the one above, thus forming the pivot upon which the head turns. A ligamentous band keeps the tooth-like projection of the second vertebra in the depression of the first; and nothing can better show how completely our life, during every instant of its duration, depends on the maintenance of every single part, however minute, in order: if this ligament, scarcely thicker than strong paper, were to give way, instant death, from pressure on the spinal marrow, would ensue. The bones of the spine rest upon the *pelvis* (*s s*), a hollow, basin-shaped cavity, which is formed of two large bones, and composes the lower part of the trunk, giving to it firmness and stability. The spine rests on it by means of the *sacrum* (*r*), a series of five imperfect vertebræ, consolidated into one piece in advanced life, which sink like a wedge between the pelvic bones of each side. The sacrum terminates in a loose osseous peak, called the *os coccygis*. The strong, hollowed, cup-like bones of the pelvis, are marked by large round depressions on the outer and under surface of each, which form sockets for the two upper bones of the leg.

At the top of the spine, immediately below the vertebræ of the neck, are situated on each side the collar-bones or *clavicles* (*p p*), which are long and narrow in shape, and pass in a semicircle or arch from the front of the chest backwards, or, in other words, from the *sternum*, *x* (breast-bone), to the top of the shoulders.



On the back of the ribs, at each side, lie the shoulder-blades or *scapulæ*, which are thin flat bones, of a triangular shape. They rest loosely on the back, having scarcely any attachment except by muscles to any of the neighbouring bones. By this means they have a free and easy motion, and also communicate the same property in part to the arms, the upper bone of which is attached, on each side, to the scapula. A very small cavity in the latter bone admits the round ball-like head of the humerus, giving to it the most unconfined play of movement, whether of a rotatory kind, upwards, downwards, or sideways. Nothing can be more beautiful than the whole arrangements for permitting the arm to perform the multifarious motions which man requires from it. The *humerus*, a single bone in each arm (*b b*), cylindrically shaped, is united at the elbow-joint (*c c*) to the two bones of the fore-arm, termed the *radius* (*d d*) and *ulna* (*e e*). One of these, the ulna, is attached to the humerus by a hinge-joint (like that of a common door), while the radius is connected to the same bone by a round button-like head, which, being slightly concave, receives a projecting knob of the humerus, and admits of rotatory movements being performed by the lower part of the arm. These peculiarities of structure are essential to the free use of the hand. At the wrist, the position of the radius and ulna is in some measure reversed, the radius forming with the *carpal* bones (*f f*) a joint like that of a door-hinge, while the ulna is in a measure left loose. The carpal or wrist bones are eight in number. They are of small size, and lie in two rows, being jointed together in a manner that combines great strength with a certain degree of mobility. In the direction of the points of the fingers, they are united with the *metacarpal* bones, forming the palm of the hand, and to which the *phalanges* (*g g*) or finger bones are attached. Each finger has three bones in it; the thumb, or opposing finger, has only two.

As has been said, the bones of the pelvis, on each side, are marked by deep cup-like concavities, which receive the heads of the thigh-bones, *h h*, *i i* (*femur*), the upper bones of the lower extremities. As was required by the different nature of the purpose to be served, the ball-and-socket joint of the leg is much stronger than that of the arm, and permits of much less freedom of motion. The *femur* or thigh-bone is a rounded cylindrical bone, terminating at the knee in a connection with the *tibia* (*m*), the principal bone of the inferior part of the lower extremity. The knee-joint is a hinge one, but permits of a slight rotatory motion when the leg is bent. The tibia has a smaller bone, the *fibula* (*n n*), placed by its side, and over the knee-joint is situated a small bone called the *patella* (*l l*), or knee-pan, to which the principal muscles that move the joint are attached, and which serves to protect the parts against injury. The tibia and fibula form a union at the ankle (*o o*) with the bones of the tarsus, which are seven in number, and constitute the heel or back part of the foot. These again are united to the *metatarsal* bones (*p p*), forming the body of the foot, and five in number. To these again are joined the *phalanges* of the foot, fourteen in all, two being attached to the great toe, and three to each of the others.

The *costæ* or *ribs* (*r r*) proceed from the vertebræ or backbone, and are twelve in number on each side. They bend round in a circular manner from their point of union behind, and seven of them, called the *true ribs*, are joined directly by gristle or cartilage to the breast-bone, while the remaining five terminate anteriorly in a common cartilage, which unites with the sternum below. Altogether, the ribs form a large hollow space for the reception of the lungs, heart, and other organs, and protect them from injury. The ribs move in an easy joint formed with the back-bone, and, with the intercostal muscles, contract and expand to suit the motions of the lungs.

These are the principal bones forming the skeleton of the human being. All animals have not this osseous framework; it is only found, and that in a modified degree, in a certain number of classes—namely, in quadrupeds, birds, reptiles, and some fishes, all of which, from the principal feature in their structure, are called vertebrated animals. Some of the other tribes of beings have their framework, corresponding in purpose to bones, on the outside of the body, in the form of a coat of mail. This is the case with shellfish, with the crustacea, and with many insects that have a hard external covering. It is only in the skeletons of the higher vertebrata, however, that we find a real analogy to the framework of the human being. In such cases not only are the bones of the same form and construction, but of the same number also; and where we do not find them of the same number separately, several will be discovered to have been atrophied at an early stage of existence as unnecessary to the functions of the full-grown animal, or compacted into one mass. Thus comparative anatomy detects in the fore-leg of the horse, the wing of the eagle, and the paddle of the whale, the same amount of parts as are separately exhibited in the arm of man.

THE MUSCLES.

The soft fleshy substance of the body, which gives plumpness and form to the whole, is the muscular part, or *muscles*. These are the instruments of motion. And when we consider the various positions which the body and its members assume, the agility and quickness with which the most intricate movements are made, the ceaseless play of the heart, the heaving of the lungs, and the singular rapidity of articulation and speech, we need not be surprised that these muscles, upon which all such movements depend, should be many in number, and deemed important agents in the animal economy.

The muscles are of a reddish brown colour; they are composed of accumulated threads or fibres, arranged sometimes in layers, sometimes in a straight position, and sometimes obliquely. They are of an elastic nature, somewhat like a piece of India rubber, and, at the impulse of the will, are lengthened and shortened alternately. A muscle is generally thick or swelled out in the middle; it gradually gets thinner towards the extremities, and in many instances passes at one or both ends into a tendon, or tough white substance, which is attached to a bone, and serves the same purpose as a rope or cord, to fix the muscle to the point from which it is intended to act. These tendons are most numerous about the joints, especially the larger joints, where they allow of free and unrestrained action, and yet occupy little space in situations where a large swelling muscle would have been inconvenient. About the larger joints, such as the knee, elbow, and shoulder, there are also numerous glands, which pour out an oily substance, that serves at once to lubricate the joints, and facilitate the play of the tendons.

There are from four to five hundred muscles in the human body, all necessary for performing the various movements and operations of the complicated machine. On each side of the backbone there are several layers of strong muscles, which are fixed by tendons to every projection of the numerous bones composing the spine. These muscles keep the trunk of the body erect, and also permit of the various motions of the back. There are a multitude of small muscles about the face, head, and eyes, whose various action imparts that expression to the human countenance which indicates the prevailing feelings and passions of the individual. The tongue is also supplied by intricate muscular fibres, giving to it that amazing volubility of action by which the vast number of sounds composing language are expressed. Many are attached to the lower jaw; but two in particular, the temporal muscles, proceed upwards through an arch formed by a projecting arm of the temple-bone, and are fixed to the tendons of the head. These two muscles are the most powerful in moving the jaws in the operation of chewing the food, and are very large in several animals of prey. Another flat muscle inside the cheek is called the trumpeter-muscle, because it assists in blowing from the mouth and in sounding wind instruments. The chest is supplied with numerous muscles, which move the ribs upwards and downwards in the action of breathing. A large flat muscle, called the diaphragm, stretched across the trunk from side to side, and separating the hollow of the chest from that of the belly, also contributes mainly to the process of breathing. The arm and hand are rolled inward and outward by a set of muscles, which are placed on the outer and inner sides of the respective bones; thus, the outside muscles act in a contrary manner to the inside, and reverse motions may be alternately performed. The muscles of the fore-arm are fixed to the scapula or shoulder-blade, to the chest, and to the clavicle, at the upper end, and to the bone of the arm at the other. The fingers are moved by muscles situated in the fore-part of the arm, and have long slender tendons, by which they are attached. Two beautiful provisions of nature are here observed: at the wrist, a circular ring of tendinous substance binds down the long tendons, which would, in their various motions, otherwise start up from their places. This ring at once keeps them in place, and permits their free and unhampered play. The other provision is seen in the construction of the tendons of the fingers. There are two principal muscles which move the joints of the fingers, and two sets of tendons, which are inserted, the one into the middle bones of the finger, the other into the third row of bones, or the extremities of the finger. In order to preserve their free action, and to make them lie in the most convenient manner, there is a loop or slit in the shorter tendon, by which the other passes through to its insertion in the point of the finger. By this means the longest and strongest muscle moves the extremities of the finger, where the greatest power is wanted, without impeding the action of the other. The muscles which move the lower extremities are thicker and more powerful than those of the arms. Several large muscles, acting in opposition to each other, are situated around the thigh-joints, and move them. They are fixed, one end to the trunk of the body, some pretty far up, especially two, which are spread upon the front of the abdomen or belly, on each side of the spine; while the other ends are attached to the thigh-bone. Several thick muscles, also, are situated at the back of the trunk. Two large muscles compose the *calf* of the leg, and join to form the tendon of *Achilles*, which is fixed to the heel-bone; these muscles act powerfully in bending the ankle, and in supporting the body in walking. The foot and toes are moved by several long slender muscles, situated in the leg, which have tendons attached to them, and terminating on the toes, exactly like those of the hand and fingers.

The pelvis and lower limbs of man differ greatly from those of all other animals in their superior proportional strength, and in the number and fulness of the muscles. This was necessary, as man has been evidently intended by nature for the erect position. In the monkey tribe, whose general form approaches nearest to that of man, the narrowness of the pelvis or hip-bones, and the smallness of the muscles of the lower extremities, clearly show that they were not destined by nature for the erect attitude; in fact, all animals of this class are furnished with *four hands or paws*, the hinder pair exactly resembling those in front. When they attempt to walk on the hind extremities, they cannot put the sole to the ground, but press on it edgeways. By the nice balancing of the muscles, and the great force which they exert, man is enabled to stand erect, and to maintain a firm position, or move forward at pleasure, notwithstanding that the body diverges from the perpendicular line of the centre of gravity. The head is also balanced upon the neck by means of strong muscles, whose constant though unobserved exertion is necessary to maintain it in its position; for in young children, when the muscles are as yet weak, and in persons asleep, the head has an inclination to droop, and in the dead body it falls down on the shoulder or breast. The muscles of the neck, therefore, may be said to exercise a power in some degree involuntary, or not under the command of the will, as the majority of the muscles of the body are. But there are other muscles still more distinctly removed from under the guidance of the will. The heart is nothing else than a hollow muscle, which contracts and expands without the consciousness of the being; and, in like manner, the muscles which perform the act of respiration are not moved by the will.

This division of the muscles into two classes—*voluntary* and *involuntary*—shows, as perfectly as anything could do, the care with which our frame is constructed. Had those muscles on which respiration and the action of the heart depend, been placed under the control of the will, their functions would have been liable to be impeded at every turn by circumstances. Now, these organs cannot cease to act for the most trifling interval without fatal consequences. The arrangement, therefore, which renders their operation involuntary, is one to be admired as essential to life and comfort.

THE BLOOD—BLOOD-VESSELS.

The blood.—The blood is the medium by which all the solid and fluid parts of the body are supplied with nourishment. In its composition, therefore, will be found the majority of the substances of which the body is composed. The blood consists of a solid coagulable matter, called *fibrin*; of a series of *red globules* which form the colouring matter; and of *serum*, or whey-like matter, which gives the whole the necessary fluidity. From the heart, the centre of the circulation, the blood is conveyed through the body by vessels called *arteries*, and is brought back to the same part by *veins*. The purpose of its thus making the circuit of the whole body, is to supply the necessary materials for increasing the bulk and repairing the daily waste which takes place by perspiration and the perpetual operation of the numerous excretory organs. The blood is restored to its nutritious state by the chyle, a juice formed in the stomach and intestines from the digested food; this chyle reaches the heart by one of the large veins called the left subclavian; from the right side of the heart it goes along with the venous blood to the lungs, and there it is mixed with the oxygen, or vital portion of the atmospheric air, by which process it is converted into bright red arterial blood. In short, there are two distinct circulations of the blood in the system. By the one, the blood is conveyed and distributed over all parts of the frame, imparting, at every pulsation of the heart from which it issues, new life and nourishment to the whole. After traversing the body, it returns to the heart, deprived of its nutritious properties, and changed in colour from a bright to a dark red. Here the second circulation, which is through the lungs, commences. The blood is poured from the right side of the heart, which has divisions for the purpose, into large vessels which carry it to the lungs, and, spreading out into countless branches, penetrates and permeates their whole substance. Collected again by other vessels of equal number and extent, it is conducted by them to the left side of the heart, to be propelled anew through the frame, restored to its bright red hue, and repossessed of all its vivifying qualities. Both these changes are effected in the lungs. The chyle, which may be called the essence of our food in a liquid state, is conveyed from the stomach through the chest by a duct, which empties itself into one of the veins, immediately before the blood is transmitted through the lungs. It is in these organs that the chyle is thoroughly mixed up with the circulation; and it should be remembered, that this chyle is the only benefit, the only real food, extracted from all the substances received into the stomach, the remainder being entirely useless and excrementitious. From the chyle comes the material of the bones, of the fleshy or muscular parts, of the brain and nervous cords, of the hair, nails, enamel of the teeth, and, in short, of every different structure of the system. The average quantity of blood contained in an ordinary-sized person, is calculated at about 30 lbs. weight. The coloured globules of blood do not enter into the smallest vessels of the body, but only the thinner part of it, which has no colour; thus, in the eye, there are numerous blood-vessels, but these are so minute as not to admit the red parts of the blood; and this is a necessary provision of nature, in order that these organs may retain their pure transparency for the purpose of vision. In inflammation of the eyes, when these vessels are much enlarged, the red globules sometimes enter, and the eyes are then said to be bloodshot. What is called the pulse, is the flow of the blood through the arteries, which is caused partly by the impulse of the heart's contractions or beatings, and partly by the contractions of the coats of the arteries. The rate of pulsation in a person in the prime of life, is from 65 to 75 beats in a minute. In childhood the pulse is much quicker—from 100 to 140 beats; and in old age it again becomes slower than the medium standard. In fevers, inflammations, and other diseases of excitement, the action of the heart is increased sometimes to from 100 to 140 pulsations in a minute.

Blood-Vessels.—These consist of the heart, with its arteries and veins, that branch out through every part of the body, and carry the blood, by a constant circulation, through them. The heart is placed in the left side of the chest, a cavity divided into two parts by a thin membrane running perpendicularly down the centre, and supported below by the diaphragm. It is of a round or conical shape, with the base or broad part uppermost, and the point slanting downwards and towards the front surface of the chest. It is of a thick muscular substance, with hollow cavities inside, and numerous cords or pillars of fleshy or tendinous substance stretching through these to give them support. In man and all the more perfect animals that breathe air through the lungs, it is double, or has two distinct sides, each performing separate offices. In fishes, again, the heart is single; in insects there is no proper heart, but a vessel that runs along the back, somewhat like an artery, through which the fluid corresponding to blood circulates through their bodies; other animals, still more simple in structure, have no trace of heart or blood-vessels. For these ends, the heart in man has two sides, a right and a left; and each of these sides contains two hollow cavities—the one called an auricle, from its fancied resemblance to the ear; the other a ventricle, or belly. The manner in which the circulation of the blood is effected may thus be described in detail:—Two large veins, one from the upper part of the body, the other from the lower, enter the right auricle of the heart, and carry the blood, which has made the round of the body, into this cavity. Here it is of a dark purple colour, and it is called venous blood, from its coming from the veins. From the right auricle it is sent, by a sudden contraction or forcing together of the two sides of the cavity, into the right ventricle, immediately below the auricle, and communicating with this by a small opening furnished with a valve; by the right ventricle contracting, it is conveyed by the pulmonary arteries into the lungs, the two large cell-formed substances on each side of the chest, surrounding the heart. After passing through the lungs it is returned by the pulmonary veins to the left auricle of the heart; from this it is sent into the adjoining left ventricle; and, by a powerful contraction of this muscular cavity, it flows out by the great artery of the heart, the carotid, which distributes it through every part of the body, again to be returned by the veins: and thus the round of circulation is continually going on.

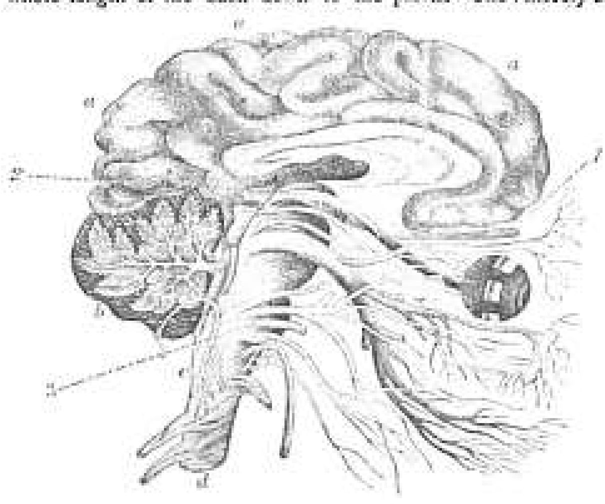
The heart being an extremely thick muscle, the force with which it contracts is very considerable. The left ventricle of the heart, too, although somewhat smaller, is much thicker and more muscular than the right, it having to send the blood through the whole of the body. A beautiful provision is observable in the heart, to prevent the flowing back of the blood into its different cavities during their alternate pulsations. In the passage of communication between the left auricle and ventricle are placed valves, which, when the ventricle contracts to send the blood through the aorta, close accurately, so as to prevent a reflowing into the auricle. There is the same provision between the right auricle and ventricle, and also at the mouth or commencement of the aorta and pulmonary arteries, and the veins which communicate with the right auricle. Some of these valves are of beautiful structure; they are composed of three flaps that join accurately over each other; and to prevent their being pushed by the impetus of the blood beyond their proper position, they have little tendinous cords attached, of exactly the length required. In the child before birth, as it cannot breathe, and therefore the lungs are not used, there is a small hole or communication between the right and left auricles, by which the blood from the veins flows directly through to the arteries, and thus avoids going to the lungs; this hole closes up whenever the child begins to respire. The aorta, or great artery of the body, after it leaves the heart, passes upwards in the form of an arch, when it gives off the carotid branches to supply the brain, and face, and arteries to the arms and chest. It then bends downwards, and gives off branches to the stomach and other viscera; and when it comes to the lower part of the belly, it divides into two main parts, which become the arteries of the pelvis, thighs, and legs. The arteries of the body are composed of three coats or coverings, the principal one being a thick muscular ring, which encircles the artery, and which contracts and expands so as to assist in sending the blood onwards. The principal trunks of the arteries lie deep in the fleshy parts of the body; but their ramifications are so numerous and minute, that they pervade every particle of the human structure—bones, gristle, and every other texture. These extreme branches of the arteries being so minute, anatomists have had great difficulty in tracing the exact point at which they pass into veins. That they do so, however, is undeniable, and is partly seen on the surface of the brain. The veins are another system of vessels, which return the blood from the extremities of the body to the heart. They are larger and more flaccid than the arteries, and are distinguished from them by having no pulsation. A large vein generally accompanies the corresponding artery, but the great proportion of the veins lie more towards the surface, and are easily distinguished, swelling out under the skin. The numerous veins from the lower extremities join into one trunk in the belly, which vein, after passing through the liver, as will be afterwards described, joins the right auricle of the heart, the blood from the upper half of the body joining also by another similar vein. In the veins of the extremities that hang downwards, and are apt to be gorged with blood, there are inserted numerous valves, at short distances, which prevent reflux of any kind.

THE BRAIN—NERVES AND NERVOUS INFLUENCE.

The brain, as already mentioned, is contained in the cranium. It is a soft mass of matter, enclosed in certain protecting membranes beneath the bones of the skull. As the organ by which mind acts, and chief seat of the nervous energy, the brain may be described as the most important and dignified of man's bodily parts, and well deserves the most careful investigation. The brain is divided by strong membranes into two main sections—the cerebrum or proper brain, which lies in front beneath the brow and on the top and sides of the head, and the cerebellum or lesser brain, which lies behind. Both are longitudinally divided into halves or hemispheres, and also into lesser parts called lobes. The annexed figure offers a lateral representation of the different parts of the brain, as it lies beneath the skull, with its beautiful and minute radiation of nerves proceeding to the eye and other external instruments of the organs of sense.

The cerebrum or principal part of the brain is indicated by the letters, *a a a*. The cerebellum, distinguished by the letter *b*, terminates below in the *medulla oblongata*, *c*, the cylindrical pulpy cord by which a union is formed between the brain and *spinal marrow*, *d*. The latter part is the long cord of soft matter formerly mentioned as lying in the canal formed by the range of the spinal bones. It is round, of the thickness of the finger, of the same kind of substance as the brain, and formed of smaller nervous cords, running parallel to each other: it runs along the whole length of the back down to the pelvis. The nerves are small whitish-looking cords, which proceed from the brain and spinal marrow, and spread out in innumerable branches to every part of the body. A large branch of a nerve generally accompanies every large artery, and every important part of the body has a branch of a nerve sent off to it. The nerves for supplying the organs of smell (1), of seeing (2), of hearing (3), together with the great sympathetic nerves, which give branches to the heart, lungs, stomach, and other important viscera, proceed directly from the brain. The nerves of motion and sensation sent to the various parts of the trunk and extremities, take their origin, with a few exceptions, from the spinal cord. Two sets of nervous branches proceed from the cord on each side, corresponding nearly to the junction of every vertebral bone; and it is found that a branch of these nerves imparts motion, and the other sensation or feeling. The brain has a covering of three thin membranes; the outward one strong and thick, the inner extremely thin and delicate. The nerves, which are soft and pulpy inside, have also a thin external covering which protects them. The nervous branches are never seen or felt in the living body, and what are vulgarly called nerves, are the tendons of the muscles, the erroneous title being given chiefly to those about the wrists, fingers, and ankle-joints. Their great numbers and minute divisions are manifest, however, because we cannot prick any part of the body with the sharp point of a needle, without wounding some of them, and thereby causing the sensation of pain. When the nerves are injured in their powers by disease, the sense of feeling in the part is entirely lost. The brain in the lower animals is not generally nearly so large, in proportion to their bulk, as in man; and the cerebrum, or upper brain, is often smaller in them than the cerebellum, or lower brain. In many classes of the inferior animals there is no distinct brain, but only nerves running along their bodies, and joining into knots or ganglions. The nervous system of insects and worms is of this description. In the polypus, and some other similar animals, a distinct nervous system can scarcely be traced.

It may be proper here to make some observations on the functions of the brain, considered abstractly from its anatomy. Man surpasses all other animals in the height and proportions of the forehead, and in the comparative mass of brain in the upper part of the skull. In the human head the lower parts of the face bear a smaller proportion to the forehead than in the brutes. The face is placed in nearly a perpendicular line with the forehead, instead of projecting outwards into a snout, as in the lower animals. The brute face is merely suited for the purpose of animal wants and for defence; the jaws are long and narrow, supplied with thick, strong muscles, and short teeth; there is not the elevated nose, which in man forms a distinguishing feature—the arched eyebrows—the exquisitely formed lips, and the rounded chin; above all, there is not that play of varied expression, that air of intelligence, and that indescribable emanation of a rational mind, that ray of divinity, at the appearance of which the most wild and ferocious of the brute creation are awed and subdued. But, besides, the Creator seems to have allotted characteristic external signs to express the passions of the mind, that in social life man might not easily impose on his fellow-man; for the various muscles of the face express the several passions of the mind so faithfully, that they may be even represented in painting. This is said to be the natural expression, and would appear to be understood even by animals; for a dog, on looking to the countenance of his master, easily recognises the mute expressions either of commendation or dissatisfaction. From the action of these muscles being so often repeated,



The Brain.

physiognomy arises; the action of the prevailing muscles fixes an enduring expression on the features; and thus traces of frequent anger often remain in the countenance after the passion itself is gone off. With the power of speech and reason, man has also the means of expressing his feelings and passions by laughter and weeping, manifestations which are not found in the lower animals. Weeping proceeds from a deep emotion of the mind, and seems an effort of nature to relieve the system of grief. It usually begins with deep inspirations of the lungs, after which follow short alternate inspirations and expirations, and it is finished with a deep long-drawn expiration, which is immediately followed by an inspiration. When moderate, it certainly relieves the distress arising from grief. Laughter has its rise from some ludicrous ideas impressed upon the mind, and would seem to arise directly from a sort of titillation conveyed to the branches of certain internal nerves, probably those of the diaphragm; immediately to this succeeds a number of imperfect inspirations and expirations, which seem to be checked by the contraction of the glottis in the throat or larynx. Laughter in a moderate degree may be conducive to health, as it gives impulse to, and ultimately promotes, the circulation; carried to excess, however, it may prove dangerous, from accumulating too much blood in the lungs. Sneezing consists of one deep inspiration, succeeded by a powerful single expiration, and seems to consist of a convulsive effort of the muscles of breathing to throw off some cause of irritation in the sensitive membrane of the nostrils. The common hiccup is a spasmodic action of the muscles of the stomach, caused by something irritating the stomach itself. Some of the causes by which our mental happiness is either increased or diminished, proceed entirely from the bodily sensations. Any gentle stimulus applied to a nerve seems to cause a feeling of pleasure; strong stimuli, or any causes disturbing seriously the natural condition, produce pain. Itching is akin to pleasure, and in both cases the flow of blood is increased into the part in which either pleasure or titillation is perceived; but when further increased, it degenerates into pain, or excessive sensations in the nerves. Anger violently excites the motion of the spirits, increases the motion of the heart, the frequency of the pulse, and the strength of the muscles; forces the blood into the extreme vessels; and even sometimes bursts the smaller vessels themselves: passion also increases the secretion of bile. Grief weakens the strength of the nerves and action of the heart, retards the pulse, destroys the appetite, and frequently produces paleness, looseness of the bowels, indigestion, and those slow or lingering diseases that take their rise from an interruption of the secreting glands, and a disease of their structure. Fear diminishes the force of the heart, weakens the muscular motions, relaxes the whole system, and, if long continued, causes a general sinking of the body. Excessive terror often increases for the moment the muscular strength, even to convulsions; excites the pulse, interrupts the course of the blood, and in not a few instances has produced sudden death. Love, hope, and joy, promote all the salutary actions of the body, gently quicken the pulse, promote circulation; increase the appetite, and aid the cure of diseases. Excessive and sudden transports of joy, however, often prove fatal, by increasing the motion of the blood, and exciting a fit of apoplexy. Shame, in a peculiar manner, retains the blood in the face, as if the veins were obstructed; when felt in an extreme degree, it has also been known to prove the cause of sudden death.

THE LUNGS OR BREATHING APPARATUS.

In the highest part of the cavity of the chest, on each side of the breast-bone, the lungs are situated. A membrane passing from the breast-bone to the back, divides them into two portions, the right lung and the left lung. The right lung consists of three sections called *lobes*, the upper, middle, and lower; the left lung, rendered smaller in bulk by the presence of the heart in the same cavity, has only an upper and a lower lobe. The lungs have a dark bluish appearance, a familiar example of which is afforded in the *lights* of sheep, that part generally appended to the heart and wind-pipe. Inside they are composed of an immense number of cells, which alternately inflate or collapse as the lungs are filled and emptied of air. When an inspiration is made, and the lungs are filled with air, these cells become expanded; and the blood sent from the right side of the heart, and spread over the cells, is exposed through an extremely thin membrane to the air. An important change, as formerly alluded to, here takes place on the blood: from being of a dark purple colour, it immediately changes to a bright scarlet, having absorbed or taken up all the oxygen, or vital part of the air, and parted with a corresponding volume of carbonic acid gas or fixed air, which it had acquired in its circuit through the vessels of the body. So essential is the matter imparted by the air to the blood for sustaining animal existence, that the breathing cannot be suspended even for a very short period without extinguishing life. It is probable, too, that the heat of the body is generated, and constantly kept up, in some way or other, by means of this process of breathing, and the change which the blood undergoes. We know, at least, that the evolution of carbonic acid cannot go on, in ordinary chemical processes, without an accompanying discharge of heat; and hence it is presumed that the vital warmth, derived by the body from the blood, may be in this way produced. The lungs, like every other internal organ, are covered with a thin transparent membrane called the *pleura*: this membrane, as well as the substance of the lungs themselves, is liable to inflammation; and hence the name of the disease called pleurisy. The trachea or windpipe, the communication between the mouth and lungs, is a hollow tube, having a series of cartilaginous rings passing round it, to prevent the possibility of its being compressed either by external means, or from the food in the act of swallowing, and, in consequence, the breathing obstructed. It takes its rise from the bottom of the mouth, and passes down in front of the neck, where its strong cartilage may be seen and felt. At its lower part it divides into two branches, one going to join the right section of the lungs, the other the left.

Lungs for the breathing of air are only found in the higher classes of animals. Fishes are furnished with gills, those comb-like substances which lie within a flap on each side of the head; over them a stream of water is constantly sent by inhaling it at the mouth in a similar manner to breathing. The air, which is always present in considerable quantities in water, is thus absorbed by the blood-vessels while ramifying over the gills, and all the purposes of breathing are answered. In insects there are no lungs, nor do they breathe by the mouth, but along the sides of their bodies, by means of numerous holes with small tubes or spiracles, leading to a longer middle tube, by which the air enters and mixes with their fluids. When we descend lower in the animal scale, even this substitute for breathing ceases, and probably the vital air is absorbed by such animals by simple pores or openings in the skin.

THE TEETH.—DIGESTING APPARATUS.

The first process performed in connexion with the supply of nourishment to the body is that of masticating the food, and this is the office of the teeth.

The Teeth.—These are placed in the upper and lower jaw, to which they are attached by roots, which sink into the porous sockets of the jaw, somewhat in the same manner as a nail is fixed in a piece of wood, though they are retained in place chiefly by the softer parts around. The teeth are composed of bony matter, covered externally with a thin coat of an extremely hard substance, called enamel. The teeth are furnished with nerves and blood-vessels, and have thus vitality like the rest of the body, although possessing it in a less perfect degree than most other parts of the structure. Hence they are very liable to disease and decay. In decaying teeth a blackish spot is first perceived upon the outer crust or enamel; this substance gradually gives way, and then the bone below proceeds to rapid decay. The irritation of the air, and particles of the food, inflame the nerves and soft pulpy parts inside, and thus the excruciating pain of toothache is produced. The first set, or temporary teeth, begin to make their appearance in the child about the fifth or sixth month, and towards the end of the eighteenth month the whole set of temporary teeth, consisting of twenty, have generally cut through the gums. These teeth continue till about the sixth or seventh year, from which time, till about the twelfth or thirteenth year, they gradually fall out one by one, and are succeeded by the second or permanent teeth. The roots of the temporary teeth are much smaller, and sink less deep into the jaw than their successors. The rudiments of the second set of teeth begin to form early in cavities below the others, and, gradually growing and pressing upwards, displace them. The number of the permanent teeth is thirty-two, consisting of sixteen in each jaw. The four front teeth are called the incisors, and have one long root; on each side next to these is one eye or dog tooth; then there are placed two small grinders on each side, having double roots, and three large grinders, or molar teeth. The last of these is called the wisdom tooth, from its making its appearance latest in the jaw, from the seventeenth to the twentieth year, or even later. By this change and gradual succession of teeth, we have a beautiful provision of nature for permitting the jaws to increase in size, and, at the same time, for preserving the relative positions and regularity of the different teeth; for had the first teeth of childhood been permanent, it is impossible that the jaw could have increased in growth without deranging the order and position of the whole.

The teeth of animals differ according to the kind of food on which they live. In the carnivora, or flesh-feeders, the teeth are sharp-pointed, and adapted for tearing their prey to pieces; in the graminivora, or those that live on grasses and other herbage, the teeth are of a rounded form, with broad surfaces, and the grinders are furnished with several layers of the hard enamel, following each other in succession, with a slight layer of common bone interposed; so that, when the grinder is worn down by the friction of chewing, it is not rendered useless, but a new layer of the enamel is presented at the worn-down surface. Some animals, as the hare, rabbit, beaver, and mouse, have the front teeth of a chisel shape, with enamel only on the outer side of them. These animals are called gnawers, because they chew or gnaw down their food in this particular manner; and by the inner soft part of the tooth being liable to be worn down, while the outer is harder, the enamel is thus always kept with a sharp edge. Some animals have large projecting tusks for defence, as the elephant, wild-boar, &c.; others, as fishes, are provided with teeth more for holding fast their prey than for mastication. Many have no proper teeth at all, as birds, worms, and other soft formed animals. Man is characterised by having all his teeth set close to each other in a half circle; they are of a medium form, between that of carnivorous and herbivorous animals; the front teeth are adapted for cutting; the canine are sharp, though not of undue length; and the grinders are suited for masticating vegetable and farinaceous matters, as nuts, &c. In short, the form of the teeth of man evidently points out that he is adapted to live on a mixed kind of diet, or a conjunction of vegetables and flesh.

Stomach.—Behind the windpipe, taking its rise also from the bottom of the mouth, lies the oesophagus, or tube which passes into the stomach. This tube expands at the top into what is called the pharynx, forming the whole of the upper part of the throat immediately behind the tongue. Into this cavity the windpipe opens, and, to guard against any particle of the food or drink passing into the windpipe instead of into the passage to the stomach, there is a little tongue or valve which closes accurately over the mouth of the windpipe every time food or drink is swallowed. When the substances have passed, the valve again springs open, and admits of free breathing. To show how accurately and precisely every part of the human machine performs its duties, a celebrated writer has instanced this same valve, which, in a multitude of persons dining together, not one time out of a hundred in any one individual instance is at fault. When a drop of fluid or particle of food does by chance insinuate itself into the windpipe, so sensitive is this tube, that a convulsive cough is excited till it is again expelled. There is another little tongue or flap attached to the roof of the palate, and seen above the tongue when the mouth is opened. This, which guards the passage to the nose, is not, however, to be confounded with the other, which is farther down the throat, and invisible. The oesophagus, or gullet, passes down through the chest, traverses a ring in the diaphragm, that large muscle which stretches across the lower ribs, and which assists so materially in breathing. Immediately below this muscle, on the left side, is situated the stomach, which is partly sustained in its place by being attached to the oesophagus, or tube from the mouth. The stomach is an oval bag of considerable size, occupying a slanting position immediately below the heart, with its right side overlapped by the left edge of the liver, and extending to the lower end of the breast-bone. The stomach has three coats—an external membranous one, a muscular, and a soft villous inner covering. The upper passage, by which this bag communicates with the oesophagus, is called the *cardiac* opening; the lower, where the first gut commences, is called the *pyloric* orifice.

Digestion.—One of the most important operations in the animal economy, is that of digestion, whereby the various substances used for food are dissolved in the stomach, and undergo changes, by which they are formed into matter fit for entering into the composition of the different parts of the body, to nourish its growth, and supply the daily waste which takes place in the system; for such is the constitution of animal bodies, that the substances of which they are composed are liable to constant waste; the solid parts are worn down, and a large quantity of fluid is constantly given off by the exhalent vessels, both from the skin and the surface of the lungs. This is manifest in the sweat and the vapoury exhalations constantly passing off by the mouth; and there is also an imperceptible perspiration regularly proceeding from the surface of the body, which has been computed to amount to several pounds in the course of a day. It must be evident, therefore, that if this waste was allowed to proceed but for a very short period, the body would soon be reduced to a state of complete decay. A constant supply of new material is therefore daily needed, to replace that which is wasted; and thus it has been supposed that a human body changes its whole materials many hundred times from the period of its birth till death; and that an individual, as regards his mere corporeal structure, is not at all the same at the period of manhood to what he was when a boy, nor in old age what he was in his prime. Although this change then is complete, even to the bones and most solid parts of the frame, it is brought about so gradually, and with the regular and minute substitution of one particle for another, that it is never perceptible. Man has been called, with relation to his diet, omnivorous, from his being adapted to live on every kind of food, whereas most other animals are confined to one particular description. The carnivorous animals live on flesh alone, the graminivorous on grass and green herbs, and the granivorous on grains and other smaller seeds. These animals never change their respective diets; nor, from the construction of their teeth, stomachs, and intestines, were they ever intended to do so. But in man it is plainly evident, from his anatomical structure, that he was intended to feed on every sort of food promiscuously, or that he could adapt himself to either animal or vegetable fare, as habit or necessity impelled him. Man also differs from brutes in resorting to the arts of cooking, whereby the food is put into a state more fitted for digestion, and for yielding a sufficiency of nutritious aliment. The food being received into the mouth, is broken down and masticated by the teeth. It is here also reduced into a soft pulp by the saliva, which flows into the mouth by the salivary glands; and thus being sufficiently broken down and softened, it passes into the stomach. The stomach has numerous glands situated on its inner coat or surface, which secrete a peculiar fluid called the gastric juice, which is clear and colourless, with little taste, or smell, or sensible qualities. On this fluid depends the important office of digestion. It has the power of coagulating substances in the stomach, of preventing the contents of the stomach from passing into a state of fermentation or putrefaction, and of dissolving the whole into one homogeneous mass. When the stomach is first filled with food, it appears to remain there for a short period without undergoing any change; gradually, however, successive portions of the food, as they come into contact with the gastric fluid, are dissolved; till at length, in a shorter or longer period, the whole is collected into a thin greyish paste, called chyme. In the upper or left division of the stomach, it would appear, from some recent observations, that the food is freed from its superabundant moisture, which drains off by some undiscovered means to the blood-vessels, and from thence to the kidneys. The chyme then, as it is gradually formed, moves to the other extremity of the stomach, called the pyloric, where it passes out to enter the intestinal canal. It would appear, also, that the pylorus, or lower mouth of the stomach, has a sensitive power, whereby it freely permits the digested chyme to pass out, but refuses exit to the undigested matter. The chyme having passed into the first part of the intestines, or duodenum, is then mixed with the bile from the gall-bladder, and with the pancreatic juice. Both these substances, especially the bile, seem essential for the conversion of the chyme into proper alimentary matter, but their peculiar action has not yet been satisfactorily explained. That the liver and bile ducts are of the utmost importance, however, cannot be doubted, from their magnitude, and the care with which they are supplied with numerous vessels, and from their being universally present in a great proportion of animals. The chyme having passed through the duodenum, and having been mixed with the bile and pancreatic juice, now changes its appearance and properties, and becomes the chyle, or nutritious matter destined to supply the various parts of the system with nourishment. The digested mass is passed gradually along the course of the small intestines, urged forward by what is called their *peristaltic* motion, which is effected by a successive contraction of their fibrous coats. Here the minute mouths of the lacteal vessels, opening on the inner surface of the small intestines, take up the chyle, and carry it, as has already been described, to the receptacle of the chyle, and then by a duct running up the chest along the spine, called the thoracic duct, it joins the blood-vessels. The refuse of the aliment which has not been taken up by these lacteal vessels passes on through the large intestines, and at length is ejected from the body. Digestion is not brought about, as has by some been supposed, by any mechanical means, as by the grinding powers of the coats or sides of the stomach, nor by heat alone, nor fermentation, nor by the simple resolution of the food into a fluid; but it is evident that it undergoes a series of chemical actions in the stomach and bowels, whereby its nature and properties are completely changed; and thus animal and vegetable substances, however different, are reduced to one peculiar kind of fluid, the chyle, which, though it may be found to vary slightly according to the kind of food, is, in its general properties, always the same. The gastric juice varies in different animals. In those which feed on vegetable matter, it dissolves these substances only; whereas grain and vegetables pass through the stomach of a purely carnivorous animal without undergoing any change. The gastric juice has this singular property, too, that although it readily dissolves dead animal matters, and reduces them in a short time to a thin pulp, it will not usually act on the living fibre; so that, after death, the coats of the stomach have been found dissolved into holes, by the same juice, which, in the living healthy body, had no such effect.

A stomach of some kind or other is found in all animals; for it is by this organ that nutrition and growth are solely promoted. There are some very simply formed animals whose whole body consists of an oval hollow bag, or stomach, with a simple outlet for the mouth to take in nourishment, and no other organ whatever. The common polypi have simply a mouth and hollow stomach, with several tentacula, or arms, by which the creature seizes the worms and grubs on which it feeds; these it swallows, abstracts their juices, and then voids the remainder from its mouth. The common leech has its whole body divided into a number of small cells, like a piece of honey-comb; and these receive the water, and sometimes blood, on which it feeds. Flesh-feeding animals have a simple bag for a stomach, and their food is easily and soon digested. Those animals, again, that feed on grass, which is of more difficult digestion, have three and four stomachs, into which the food successively passes after it has been masticated or chewed a second time in the mouth. This is the case with cows, sheep, deer, &c. Birds that feed on grain have first a sap-bag, or crop, into which the food enters, and remains for a considerable time, mixed with a juice somewhat like saliva; here it is softened and rendered moist, preparatory to its passing into the true stomach, or gizzard, which is an extremely strong muscular bag; in this, with the assistance of a number of sharp-pointed pebbles, which such birds always swallow, it is ground down and acted on by the gastric juice. This compensates for the deficiency of teeth in fowls. Crabs and lobsters have no teeth in their mouths; but in their stomachs will be found three or more teeth, which assist in grinding down the tough sea-weed on which they feed. By domestication, the qualities of the gastric fluid may be so changed, that animals accustomed to live entirely on flesh will exist and thrive on a vegetable diet. This is the case with dogs, and many birds. All these peculiarities in the natural history of animals illustrate, at least directly, the uses of the digestive organs in the human being.

THE LIVER, &c.

The Liver.—Opposite the stomach, on the right side, lies the liver, a large flat substance, of a dark brown colour, divided into two lobes. The liver has a round, convex upper surface, and is hollow or concave below; it is also thick and solid at the back part, and its edge becomes thinner towards the front, where it lies over a portion of the stomach and bowels. It is suspended in its place by several ligaments attached to the surrounding parts. In the under side of the liver, in a small hollow, is situated the gall-bladder, a small oval bag which contains the bile. A tube from this bladder, called the bile-duct, passes into the upper portion of the bowels, carrying the bile there. The liver is supplied by several branches of an artery in the usual way that the other organs are, but it has also a peculiarity which no other organ of the trunk possesses. The large veins, which return the blood from the lower part of the bowels, before going to the heart, enter the substance of the liver, and there spread into innumerable branches throughout its whole surface. From this venous blood the bile is supposed to be secreted, and after having yielded this substance, the vessels collect again into one large trunk, and join the large vein which carries the blood to the heart. The liver weighs, on an average, from three to four pounds weight, and the quantity of bile which it secretes, taking into account its large supply of blood, must be very considerable. The greater proportion of animal beings are provided with an apparatus of some kind or other for preparing a supply of bile, and in many the liver bears a large proportion to the other contents of the belly. In some animals, as the horse, the gall-bladder is awanting, there being merely a duct to convey the bile into the intestines. In the lowest classes of animals, all traces of liver or gall-ducts disappear.

The Spleen.—This substance is situated below the stomach, on the left side, betwixt it and the ribs. It is in shape a flat oval, and of a dark iron colour. No duct or opening has been discovered proceeding from it, nor has its use been as yet accurately ascertained. It possibly serves to relieve the stomach of its surplus quantity of blood while this organ is distended with food; and the splenic vessels have also been held by some to contribute to the secretion of the gastric juice. The spleen, it is remarkable, has been frequently cut out from living dogs, without causing any apparent derangement in the health or digestion of these animals.

The Pancreas.—This substance, known under the name of the sweet-bread, is a large oblong gland (or *secreting* organ), lying across the back part of the belly, extending between the spleen and the middle of the liver. This gland pours out a substance something like the saliva or spittle of the mouth; and by means of a small duct or canal, empties it into the upper bowels, along with the bile from the gall-bladder, both these substances aiding in digestion, and the preparation of the nutritious fluid to be afterwards mentioned.

Lacteal Vessels.—These are innumerably small tubes, proceeding from the ileum or small intestines, along their whole course, and spreading along the mesentery, where they form an immense number of small knots, or glands, by joining together. These are the vessels which take up the fluid chyle, or milky-like substance, after it has been digested and properly prepared in the stomach and bowels. From these mesenteric glands, the chyle is conveyed by these ducts or canals to another large gland, situated in the loins, on the right side of the aorta, and immediately below the diaphragm, called the receptacle of the chyle. From this receptacle the thoracic duct arises, and passing upwards by the side of the aorta, or great artery of the body, it joins the left subclavian vein, lying under the left clavicle or collar-bone, and thus pours the whole of the chyle into the general circulation.

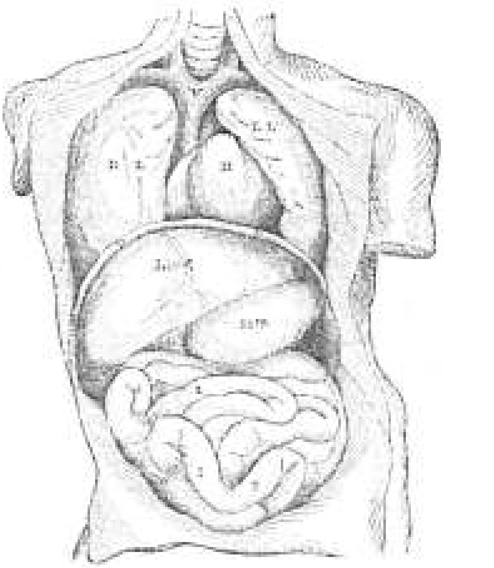
The Kidneys.—These are situated in the loins, one on each side of the back-bone, about one-third up the spine. They are in shape somewhat like a French bean, and their internal structure consists of a number of minute porous tubes. They each at the middle hollow part receive a large artery, and their use is to filter from the blood the superabundant fluid, and salts and juices unnecessary for the system, and transmit these, by means of two small tubes, called the ureters, to the urinary bladder. These tubes enter the back part of the bladder in a slanting direction, which serves the purpose of valves, preventing a flowing back of the fluid when the bladder is full. The bladder is situated in front, immediately above the bone of the pelvis, called the pubis.

The whole cavity of the belly is lined by a thin membrane, called the peritoneum, which is double, being reflected from the sides of the cavity over the whole of the intestinal organs. This peritoneum is liable to inflammation, in the same manner as was mentioned of the pleura, which produces a very violent disease. The coats of the intestines, too, are also subject to the same affection. Dropsy may arise from water being formed between the two folds of the peritoneum.

The Lymphatic Vessels.—These are another distinct set of vessels spread over all the inner cavities of the body, and also throughout the skin, on which they open by innumerable small mouths. Their office appears to be to take up from the blood a thin lymph, which they convey into the receptacle of the chyle and thoracic duct, and also to exhale or carry off from the skin the superfluous moisture of the body. This moisture forms the sweat, and several pounds of fluid are daily drained off from the body in this manner, even when little or no bodily exercise is taken, for perspiration continually goes on insensibly. These vessels are composed of a series of extremely small tubes, and, joining and interweaving, form numerous glands, especially in the groin, armpits, and neck; when swelled by disease, they harden and enlarge, forming knots like a pea or bean. But they are no less numerous on the surface of the inner cavities of the body as on the skin; they are found in the brain, on the surface of the lungs, where they give out a large proportion of vapour at every expiration of the breath, and in the abdomen or belly. It is a disease or sluggishness of these vessels, whereby they do not perform their necessary duty of taking up all the superabundant fluids, that causes accumulations of water in the chest, belly, and legs. The branches of the lymphatics of the lower half of the body join the receptacle of the chyle; those of the upper part enter the thoracic duct just before the latter pours its contents into the subclavian vein.

THE BOWELS.

From the lower or pyloric orifice of the stomach, the duodenum, the first portion of the intestinal canal, takes its origin. This gut passes below the liver and receives the bile-duct, and the duct from the pancreas, when it terminates in the jejunum, which again passes into the ileum, or principal portion of the small intestines. These are of great length, and occupy a great part of the abdomen, being folded and twisted backwards and forwards in many intricate windings. At the end of the ileum, the colon, a large gut, makes an arch upward towards the right side, and across the belly, and descending at the back part, ends in the short bag, called the cæcum, which joins the rectum, the termination of the intestinal canal. The whole length of the intestines in man is generally about six times that of his average height, or from thirty to thirty-six feet. In all animals that feed on vegetables, the intestines are of great length; whereas, in those that derive their nourishment from animal food, they are of much shorter proportions. Two membranous substances, called the omentum and mesentery, run along nearly the whole length of the intestines, and serve as a means of their attachment and proper suspension in their places. The bowels have three coats—an external one, common to them with the other viscera, a muscular coat, and an internal mucous covering.



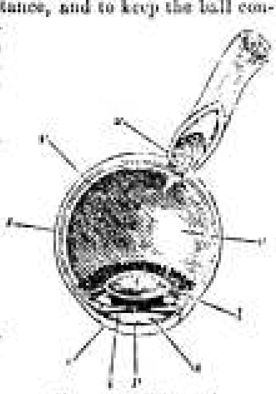
Organs of the Chest and Abdomen.

R L, the right lobe of the lungs; L L, the left lobe; H, the heart; V, the great arteries; D D, the diaphragm, a muscle separating the chest from the lower regions; Liv., the liver; Stm., the stomach; G, the duodenum, or beginning of the small intestines; I I, the intestines or bowels.

THE SENSES.

Man possesses five senses—sight, hearing, smell, taste, and touch—each of which acts through the medium of appropriate instruments, and all regulated by and acting in connection with the brain.

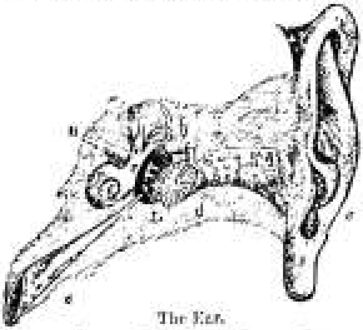
Sight—the Eye.—The eye is the exterior instrument of sight, and is a most beautiful and ingeniously constructed object. The eye may be compared in its structure to a telescope, the purpose of both being to collect the rays of light proceeding from the surface of bodies, to concentrate these rays, by means of a refracting lens, into a focus, and, therefore, to form a very small image or picture of the object before them. The human eye is placed in a large hollow or socket in the upper bones of the face, surrounded by fatty substance, and the various muscles necessary for moving the eyeball and eyelid. At the upper and outer angle of the eye-socket is placed a gland, which secretes the tears that serve to moisten the delicate surface of the eye, to wash off any dust or other substance, and to keep the ball continually wet and transparent, for the purpose of perfect vision. The tears, after spreading over the eyeball, collect at the inner angle, where, at each corner of the eyelid, both above and below, there is a small aperture visible, which carries the tears down a passage into the nose. The edges of the eyelids are also supplied with glands, which pour out a mucus that prevents them from adhering together; and these, when irritated and inflamed, are often the seat of disease. The membrane which covers and imparts the white colour to part of the eyeball in front, is called the sclerotic coat (s). The middle transparent part of the eye in front is called the cornea (c), which is filled with the aqueous humour (a) of the eye. Immediately behind the cornea is seen a circular fringed-like substance (i), which varies in colour in different individuals, being blue, black, hazel, &c.; hence it is called the iris, or rainbow curtain. This iris has the property of opening and closing, according to the quantity of light which falls upon the eye; and thus the pupil (p), a black circle contained within the iris, is enlarged or lessened. Behind the iris is situated the crystalline lens (l), in shape resembling the small lens or ground glass of a common telescope, but of unequal swell on each side, being more flattened before than behind. This lens is contained within a capsule, or thin covering of delicate membrane. A familiar example of the lens of a fish's eye is presented every day in that white globular substance found in such eyes after boiling. The heat coagulates the lens, which is of the same nature as the white of an egg; and in the fish it is nearly a circular body, to adapt the animal's vision to the dense medium of water. The lens is the substance which receives the rays of light entering the eye, and refracts or bends them inwards, whereby they are collected into one point upon the back chamber of the eye or retina, and thus a minute picture of the object seen is formed. If a bullock's eye is taken when fresh, and a hole cut in the skin covering the back part, and then presented to the light with a piece of white paper put opposite the hole, a representation of the objects in front of the eye will be distinctly traced on the paper. When through disease the lens becomes of an opaque white colour, and will not transmit the rays of light, the affection is known as *cataract*, producing blindness. The fluid filling the lens is called the crystalline or vitreous humour (v). Behind the lens is the back chamber of the eye, filled with a fluid, called, from its thickness, the *crystalline* humour. Over this back chamber the retina (r) is spread out like a lining or covering. It is covered over with a black pigment, the better to prevent the intermixture or reflection of the rays of light. On this membrane the optic nerve (o), which comes from the front part of the middle brain, and enters the eyeball at the back part, spreads out in numerous branches; and here the small images of the outward objects presented to the eye are painted in miniature. All these objects are painted on the retina in a reversed position, or turned upside down, the same as happens in a common microscope; and how they are perceived in their upright position through the medium of sensation, is a curious question, not easily admitting of explanation. Each eye, too, forms a distinct impression of every object; and yet things are not seen double, but both eyes combine to give one impression to the brain or seat of perception. Besides the numerous muscles which roll the eyeball in various directions, to adapt it to the various positions of vision, there seems also a power, in the cornea or front portion of the eye, whereby it can flatten or become more convex according as the object viewed is at a greater or less distance from the eye; thus adapting itself to the focus of vision in a similar manner as the joints of a telescope are drawn out or pushed inwards. When the cornea is, from its natural form, of too rounded or convex a structure, distant objects are always seen imperfectly, hence causing what is called nigh-sightedness; on the other hand, when it is too flat in form, near objects are then seen indistinctly. This change occurs generally to the cornea as old age approaches; hence spectacles, or artificial rounded lenses, to aid the flatness of the eye, are in such cases made use of with the desired effect. From the different densities of the three humours composing the eye, the refraction, or breaking of the light into the various coloured rays, is avoided. This for a long time was a great objection to telescopes, till different kinds of glass were joined together in the lenses, thus imitating the resources of nature in the eye. The eyes are supplied by two large optic nerves proceeding by separate trunks from the brain; they join together for a short space within the cranium, where they again separate, and each entering an opening at the back part of the orbit, spreads out into branches over the retina. Sometimes these nerves lose their power of sensibility, and total blindness is occasioned without any perceptible disease of the eye: this is called *amaurosis*.



Human Eye Dissected.

All the higher classes of animals are possessed of evident organs of sight. Birds have, in general, very acute vision, especially birds of prey, to enable them to distinguish their victims at a great height in the air. They have also a third eyelid, or transparent membrane, which covers the eyeball when they are darting suddenly through the air, and which thus protects the delicate organ of the eye from injury, at the same time that it allows the transmission of a sufficient quantity of light. Fishes have eyes of a somewhat different form from land animals, to adapt their vision to the denser medium of water, through which the rays of light pass. Insects have great numbers of small eyes clustered together, like the facets of a gem. Many of the inferior animals, as shellfish, worms, &c. have no perceptible organs of vision.

Hearing.—The ear is the instrument of this sense. The outer part or conch (c) of the ear is formed so as to collect and transmit the currents of air into the passage (m) which leads to the tympanum or drum (t). This passage is defended at its mouth by a number of small hairs growing up in it; there is also a waxy substance constantly secreted, which keeps the whole moist, and is an effectual bar to the entrance of insects or other offensive substances. At the inner end of this winding passage is the thin membrane or drum (d), which is stretched out on four small bones (b), and which, by its vibrations, conveys through the medium of the nerves the sensations of sound. There are also attached to these small bones several muscles, which, by their contraction and relaxation, modify the tension of the thin membrane, and prevent sounds from acting too strongly on it, or render it tighter, in order to be even sensible to feeble vibrations. Behind the cavity of the tympanum or drum, there is another passage which leads from the ear to the mouth, called *the Eustachian tube* (c), the object of which is most probably the same as the holes in the common drum, to allow the air to escape from behind, and thus promote the vibration of the membrane of the tympanum; for it is found, that if such holes are not made in a drum, little or no sound will be produced; and in the human body, when this tube, leading to the mouth, is choked up by the inflammation of a common cold, deafness is produced. There is another cavity called the vestibule of the



The Ear.

ear (r), covered over also by a thin membrane; on this membrane the nerves of hearing are expanded, and convey the sensations of sound to the brain by a, the auditory nerve. The sense of hearing is very acute in some animals, especially those that live by prey. In the lower orders of beings the sense is wanting, but is compensated in a considerable degree by the extreme acuteness of feeling, or touch, which is so diffused over their bodies as to make them sensible of the least agitation in the air by which they are surrounded.

Smell.—The nose is the instrument of smell, and is of comparatively simple structure. The bones forming its inner cavity are of a spongy nature, or rather are composed of a number of very thin plates, covered with a soft membrane, over which the branches of the nerves of smell are minutely exposed. The effluvia proceeding from bodies, and which imparts their peculiar odour, must pass in a stream or current through the nose before the odour is perceptible. If the air is perfectly still, and no current allowed in the nose, by suspending the breathing through that organ, the strongest smells will make no impression. In some animals the sense of smell is acute and powerful, beyond the conception of human beings; thus a dog, by the acuteness of this sense, will distinguish the footsteps of his master amid those of a hundred other people, and can thus trace him for miles, although he has been a long while out of sight; pointers also scent game at a great distance. On the other hand, this sense seems entirely denied to many of the lower animals.

Taste.—The sense of taste is nearly allied to that of smell. The nerves of taste are spread over the upper surface of the tongue, and are raised up in innumerable small points or *papillæ*, like the pile of velvet. No other part of the mouth is endowed with the property of tasting except the tongue, as may be proved by touching any part of it with a piece of salt or sugar, when no sensation of taste will be communicated until the tongue has come in contact with the part so touched. That the taste or flavour of many bodies is heightened by the accompanying effects on the organ of smell, is evident; because, if the nose is stopped up so as to prevent the exercise of its functions, many substances having different flavours will taste alike. This is the case with the various kinds of wines, but especially with the ardent spirits. The tongue and whole cavity of the mouth and throat are kept moist by the saliva, or spittle, which continually flows into them from repositories placed around the cheeks and under the tongue, called salivary glands, which communicate with the mouth by means of small ducts. This saliva flows in greatest quantity during meals, and may even be excited by the sight of food when the appetite is good. It is of essential service in moistening the food, and preparing it for the process of digestion in the stomach. The sensation of taste is in all probability diffused among every class of beings, however low in the scale of existence, although it is probable many animals possess little of it in their mouths, especially when these are formed of hard horny substances, as in many insects, in the lobster, crab, &c. and where any organ corresponding to a tongue is wanting.

Touch.—The sensation of touch is diffused more or less over every part of the body, but is most perfect at the points of the fingers, which in man are generally used to examine the figure and texture of bodies. For this purpose they are furnished with a large supply of very minute blood-vessels and nerves. It would appear that there are different nerves that convey the sensation of touch, distinct from those which are the nerves of motion; and that these proceed in pairs from the spinal marrow; and that, moreover, the sensation of heat or cold may be perceived very distinctly, in cases where the pricking of a needle or contact of other bodies is never felt. The sense of touch may be said to belong to every animated being, and is one great characteristic of animal life. Vegetables possess a peculiar kind of vitality, and show what is called irritability of their fibres; but they have no sensation, properly so called. It is probable, however, that sensation is not by any means equally acute in all animals; some feel more intensely than others; and it is a happy provision of nature that it should be so. The lower insects and reptiles, from their structure and habits, are continually exposed to injury; and did they feel it as acutely as the larger animals, the degree of animal suffering throughout nature would be excessive. Many animals bear the loss of limbs with impunity, and some have even the power of restoring those lost members in a very short time. It is probable that, according to the perfection of the nervous system, is the acuteness of animal sensation.

On thus reviewing the different parts of the human body, it will be observed that most of its organs are double. On a line being drawn in the middle, on each side will be found parts which are exactly similar to the corresponding side. This is the case with the brain, which is a double organ, having two series of nerves proceeding out from each side of it to go to the respective sides of the body. There are two eyes also, each reflecting a distinct image on the retina; yet the nerves communicate so that only one impression is conveyed to the sense. The arms are double, to suit the various purposes for which they are employed, and so are the lower limbs an essential requisite for the support of the body, and for progressive motion. The lungs, too, may be said to be double, having two distinct lobes; and it sometimes happens that one of them is entirely shrunk or diseased, and yet the important office of respiration is still carried on. The stomach, the liver, and some of the other viscera of the abdomen, are, however, single, their several offices being common to the whole body.

THE HAIR AND NAILS.

The hair grows out from the skin somewhat in the manner of a vegetable production. Hairs are fixed by roots in the skin, from whence, by a series of minute vessels, they draw nourishment, and continually increase in length. They possess no sensibility, however; and, unlike the other parts of the frame, may be cut off without producing the least pain. Hair is of different colours in different individuals—is fair in those of light complexion, and deep black in the swarthy. As old age approaches, and even in many young persons, where there is a particular disease in the hair, or dryness in the skin, this colour changes to grey and white. The colouring matter of the hair is contained in the centre, which is of a hollow form, and consists of an oily substance, in which carbon or charcoal, in minute particles, is more or less mingled. The nails are somewhat like hair in their production and composition; they are, like hairs, insensible to the touch, and may be cut or pared without producing pain. They receive nourishment from the blood-vessels of the extremities, and have a constant growth or renewal of their substance. Nails serve as a defence to the tender parts of the fingers; in animals they form formidable weapons of attack. The horns of cattle are exactly of the same nature as nails, and are chiefly composed of animal gelatine.

The manner in which the various secretions take place in the system, that are to form hair, nails, wax for the ears, blood, perspiration, &c., cannot but excite our admiration; for the whole is a chemical process of the most perfect kind, and such as art possesses no power to imitate.

THE SKIN.

An external compact membrane or skin covers the whole body. The outer skin, or cuticle, is unprovided with any blood-vessels or nerves, and consequently is insensible; in this manner it is well suited for a protection to the parts beneath; it is pierced by innumerable minute pores, which are the mouths of the exhalant vessels: it is thicker in the palms of the hand and soles of the feet than in any other parts of the body. Below the outer skin is a thin membrane, called the *rete mucosum*, which, assuming different hues in different nations, gives rise to the variety of colour in the human race. Some have held this membrane to be double, but this is not established. In Europeans it is white, passing into yellowish brown; in native Americans, of a copper colour; in Negroes, of a deep black. The common belief is, that climate has the effect of modifying the colour of the skin, as the black skin only occurs in tropical regions, and it is found that there it is a protection against the scorching influence of the sun's rays. Negroes will remain cool and comfortable exposed to a sun which would be intolerable to a white-skinned person. Their free perspiration seems to be of great service. Immediately below this network is the *cutis*, or true skin, an extremely sensible membrane, so thickly studded with minute blood-vessels and branches of nerves, that the smallest-pointed needle cannot prick it without touching many of them. On the points of the fingers, lips, and other parts of the body, these vessels are very numerous; and hence these parts are endowed with exquisite feelings of touch. Below the skin is situated the cellular membrane, which is a network, whose interstices are filled with fat, and it thus serves to fill up the spaces between the muscles, and to make up the shape, and preserve the symmetry, plumpness, and beauty of the whole frame. In cases of emaciation, this fatty matter is sometimes entirely taken up by the absorbent vessels—as after a tedious fever or other lingering disease—when the rough outlines and indentations of the muscles, and the projections of the bones, become painfully apparent.

SLEEP.

The various functions of the body are divided into voluntary and involuntary. When we eat we perform a voluntary motion, but digestion is performed without the action of the will, or is involuntary. The whole interior functional operations are involuntary, and go on whether we are awake or sleeping.

As a constant supply of food is necessary to repair the waste of the grosser parts of the body, so sleep is essential for the repose and renovation of the finer and more subtile nervous energy. Mere rest alone will not recruit the animal frame, but sleep, or a profound oblivion of feeling and sensation, and of every external circumstance, seems essentially necessary at every periodical revolution of the day. Toward the close of a day of exertion, the muscular powers which have been employed in motion, and in sustaining the body erect, begin to suffer particularly; the eyes become dim and heavy, and the eyelids close involuntarily; the lower jaw falls down; the circulation of the blood through the lungs is sluggish, hence frequent yawning is caused; the head nods forwards; all external objects affect us less and less; the thoughts become confused; and at last the profound oblivion of sleep ensues. We are unconscious of the exact moment when we pass into sleep, but occasionally it happens that immediately afterwards we are awaked by a convulsive start, which is caused by the sudden breaking in of the powers of volition, when as yet but newly and imperfectly lulled to rest. Sleep is quite essential to existence. Deprive a person of sleep, and the body sinks under the privation more rapidly than under famine. Indeed, no circumstances, however urgent, will prevent the approaches of sleep for any length of time; and under the severest calamities, and even while in the hour of battle, or when suffering from extreme fatigue, or cold, or hunger, sleep steals upon us to steep the senses in oblivion. Healthy sleep is so profound as to resemble, in all that regards self-consciousness, death itself. Sometimes, however, the mind exerts its activity, though it is but a partial exertion; and hence dreams, or thoughts of sleep, are made up of all incongruous associations, such as thoughts of the past day and incidents of long bygone years; scenes of actual experience, and others totally imaginary, being all mixed up and jumbled together. In sleep the heart continues to beat with regularity, and the circulation of the blood is carried on throughout the body; the lungs perform their functions, the stomach digests, and the bowels, and all the glands for secretion, carry on their operations; in short, every thing is carried on connected with the sustenance of the body and the existence of the vital powers; but for the most part all other powers, such as those over which we have a control in our waking hours, are at rest. This is not always the case, however, as walking during sleep, or somnambulism, is a peculiarity to which some individuals are liable. Dreams are most common when the sleep is imperfect or too long continued, and thus they occur frequently towards morning, or through the night, if the stomach is loaded and oppressed with food, or the mind harassed and deeply impressed with cares and solicitudes. In a state of health and serenity of spirits, the most profound and most refreshing sleep is during the first period of the night. When asleep, the circulation and breathing are both somewhat slower than when awake, hence the animal heat becomes diminished; and this is the reason why more clothing is required in bed than during the day. This is the reason, too, why a person lying down to sleep out of doors, or on a sofa, with the usual allowance of clothes, feels chill and uncomfortable on awaking. Digestion, too, would appear to go on less vigorously during sleep; and hence the impropriety of going to bed with a full stomach. During the night and darkness is the most natural and obvious time to select for repose, and it is only the absurd encroachments of fashion that have well nigh turned day into night. By going early to bed, the damps and colds of night are avoided, which is of essential consequence, especially for the delicate. There is also a natural connexion of the functions of the body with the periods of day and night, which makes sleep taken in the first part of the night peculiarly refreshing. The absence of every irritation of the head and other parts of the body—the perfect rest of the mind and external senses—have also great influence in promoting sleep. Again, a variety of causes which weaken and debilitate the body, incline to sleep; such as great losses of blood, cooling medicines, purgatives, coldness of the atmosphere; and narcotics, such as opium and tobacco, drinking largely of wine or spirituous liquors, by first causing great excitement, and afterwards a corresponding debility of the system, also predispose to profound and lethargic sleep. Injuries of the head, by pressing on or otherwise interrupting the functions of the brain, also induce sleep; and great corpulency, by retarding the return of blood through the veins, and thus keeping up a pressure upon the head, is generally accompanied by a disposition to sleepiness.

The period required for sleep, by different individuals, depends much upon temperament and peculiarities of constitution, as well as on mode of life and habit. While some cannot sleep beyond five, six, or seven hours, others, again, cannot well do with less than eight or nine hours. Children sleep more than half of their time, and require it, and thrive under it; while adults need much less repose. On a general average, eight hours has been reckoned a good allowance. Certainly sleep beyond this does no good, and often does harm. In order to enjoy grateful and uninterrupted sleep, it is necessary that due exercise shall have been taken during the day; that temperance in food and drink shall have been observed; that strong tea or coffee, which have a stimulating effect on the system, shall not have been taken within an hour or two of going to bed; and that there has been no supper, or a light one. It is true, gluttony and intoxication produce sometimes deep sleep, but it approaches more to an apoplectic stupor than the calm repose of the temperate.

THE SEXES.

In almost all animals the sexes are distinguished by a difference of form and texture of their bodies; and in many a superior gloss of colour in the hair or fur, or a superior brilliancy of the plumage, very generally characterises the male of the species. In most animals, too, the males are of superior size, and endowed with greater muscular strength. In the human species man is marked by a larger and more muscular body than the female; his chest is square and capacious, and particularly at the shoulders, whence it tapers gradually downwards; his bones are large, and his joints firm and sinewy; his muscles are round, tense, and conspicuously marked; his limbs thick and fleshy, and his arms powerful; his skin is firm and tense, and his hair strong, crisp, and often curly. The female figure, again, is smaller, less powerful, and, in every respect, more delicately formed; the bones are less projecting, the muscles softer, less conspicuous, and more smoothly blended one into the other; the shoulders are narrow and rounded; the greatest breadth of the body being at the pelvis, from whence it gradually tapers upwards; the skin is soft and delicate; the hair smooth, and of a silken appearance. The mental qualities and dispositions differ somewhat also. Man is commanding, resolute, daring, adventurous, addicted to deep and abstract thought, as well as to high and imaginative speculations. Woman is gentle, submissive, timid; with a mind, perhaps, little inferior in compass to man, she is more commonly distinguished for acute penetration, nice and delicate discrimination, refined and chastened taste, and elegant and playful fancy. It was the opinion of Plato, that, with regard to the mind, there is no natural difference between the sexes, but in point of strength. "When the entire sexes are compared together," says he, "the female is doubtless the inferior; but in individuals, the woman has often the advantage of the man." With warm and tender attachments, pure morals, and high religious feelings, she is admirably calculated for the sacred charge of watching over and training up the young, and of instilling into their tender and susceptible minds the beautiful lessons of early wisdom—of faith, truth, and charity. All nations, as they have advanced in civilisation, have uniformly increased in that respect and refined attention which is due to the softer sex; and one of the most powerful minds and of the most splendid endowments has been the foremost to appreciate those superior qualities which are to be found in a gentle and unsophisticated female. The late Professor Dugald Stewart thus introduces a quotation from a well-known traveller, which affords a just and beautiful estimate of the tender disposition of woman:—"From the greater delicacy of their frame, and from the numerous ailments connected with their temperament, combined with their constant familiarity with distresses which are not their own, the sympathy of women with the sufferings of others is much more lively, and their promptitude to administer relief, wherever it is possible, is much more eager than in the generality of men. To the truth of this remark every day's experience bears witness; and, from the testimony of travellers, it appears that the observation extends to women in all the different stages of society."

TEMPERAMENTS.

There are certain conditions of the bodily frame which evidently give rise to varieties of the human constitution, and which have been called temperaments. These have been peculiarly the object of attention to Dr Spurzheim, and others of the phrenological philosophers. As their views on this subject seem to us of a very clear order, a passage is here extracted from one of the journals devoted to that science. "Dr Spurzheim," says the journalist, "recognises four primary or cardinal temperaments, to which he considers all individual cases may be advantageously referred, either as pure, or much more frequently as consisting of two or more combined. I shall first give Dr Spurzheim's brief description of them, and shall afterwards enlarge upon each in detail.

1. 'The lymphatic, or phlegmatic temperament, is indicated by a pale white skin, fair hair, roundness of form, and repletion of the cellular tissue; the flesh is soft, the vital actions are languid, the pulse is feeble, and the whole frame indicates slowness and weakness in the vegetative, affective, and intellectual functions.

2. The sanguine temperament is proclaimed by a tolerable consistency of flesh, moderate plumpness of parts, light or chestnut hair, blue eyes, great activity of the arterial system, a strong, full, and frequent pulse, and an animated countenance: persons thus constituted are easily affected by external impressions, and possess greater energy than those of the former temperament.

3. The bilious temperament is characterised by black or dark hair, yellowish or brown skin, black eyes, moderately full but firm muscles, and harshly-expressed forms. Those endowed with this constitution have a strongly-marked and decided expression of countenance; they manifest great general activity and functional energy.

4. The external signs of the nervous temperament are fine thin hair, often inclining to curl, delicate health, general emaciation, and smallness of the muscles, rapidity in the muscular actions, vivacity in the sensations. The nervous system of individuals so constituted preponderates extremely, and they exhibit great nervous sensibility.'

The pure lymphatic temperament is characterised by a pallid complexion, soft skin, mostly free from hairs, the hair flaxen, the pulse weak and low; a general tendency to corpulence, and a deficiency of expression in the face. Instances of pure lymphatic temperament are more rare than of either of the others, and perhaps are never to be found, except amongst females and habitual invalids, when past middle age, who, from the want of exercise, have lost all trace of some other temperament which they may have possessed in youth. The mental characteristics of the lymphatic temperament are soon told; an insurmountable tendency to indolence, an aversion to exertion of either body or mind, form the hopeful traits. It is, therefore, obvious that the restraining faculties, Cautiousness and (in some of its manifestations) Secretiveness, are the only organs with the operation of which it will correspond; while all the other propensities, and the intellectual faculties, will be enervated and restrained by it.

It has been generally supposed that the sanguine constitution is produced by the perfection or redundancy of the circulatory system; and it seems such a natural supposition, that it is difficult for us to allow its proper force to the fact, that individuals of other temperaments are frequently found who can bear loss of blood, by phlebotomy or otherwise, as well as those of sanguine constitutions, and in many instances much better. There is, however, one anatomical peculiarity which appears always to attend the sanguine. The skin is much less disposed to transpiration than the bilious or nervous; and, in consequence, Dr Prichard, in a work lately published, considers that individuals possessing it are much better calculated to bear cold than others. The Fins, who, as a nation, are decidedly sanguine, bear extraordinarily cold winters much better than their more bilious neighbours the Laplanders. Dr Prichard adds, that as the sanguine temperament is very rare in those warmer countries, near the spot where man was first placed by his Creator, he considers the sanguine temperament as the result of a natural adaptation to external circumstances, analogous to the white hares and other animals of northern regions; but, if this is the case, it is difficult to imagine how it is that Laplanders should continue tawny, while the Fins, situated farther south, are fair. The most striking moral feature of the sanguine temperament appears to be a tendency to enjoyment of the present time, with little inclination to regret the past or to dread the future; and, in general, to look at either past or future no more than is necessary to happiness. The bilious temperament is characterised by a decided cast of features, complexion inclining to brown, dark eyes, and black or dark brown hair, with the muscles firm and well marked, and the figure, in general, expressive of vigour, with every motion significant and decided. In combination, it is frequently traced in a slight yellowness of the skin, which can only be detected by comparison, or an extraordinary acute perception of colours; for example, you may frequently find two persons, particularly ladies, the one with dark hair and eyes, the other with flaxen hair and blue eyes. The complexions of both would be denominated fair; on observing them near each other, however, it will be seen that the fairness of the dark-haired one differs considerably from the clear snowy whiteness of the sanguine.

With respect to the nervous temperament, it manifests itself in a remarkable quickness to learn and readiness of comprehension, but little tendency to sensual gratification, and an extraordinary power of passing from one subject to another."

MAN ADAPTED TO LIVE IN ALL CLIMATES.

Man has this superiority over other animals, that he can inhabit almost every region of the globe, and there exhibit a greater or less degree of civilisation. He is found under the scorching sun and amid the arid plains of Africa, as well as in the frost-bound regions of Spitzbergen; and not only is he found to endure under these extremes, after a gradual naturalisation of ages, but he can even move from one country to another, and undergo a vicissitude of climate with comparative impunity. Thus we see, even from our own country, emigrants going forth, and naturalising themselves amid the cold regions of the north, onward to the very verge of the equator. The Esquimaux and the Canadian savage will prosecute their usual employments of the chase in a temperature where mercury freezes into a solid mass, and where even brandy congeals to ice in apartments containing fires; while the African negro, again, feels quite at his ease in a burning climate, where the thermometer in the shade ranges from 90° to 100°, and upwards. Man has an equal facility in adapting himself to the pressure of the atmosphere attendant on low or elevated situations. In Mexico, he is found living in elevated regions, from 6000 to 8000 feet above the level of the sea; and the hamlet of Antisana, in Quito, is 13,500 feet above the level of the ocean. On the contrary, we find almost all animals only adapted to live in the regions in which they are naturally found; and if they are removed from such localities, they seldom enjoy the natural period of their lives. Even the dog and the horse, the domesticated companions of man, degenerate and change their natures under extreme varieties of temperature; and the monkey tribe, which, in the structure of their bodies and in the substances on which they feed, approach the nearest to man, become sickly and diseased, and never propagate their species, when removed into any of the colder regions of the globe. In order to enable man thus to subsist in regions having such a diversity of natural productions, he is endowed with the power of feeding on and digesting every possible variety of food—he is, as compared to other animals, in respect to diet, omnivorous. We thus find the Greenlanders and inhabitants of frozen regions living almost exclusively on the fat and flesh of land and sea animals, the only species of food which the barren and ungenial nature of the climate affords, but one, nevertheless, which, from its stimulating and nourishing nature, is the very best for enabling them to live under such an extreme depression of temperature. The inhabitants of hot countries, again, will be found living on rice, fruits, and other vegetable substances, which the warm and genial soil produces in abundance, and which, from their nature, are less heating and stimulating than an animal diet. In the intermediate and temperate regions, a mixed diet of animal and vegetable food is preferred. Much discussion has arisen whether man be more a flesh-feeding or herb-eating animal; experience demonstrates that he is equally adapted to become both—that he will live on an almost purely animal diet, as well as on one purely vegetable; although, were we strictly to compare the form of his jaws and teeth, and the general structure of his intestines, with those animals that live on nuts and other fruits, and farinaceous or mealy substances, as, for instance, the monkeys, the near approach of these to the human structure would indicate to us that at all events a farinaceous diet is the most suitable to his natural organisation. We thus find among all civilised nations that bread, and the grains and mealy roots, in some shape or other, have always a preponderance in every meal. But the art of cooking, which man resorts to even in the first dawnings of civilisation, enables him to change the nature of his various food, and to render it more suitable both for digestion and the purposes of nourishment, and thus gives him a wonderful superiority over all the rest of the animated world. Indeed, it is by this improved mode of preparing his food, perhaps, as much as by original strength and perfection of frame, joined to the other comforts of civilisation, that he is enabled to brave the vicissitudes of climate, and to prolong his life to a longer period than the great majority of other animals.

Man has been formed with a naked skin, with the evident intention that he should clothe himself by his own labour and ingenuity. Almost all the larger and more perfect animals have a covering of hair, of feathers, or of down, which is at stated periods renewed, and in some animals in greater length and abundance at particular seasons, to suit the variations of temperature. But man can always adapt his clothing to the climate he inhabits, or to the varying alterations of the seasons; and he can at all times, by his own industry, vary or renew his suits. Man, too, builds for himself a comfortable habitation, to protect him from the inclemency of the weather, and is not contented with a burrow under ground, or the casual shelter of the woods and coppices, as is the case with the animals of the forests. It is true the architecture of bees, and some other animals, is curious, ingeniously combined, and admirably suited to their necessities; but in comparative taste, splendour, or even convenience, how far are all these surpassed by the houses, and temples, and cities of mankind! Though man is naturally defenceless and unarmed, how soon does his ingenuity enable him to obtain a mastery over the beasts of the field and forest, and furnish him with weapons of defence against all his enemies! How soon does his ingenuity enable him to improve and cultivate the soil—to drain marshes, cut down woods, level mountains—to select and cultivate the best species of grain, and the most wholesome and nourishing vegetables, for food—to invent tools and engines, by which he acquires a command over the sea and land, by which he erects bridges, constructs machinery, and launches the towering vessel upon the wide ocean! And, lastly, with what skill he constructs instruments of art and of science, by which he can examine and investigate the most minute objects of nature, as well as bring within his sphere of observation the distant worlds and systems of the universe!

INFANCY—MATURITY.

At the moment of birth, the infant begins to exercise an independent existence, whereas before it formed a part, and was nourished by the vessels of its parent. A general similarity takes place in the embryo growth of most animals, and the familiar instance of the chick in the egg may be taken as an example. The egg is composed of a centre part or yolk, and of the albumen, or white part surrounding it. In this white part, a small darker speck may be seen floating, from whence the first rudiments of the chick are derived. In a few days after the hen has sat on the egg to impart to it the necessary heat, a small whitish spot will be observed, which is the first rudiments of a brain; in a few days more, vessels will be seen spreading out from a central heart, and forming a network all around; gradually an appearance of a head is seen, with indications of brain and spinal marrow; the eyeballs next are formed, then the several parts of the viscera, the projections of the wings and legs, and lastly, the skin and rudiments of the future feathers. During these periods of incubation, the chick has been nourished by the yolk of the egg, which has gradually been absorbed by its vessels for this purpose. At last, when its growth is perfected, and the whole contents of the egg converted into the materials of its body, the little animal begins to pick a hole in the shell, and, by repeated efforts, bursts from its shelly prison, and assumes an independent life.

The infancy of man is of much longer duration, and of a much more helpless nature, than the same state in other animals. A child cannot walk till it is at least twelve months old; and even for a considerable time after that period, it has to be fed and tended with the utmost care; whereas, after a very short time, the young of most animals are able to provide for themselves. A great many, a few minutes after birth, are able to walk about, to search for and distinguish the teat of their mother, and to pick up the food that is suitable for them: and having remained under their maternal protection for a short space, they leave their parents, and never know or distinguish them more. It is very different with the infant: during a long and helpless period of childhood, it is tended by a fond mother, who anticipates all its wants; while it, on the other hand, watches her smiles, and imitates her most minute actions; and thus a reciprocal bond of union is established, by which not only every species of knowledge and experience is acquired for the conduct of after life, but those moral feelings and sympathies implanted which constitute the great boast and solace of human society.

Man proceeds from infancy to maturity by a slower and more gradual expansion of the bodily structure than any other animal; and this may be one reason of his superior organisation, his greater fitness for supporting labour and fatigue, and the longer period to which his life is extended. From infancy, upwards, the mental powers also gradually expand. This is also different from animals; for in them the faculty of instinct at once is perfected, and never afterwards increases or undergoes any change. In childhood, the mental faculties are constantly active, and on the alert to catch new information, inquisitive to know everything, and imitate every gesture. The facility with which children acquire the knowledge of words, and in a few months master a language, is very astonishing, when we reflect for a moment how much time and pains it takes a grown-up person to become a proficient in any unknown language: and our astonishment will be heightened when we consider that, in the case of children, they have not only to acquire the words and their proper applications, but even to master the articulation of sounds, with all their infinite combinations.

The age of puberty, or that period when boyhood terminates, and manhood commences, varies somewhat in different climates, according to their high or low temperature; the mean period may be reckoned about fourteen years; and between twenty and twenty-five, the growth of the body generally terminates.

About the age of thirty, man may be said to be in his full vigour, with his mental and bodily powers completely developed. Females arrive earlier at a state of maturity than males: in warm climates they are full grown as early as their tenth or twelfth year; in more temperate regions, about their fifteenth or eighteenth year. The proportion of male children born to that of females is as 21 to 20; there is thus a small superabundance of males; but, from various causes, it so happens that there is generally rather a superabundance of females actually existing in society. Among these causes may be mentioned the greater hardships and labours to which men are exposed, the effects of war, and, on the whole, the longer life enjoyed by females. This regular proportion of male and female births throughout mankind in all ages, and in all parts of the world, shows the admirable design and precision of an unerring nature.

OLD AGE—DECAY.

We have seen that there is, within the animal frame, a system of operations by which a constant supply of nourishment is afforded to make up for the daily waste and decay, and that every part is constantly undergoing a renewal. To view a man in the full vigour of life, then, we might suppose that, excepting accidents, he was calculated to go on, in the course of existence, for an indefinite period. The principle of life, however, seems to have limits set to its duration, beyond which it fails to keep in healthy motion the animal faculties. The apparatus of life is evidently destined but to last for a certain time. Old age creeps on apace, and the vital flame burns fainter and fainter, till at last it sinks in the socket, and is seen no more. The commencement of decay is perceptible even in youth itself. The child at first grows quickly, from the soft and yielding state of all its vessels; but gradually these begin to thicken and get harder—a greater proportion of earthy matter is adding to the bones. The extremities grow large, while the heart itself does not increase in an equal degree; hence the circulation becomes less and less quick, till the period of full growth. When the growth of the body can proceed no farther, a degree of fatness not unfrequently occurs. This proceeds from the superabundant nourishment produced from the food, which, from the impetus or force of the circulation being more lessened by the greater extension and resistance of the body, accumulates in the cellular textures and by the sides of the extreme vessels. In every part of the body, the induration produced by approaching age becomes conspicuous—in the bones now wholly brittle, in the skin, in the tendons, in the glands, in the arteries, and in the brain itself, which gets firmer and drier. Moreover, the arteries continue to get denser, narrower, and even shut up in their minute branches. At the same time the nerves become more and more callous and insensible to the impressions of the senses, and the muscles to irritation; thus the contractile force of the heart, and the frequency of its pulsations, are diminished, and consequently every force which impels the blood into the ultimate vessels. The quality of humours is diminished in the denser body; the moisture which lubricates the solid parts everywhere manifestly decreases. Nor is the quantity of humours only diminished; they themselves likewise become vitiated. They were mild and bland in children; they are now acrid, salt, and fetid, and loaded with a great quantity of earthy matter. This circumstance of the superabundance of earthy matter is evident in the gouty concretions in the joints of old people, in the frequency of stone, and in the arterial tubes, and even the heart itself, being frequently converted into real bone. The rigidity of the whole body, the decrease of the muscular powers, and the diminution of the juices, constitute old age, which sooner or later comes upon all men—sooner, if subjected to violent labour, or addicted to pleasure, or fed upon a too scanty or unwholesome diet; but more slowly, if they have lived quietly and temperately, or if they have removed from a cold to a moderately warm climate.

There are three obvious divisions of human life—a period of youth, including the period before the age of 30; of maturity, from 30 to 50; and of old age, commencing about the period of 50 or 60. The Psalmist speaks of the age of man being, in his time, only threescore years and ten, or in rare cases fourscore years, which may be reckoned the average limit of human existence. After the period of 50 or 60 years, varying of course in different constitutions, the marks of old age begin to make their appearance. The skin becomes more lean and shrivelled; the hair changes to a gray colour, or baldness occurs; the teeth drop out, and in consequence of this, the lower parts of the face, about the mouth and jaws, incline inwards; the muscular motions of the body become less free and elastic—this is especially seen in walking, old people generally treading on the whole base of the feet, and hence having a shuffling gait; the blood circulates slowly; the animal heat is diminished; the pulse occasionally intermits, and the whole energies of the animal frame become lessened; the eyesight begins to fail, and dulness gradually comes over all the senses; the memory undergoes a remarkable change—while recent events pass through the mind and make no impression, the occurrences of early life continually suggest themselves, and are minutely called to remembrance.

Although seventy years is usually the extreme duration of human life, yet a small proportion of those born ever reach even this; a few rare instances occur where one hundred years or upwards are attained. The famous Parr lived to the age of 152 years; he married at the age of 120, and, when 130, was able to thrash, and to do every description of farmers' work. He was at last brought from the pure air and the homely diet of the country into the family of the Earl of Arundel, in London, where he drank wine and lived luxuriously. The sudden change of diet and circumstances, however, proved quickly fatal to him. Henry Jenkins, another poor man, lived to the astonishing age of 169 years, and retained his faculties entire. Some time ago, a statement appeared of the ages of the resident pensioners of Greenwich Hospital, which contained at the time 2410 inmates. Of this number, 96 had attained to or passed the age of 80; one only was above 100; 15 were 90 or more; and 60 were 80 or upwards. About 42 of the 96 were of aged families, and in some of this number both parents had been aged. Longevity has in a great number of cases been found to be hereditary. Eighty of the 96 had been married; 79 were in the habit of using tobacco in some form or other, and 48 had drunk freely; 29 were entirely without teeth; 52 had bad, and 14 good teeth. But the oldest man in the house, who was 102, had four new front teeth within the five preceding years. The sight was impaired in about one half, and hearing only in about a fifth part of the number.

Old people are not generally inclined for much exercise, nor is it suited to their stiff joints and impaired vigour; for the same reason, they cannot endure much cold. Cheerful company, especially the company of the young, is peculiarly grateful to old people. Innocent amusements and recreations are also of great consequence, and the mind should be exercised in some useful or amusing pursuit. Cities, or at all events constant and agreeable society, are favourable to the condition of old age. In lonely secluded country places, the mind sinks prematurely into a total gloom and blank, for want of sufficient stimulus and variety to keep up the vigour of thought and play of ideas. Few deaths occur from what is commonly called old age, or a gradual and simultaneous decay of all the functions. It may be said to happen when the powers gradually decay, first of the voluntary muscles, then of the vital muscles, and lastly of the heart itself; so that, in an advanced age, life ceases through mere weakness rather than through the oppression of any disease. The heart becomes unable to propel the blood to the extreme parts of the body; the pulse and heat desert the feet and hands, yet the blood continues to be sent from the heart into those arteries nearest to it, and to be carried back from them. Most commonly, however, some one part gives way, and disease gradually coming on, cuts off the lingering flame of existence. Thus the body, after having grown up to maturity, and flourished in its prime, sinks to the earth, and moulders into the elements of which its several parts are composed.

CONCLUSION.

The admirable structure of the body of the human being—its superiority in every respect to that of the lower animals—afford a most perfect proof of design in the all-wise Creator, and is one of the most striking instances of the impossibility of our formation being the result of blind chance. Paley, after going over a great number of examples of this kind of design in a Creator, proceeds to state that, in all "instances wherein the mind feels itself in danger of being confounded by variety, it is sure to rest upon a few strong points, or perhaps upon a single instance. Amongst a multitude of proofs, it is one that does the business. If we observe in any argument," he continues, "that hardly two minds fix upon the same instance, the diversity of choice shows the strength of the argument, because it shows the number and competition of the examples. There is no subject in which the tendency to dwell upon select or single topics is so usual, because there is no subject of which, in its full extent, the latitude is so great, as that of natural history applied to the proof of an intelligent Creator. Perhaps the most remarkable instances of mechanism in the human frame are—the pivot upon which the head turns, the ligament within the socket of the hip-joint, the pulley or trochlear muscles of the eye, the epiglottis, the bandages which tie down the tendons of the wrist and instep, the slit or perforated muscles at the hands and feet, the knitting of the intestines to the mesentery, the course of the chyle into the blood, and the constitution of the sexes as extended throughout the whole of the animal creation. To these instances the reader's memory will go back, as they are severally set forth in their places; there is not one of the number which I do not think decisive; not one which is not strictly mechanical; nor have I read or heard of any solution of these appearances, which in the smallest degree shakes the conclusion that we build upon them.

"The works of nature require only to be contemplated. When contemplated, they must ever astonish by their greatness; for, of the vast scale of operation through which our discoveries carry us, at one end we see an intelligent Power arranging planetary systems, and, at the other, concerting and providing an appropriate mechanism for the clasping and reclasping of the filaments of the feather of the humming-bird. We have proof not only of both these works proceeding from an intelligent agent, but of their proceeding from the same agent; for, in the first place, we can trace an identity of plan, a connection of system, from Saturn to our own globe; and, when arrived upon our globe, we can, in the second place, pursue the connection through all the organized, especially the animated, bodies which it supports. We can observe marks of a common relation, as well to one another as to the elements of which their habitation is composed. Therefore one mind hath planned, or at least hath prescribed, a general plan for all these productions. One Being has been concerned in all."

ZOOLOGY.

ZOOLOGY is that branch of Natural History which treats of the beings composing the *Animal* Kingdom. The life of every animal presents to intelligent observation a number of facts, which may be considered individually or in groups, according to their nature and character. Thus we might consider *structure* alone—that is, the animal body as composed of bones, muscles, blood-vessels, &c.—the department of science which is termed ANATOMY; or we might examine the *actions* and *functions* of these organs—in fact, the history of the living being—which is termed ANIMAL PHYSIOLOGY. In pursuing either of these, we might restrict our inquiries to a single animal, though, from the evident relationship of all animated existence, it would be highly disadvantageous to do so; but in SYSTEMATIC ZOOLOGY, the purpose is altogether different. It discovers that the several beings included in the Animal Kingdom may be regarded not only in their individual aspect, but in their relations to each other; that they form parts of one great plan, as harmonious in itself as that of a beautiful building made up of a vast number of subordinate parts; and that whilst the diversities of form and aspect seem almost infinite, they are evidently subordinate to certain general principles, which produce not only the manifest conformity, but the apparent departures from it. The grand aim of the scientific zoologist being to discover this plan—the plan upon which Nature has proceeded in the creation of animal life—he employs *classification* as a means by which to facilitate his acquaintance with the vast number of beings that claim his attention.

CLASSIFICATION.

On looking at the variety of animal forms around us, the mind naturally associates together those which have the greatest general resemblance, and separates these (although differing in some degree amongst themselves) from those with which they have greater dissimilarity. It is by pursuing this plan, from one stage or degree of resemblance and difference to another, that classifications are formed; and these will be correct according to the amount of knowledge upon which they are founded, respecting not only the external form, but the internal structure of the objects they include. At one time it was customary to divide animals into five classes—*beasts, birds, fishes, reptiles, and insects;* but the investigations of Cuvier and other modern naturalists have shown that this is an imperfect arrangement, though the most easily recognised by the uninstructed observer.

Experience teaches that the offspring of any kind of animal is similar to its parents, though slight variations may be often traced between them. A succession of beings having this general conformity is called a *race*. Now, the first object which the naturalist has to determine is, whether two races—such as the Negro and European races of man, or any two breeds of dogs—*might have* had a common origin. If he finds reason to believe that their differences are not greater than may be accounted for by the influence of accidental causes, and especially if he finds one race never producing the form of another, he considers them as springing originally from a common stock, and as of one *species;* but if he cannot thus account for their differences, he regards them as of different species. This division of all existing animal forms into species, is that on which the naturalist has to found his subsequent classification; and it is necessary to take great care to avoid errors arising from variations in the forms of animals at different periods of their existence. Thus the tadpole and the frog, the caterpillar and butterfly, would be referred not only to different species, but to different classes, were we not aware that they are only different states of the same animal; and many birds have been erroneously regarded as of distinct species, which belonged to the same, but presented varieties of plumage, depending upon age, sex, and period of the year. Again, in the dog and other domesticated animals, the difference between *breeds* is so great, that the naturalist would unquestionably rank them as distinct species, were he not induced to believe by other evidence that they had all a common origin. A number of species, differing from each other in trivial points, but having a strong general resemblance, are said to belong to one *genus*. The genera most nearly allied are united into one *family;* several families into an *order;* and several orders into a *class*. The class, therefore, contains a very large number of species, many of them differing widely from each other, but all agreeing in some prominent and important character. The classes composing the Animal Kingdom are usually arranged under four groups, on account of their correspondence in certain general particulars, and their difference in others: these are called *sub-kingdoms*. The four sub-kingdoms, as defined by Cuvier, are—VERTEBRATA, ARTICULATA, MOLLUSCA, and RADIATA.

VERTEBRATA.

The Vertebrata derive their name, very appropriately, from a feature of their organisation specially connected with that superior intelligence which forms their leading characteristic. This is the internal skeleton, which, while it appears at first sight as only a frame for the support of the muscles, is in reality formed with a more immediate reference to the nervous system, of which the chief parts (brain and spinal marrow) are contained in the head and vertebral column. The Vertebrata have red blood, which is propelled through the system by a muscular heart. The animal powers of sensibility and spontaneous motion are highly developed in them; and in accordance with these, a complete symmetry or correspondence between the two sides of the body is observed externally. But this symmetry does not extend to the organs of vegetative life, which are irregularly disposed in the cavities which they occupy.

The Vertebrated animals are divided, again, into four *classes*, of very distinct character, and occupying different grades of organisation—the MAMMALIA, BIRDS, REPTILES, and FISHES.

CLASS I.—MAMMALIA.

The Mammalia (so called as possessing organs for suckling the young) are regarded as constituting the highest group in the Animal Kingdom; being gifted with the most complex organisation and highest intelligence. In subdividing them, it has been found that certain external features, as the teeth and forms of the extremities, are of special convenience for distinction, because these indicate in a great measure the habits and general character of the animal. This is a principle from which some remarkable results have arisen—Cuvier having determined the whole character of certain extinct species from seeing only a few teeth. In following it, however, naturalists must be admitted to have decided some points of classification in a manner which will not ultimately be approved of. One highly essential distinction of a different nature—the being born with a placental envelope or otherwise—separates the mass of the Mammalia from a group chiefly resident in Australia—the pouched animals, &c.—which are wanting in this peculiarity, besides being marked by some other conspicuous features of inferiority. The next great distinction is the possession of claws or hoofs, the latter being animals (*Ungulata*) of generally innocent character, which live upon vegetable food, hence provided only with cutting and flat-grinding teeth, while the former (*Unguiculata*) are carnivorous and destructive animals, possessing in their claws and sharp molar and canine teeth the means of catching and tearing their prey. A peculiar arrangement of the incisors for gnawing gives to a group of comparatively weak animals the name of Rodentia. Another group is distinguished by the want of fore-teeth. With these slight indications of Cuvier's principle for classifying the Mammalia, we proceed to consider the following orders into which the class is usually divided:—

1. Bimana.	5. Carnivora.	9. Pachydermata.
2. Quadrumana.	6. Cetacea.	10. Ruminantia.
3. Cheiroptera.	7. Rodentia.	11. Marsupialia.
4. Insectivora.	8. Edentata.	12. Monotremata.

I.—Bimana.

Man, the *two-handed animal*, is the sole species forming this order. Regarded as a member of the Animal Kingdom, he is distinguished by his erect position, thus leaving the two anterior extremities to be used solely for prehension, which is not the case in any other species. The hand of man is adapted to a far greater variety of purposes than that of the monkeys, to which it bears a resemblance. Its power consists chiefly in the size and strength of the thumb, which can have its tip brought into opposition with that of any of the fingers; and all these are capable of being moved separately. In none of the monkeys can the thumb be opposed to the fingers with any degree of force, and in many their tips cannot be brought into contact: so that, though admirably adapted for clinging round bodies of a certain size, such as the small branches of trees, their hands can neither seize very minute objects nor support large ones. To the hand of man some have attributed his superiority; but it may be safely said that he owes this to his mind and its instruments conjointly. The hand would be useless without the mind to direct it; and mankind, if handless, would soon be reduced to a very subordinate kind of existence, if not speedily extinguished altogether.

Possessed of so remarkable a means of executing that which his mental ingenuity devises, man is less provided, in regard both to acuteness of sensibility and to muscular power than many other Mammalia. His swiftness in running is inferior to that of other animals of his size. The smallness of his face, compared with that of the cranium, shows that the portion of the nervous system connected with the external senses is less developed in him than in most other creatures. Accordingly, he is surpassed by many in the acuteness of his sensibility to light, sound, &c. But he stands alone in the power of comparing his sensations and drawing conclusions from them. Moreover, although none of his senses are very acute in his natural state, they are all moderately so, which is not the case in the lower animals; and they are capable (as is also his swiftness of foot) of being much improved by practice, especially when circumstances strongly call for their exercise.

This improvability is one of the most remarkable characteristics of the bodily as well as the mental constitution of man. It is from a gradual advance in both that the civilised races now enjoy so much of comfort, and of means of still further elevation. In the processes by which these are attained, we observe a remarkable difference between the character of man and that of his fellow-creatures. The arts of which these are capable are limited, and peculiar to each species; and there seems to be no evidence of a power of invention, or of construction for any purpose, beyond that to which the original and instinctive powers are adapted. Hence it would appear that there is no proof of any species or race among the lower animals ever making an advance towards an improvement or an alteration in its condition; and where a particular adaptation of means to ends, of actions to circumstances, is made by an individual (as is often the case where a certain amount of intelligence or rationality exists), the rest do not seem in the least to profit by it.

Man is as much distinguished, then, from the lower animals, by his mental as by his corporeal endowments. Yet they are not of a *kind* altogether different from that which we may elsewhere see. In common with the inferior tribes, he possesses strong instinctive propensities, which are kept under control, however, in a well-balanced mind. But when the reasoning powers are undeveloped, as in early childhood and idiocy, the exclusive sway of the instincts is obvious. The more violent passions and emotions are nearly akin to these; and whilst they give great activity to the operations of the mind, it is requisite that they should be duly restrained by the intellect and will. This power of internal regulation is one of the most striking characteristics of the human mind above that of animals, which possess, like it, reasoning faculties, often to no mean extent, and are actuated by emotions and moral feelings. One of the most important aids to the use and development of the human mind, is the power of producing articulate sounds, or language; of which, as far as we know, man is the only animal in possession. There is no doubt that many other species have certain powers of communication amongst individuals; but these are probably very limited, and of a kind very different from a verbal language.

The more we study the physical and mental constitution of man, the more are we led to the belief, that it is in the adaptation of the whole to a great variety of circumstances that its great perfection consists. There seems scarcely any condition in which he cannot support himself. He is capable of sustaining the lowest as well as the highest extremes of temperature. His diet is naturally of a mixed kind; but he can support himself in health and strength on either animal or vegetable food exclusively. At the same time, it is by the demands which his peculiar condition makes upon the exercise of his ingenuity, that his mental powers are first called into active operation; and, when once aroused, their development has no assignable limit. [For a detailed inquiry into the characters of the different races of mankind, see PHYSICAL HISTORY OF MAN.]

II.—Quadrumana.

The order Quadrumana, which takes its name from the peculiar conformation of the extremities of the animals composing it—all four of them having one of the toes opposed to the rest, like the thumb of man to his fingers—are remarkable for their facility in climbing, which they gain by the *grasping* power conferred upon them by the possession of *four hands*. Their anatomical structure clearly shows that the upright position is not natural to them; and it is certain that, though they may be taught in a state of captivity to walk erect like men, they usually support themselves by their anterior as well as their posterior limbs. It may be observed that those species which approach the nearest to man rest upon the outer side of the foot only, and not upon its sole, when quitting his position; and that they are very insecure in it. And to those which are intermediate between the higher Quadrumana and the succeeding orders, the maintenance of the erect position without support for any length of time is impossible. It might be supposed that the possession of 'four hands' is a character which raises the animals possessing it above two-handed man; but a little reflection will show that this is not the case, since the hand even of the highest Quadrumana is very inferior to that of man in complexity of structure and in the variety of movement to which it is adapted, whilst that of the lower shows but a slight advance upon the foot of the Carnivora. A corresponding series of gradations may be traced in the aspect of the face; for whilst, at one end of the series, the muzzle (at least in the young animal) is not much more prominent than it is in some races of man, at the other it nearly resembles that of other Mammalia. Nevertheless, throughout the order, a certain degree of resemblance to man may be perceived in the gestures as well as in the general aspect of these animals. All of them, like man and the Carnivora, possess three sorts of teeth: the canines, in the full-grown animal, are much more developed than in man; and there are intervals between them and the other teeth, which are not present in his jaws, but which exist in all the other Mammalia.

The Quadrumana may be divided into three families—the Simiadæ, or Monkeys of the old world; the Cebidæ, or American Monkeys; and the Lemuridæ, or Lemur tribe, which supply the place of monkeys in Madagascar and some parts of Africa and India. This restriction of distinct types of structure to different portions of the surface of the globe is not a little remarkable, and may be traced even in the subordinate divisions:—

1. The Simiadæ must be regarded as the types of the order; and amongst these the *Apes* manifest, in the most striking manner, the peculiar characters of the group. These are distinguished from the other subdivisions, in part by the absence of a tail, but also by the want of the cheek-pouches and of the callosities, or hard spots on their haunches, destitute of hair, which the monkeys and baboons possess; and further, by the predominance in length of the fore feet or arms over the hinder ones. The most remarkable species of this group are the *chimpanzee* and *orang-outang*; the former a native of equinoctial Africa, and the latter of the peninsulas and islands of Eastern Asia. Contrary to the general opinion, it is in the first of these that the greatest number of points of resemblance to man are to be found. Both these animals attain considerable size when full grown; probably in their native climate the former rising to five feet, and the latter to seven; but no living specimens of such sizes have ever been seen in this country. In both, there is a remarkable difference between the young and the adult form of the skull—the young bearing the greatest resemblance to that of man; whilst in the adult, the muzzle is so much prolonged, and the canine teeth are so much developed, as to give the face much of the aspect exhibited by that of the baboon.

Orang-Outang.

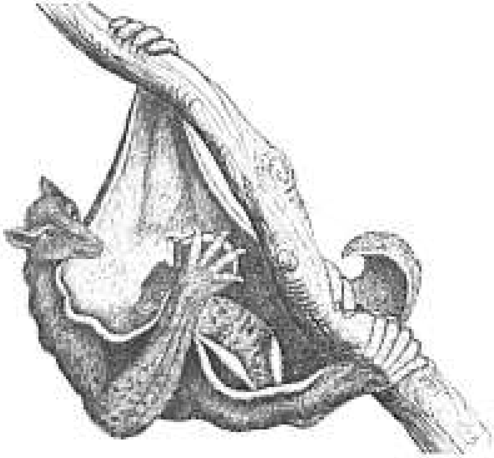
The *Monkeys* of the old world are distinguished (in addition to the characters which separate them from the ensuing family) by the possession of cheek-pouches, callosities, and a tail, which separate them from the apes; the tail is longer than in the baboons, the muzzle less protuberant, and the aspect less ferocious. The true monkeys are also remarkable for the shortness of the arms in proportion to the legs, which causes some species to walk on all-fours with difficulty, climbing being their usual mode of locomotion; but, by common observers, they are still more noticed for the beauty of their colouring, their activity of movement, and gentleness of demeanour. Their character is greatly changed, however, by confinement. They are found in almost all the tropical countries of the old world, and particular genera have a peculiar local distribution. Many of them live in societies, chiefly inhabiting the woods, but committing great devastations on any cultivated ground in the neighbourhood. In several species, the aspect of the head is extremely grotesque, as are also the attitudes of the animal. The number of species is altogether considerable. Their food seems to be rather vegetable than animal; and in one genus this is distinctly indicated by the structure of the teeth and of the stomach. One genus, restricted to Africa, is destitute of thumbs on the anterior extremities, and the deficiency is partly supplied by the great development of the tail, which is not, however, prehensile, as in the American monkeys.

The *Baboons* have usually a short tail, or none at all; but there is much variation in this respect. They are rather distinguished from the apes and monkeys by the protuberance of the muzzle, and the ferocity of aspect which is partly dependent upon this; the canine teeth are generally large and strong. The baboons have also a large bag connected with the organ of voice, by the resonance of which the power of their loud and discordant cries is greatly increased. In a state of captivity, the baboons exhibit less docility than any others of the order. They are by no means devoid of intelligence; but they do not seem capable of being steadily attached by kindness, and generally exhibit an alternation of moody sullenness and violent outbreaks of passion. Their resentment of injuries is often manifested for a long time afterwards.

2. The Cebidæ, or monkeys of the new world, differ from those of the old not only in the number of their grinders and the disposition of the nostrils, already mentioned, but in the entire absence of the cheek-pouches and callosities, and also in the conspicuous character, and the importance as a member, of the tail, which is usually prehensile in these monkeys, and capable of being twisted round branches so firmly, as entirely to support the animal. In general, the thumbs of the anterior members are not opposable; and they are sometimes scarcely developed at all. The Cebidæ are generally of smaller size than the Simiadæ, none of them attaining nearly the dimensions of the chimpanzee, orang, or mandril; they are also less malicious, more easily tamed, and susceptible of a more constant attachment; but they seem to possess less intelligence. They are found in very large numbers in the woods of South America, where they chiefly subsist on vegetable food, to which their teeth show a peculiar adaptation. The largest of them are the *Myceti*, or howling monkeys, which derive their peculiar powers of voice from a sort of hollow drum connected with the larynx. They are shaggy animals, about the size of a fox. The *Ateles*, or spider-monkeys, are remarkable for the length and prehensile power of their tails, and for the absence (in some species entire, in others nearly complete) of the thumb; whence they are called four-fingered monkeys.

3. The Lemuridæ have in many respects the aspect of the American monkeys; but the muzzle is much prolonged, resembling that of insectivorous or carnivorous animals; the teeth also are modified for animal food, presenting sharp tubercles, locking into each other; and the grinding motion of the lower jaw is reduced, so that its action possesses more of the scissors-like character of that of the animal-feeders. The four thumbs are well developed, and opposable; the claw-like aspect of the nail of the first hind finger has been already noticed as one of the most easily recognised characters of the family. The canines in the lower jaw have the character of additional incisors; and the first molars resemble the ordinary canines. The total number of teeth in each jaw is eighteen, as in the American monkeys. The *true Lemurs* are distinguished by their very large and handsome tails, which are elevated when the animals are in motion, and not trailed after them. They average the size of a large cat, but have longer limbs. They are nocturnal or twilight animals, passing the day in sleep, rolled up in the form of a ball; at night they rouse themselves, and spring with the greatest activity in search of their food, which principally consists of fruits. These are entirely confined to Madagascar, where at least thirteen species are known to exist, differing but little from each other except in colour. On the other hand, the *Galagos*, which are found in the neighbourhood of the River Senegal, are pre-eminently insectivorous.

The *galeopithecus*, or flying lemur, so much resembles the bats, as to have been placed with them by many naturalists. It is, however, a *lemur* in all its essential characters, but it has its limbs connected by thin skin, which they stretch out, as the framework of an umbrella



Galeopithecus, or Flying Lemur.

supports its covering. By this singular structure the animal is supported in the air, as by a parachute; but it has not the power of sustaining a continued flight, though it can leap a distance of a hundred yards with a gradual descent. Like the bats, it feeds on insects, and sleeps with its head downwards, suspended by its hind legs. It is a native of the Indian Archipelago.

III.—Cheiroptera.

The order Cheiroptera is perhaps the most distinctly circumscribed group of the whole class Mammalia; for all the animals composing it agree in the possession of a pair of wings, formed by an extension of the skin over the very elongated fingers of the fore legs, and connected also with the hind legs, by which they are adapted to raise and sustain themselves in the air, and also to propel themselves through it by regular continued movements, in precisely the same manner as birds. Now, although in other groups we may observe a tendency towards the same adaptation, it is never carried farther than to give to the animal possessing it the power of partially supporting itself in the air, so as to prolong its leaps, as is the case with the flying squirrel, the flying lemur, and flying opossum. None of these animals can really *fly*, like bats and birds.

We see in the bats a very interesting modification of the whole character of the mammal, to enable it to lead the life of a bird, just as in the whale tribe we see a similar adaptation to the life of a fish. The insectivorous bats bear a strong analogy to the swallow, in the character of the food itself as in the mode in which they obtain it—by the rapid pursuit of insects on the wing; the chief difference in habit being the time at which they respectively go forth in search of their prey.

The whole structure of the Cheiroptera is obviously adapted to the fulfilment of the object which is the distinguishing character of the group. All the bones of the upper extremity, as well as those which give attachment to its muscles, are very largely developed. The member itself, although consisting essentially of the same parts as in man, has its aspect greatly changed by the extraordinary prolongation of the finger bones, upon which chiefly the skin of the wings is stretched. This skin is extremely thin, and is generally devoid of hair on both sides. It extends not only between the fingers, but from the last finger to the posterior extremity, and from this to the tail, where one exists. This expansion of the tail probably serves as a rudder, enabling the animal to change its course rapidly in pursuit of its insect prey—an idea which is supported by the fact, that in the bats which feed on vegetable substances, or on animals which require less activity of pursuit, this part is either wholly wanting, or is much circumscribed in extent and power.

The four fingers of the anterior extremity being involved in the expansion of the membrane, only the thumb is left free; this is of moderate length, and is furnished with a crooked nail, which is of great use to the animal in climbing and making its way along the ground. The toes of the hind feet are short, and furnished with claws, by which the bats suspend themselves from the trees or walls on which they rest, hanging with the head downwards. They walk with slowness and difficulty when placed on the ground; the wings are folded up; and they rest upon the hind feet, and upon the claw of the thumb, by which they crawl forwards, pushing on first one side and then the other. But they can climb up perpendicular surfaces with considerable agility. The expanded skin of the wings appears to be endowed with a sensibility of a peculiar kind, enabling the animals to perceive their proximity to solid bodies without the assistance of sight. That they have a very acute perception of this kind, was long ago shown by the experiments of Spallanzani, who found that bats deprived of sight, and, as far as possible, of hearing also, were still capable of directing their flight with security and accuracy, finding their way through passages only just large enough to admit them without coming in contact with the sides, and even avoiding numerous small threads which were stretched across the room in various directions—the wings never, even by accident, touching them. It is probably through the vibrations of the air, which will differ according as the wing strikes it in the neighbourhood or the absence of any solid body, that the knowledge of the proximity of such is communicated to the delicate and expanded organ of touch. The use of this curious power to animals intended to execute rapid and varied movements in the dark, and amongst trees, buildings, &c. is sufficiently evident.

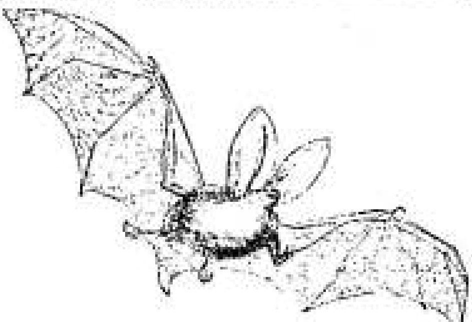
This tendency to a great extension of the skin is manifested in other parts of the body. In many bats, especially of the insectivorous kind, the external ear is enormously developed; being, in the long-eared bat of this country, nearly as long as the body. In the frugivorous bats, it is of ordinary size. The organ of smell, too, in many of the insectivorous bats, is furnished with curious leaf-like appendages, formed of the integument doubled, folded, and cut into the most curious and grotesque forms. The group in which these are most remarkable, is one which avoids the light of day even more than others: the animals composing it exist almost constantly in the darkest recesses of caverns; and it is probable that, by this peculiar conformation, they gain increased power and delicacy of the sense of smell, which in part compensates for the inutility of the organs of vision.

The families composing this order may be arranged under two principal divisions, which are strongly contrasted with each other in regard to the nature of their food, the conformation of their teeth and digestive system, and the peculiarities of structure which are connected with the mode in which food is obtained. One of these groups, which may be regarded as typical of the order, is *insectivorous*; the molar teeth are furnished with pointed tubercles, as in the order Insectivora; and the stomach and digestive system are evidently adapted to animal food. The other group is probably *omnivorous*, like many of the monkeys—feeding chiefly on fruits, but pursuing small birds, or large insects, that may be obtained without much difficulty; their molar teeth have flattened crowns, adapted for bruising and grinding their food; and the complex structure of the stomach and intestinal canal shows its adaptation to a vegetable diet. The proportional length of the intestine, in specimens of these two groups, is a remarkable illustration of this difference of adaptation. In the great bat of this country, belonging to the former group, it is only twice the length of the body; whilst in the frugivorous *pteropus* of the tropics, it is seven times.

The insectivorous group may be distributed into four families:—1. RHINOLOPHINÆ: in these, the nose-leaf is of complicated structure, and is membranaceous; the index or forefinger has but one joint; the wings are large and broad, as in the *horse-shoe* bats of our own country. 2. PHYLLOSTOMINÆ, which have the nasal appendage simple and fleshy, and an index-finger of two joints. 3. VESPERTILIONINÆ, which are destitute of nasal appendages, and have a single joint in the forefinger. 4. NOCTILIONINÆ, almost exclusively confined to tropical countries, also destitute of nasal appendages, but have two joints in the index-finger.

To the second family belongs the celebrated *vampyre*, of the bloodthirsty propensities of which such marvellous stories have been told. The wound inflicted by its teeth is very small; but its tongue is endowed with a peculiar power of suction, by which a considerable amount of blood may perhaps be drawn. There are no well-authenticated accounts of the death of any animal having been occasioned by this creature; and the story of its fanning its victim with its wings to keep him cool, and render his sleep more profound, is probably a fiction.

The family *Vespertilionidæ* includes most of the bats of temperate climates. At least thirteen species exist in this country, the largest of which is the mouse-coloured bat, the expansion of whose wings measures fifteen inches; but this is of rare occurrence. A more common one is the noctule, or great bat, which is but little smaller; this is often met with in considerable numbers, seeking its retreat sometimes in the hollows of trees, at others under the roofs and eaves of houses. Probably the most abundant is the long-eared bat, which is easily distinguished by the character implied in its name. Its ears are folded downwards during



Long-eared Bat.

hybernation or profound sleep. It is easily tamed when in confinement, and may be brought to considerable familiarity, so as to eat from the hand. It has an acute and shrill, but not loud cry.

The frugivorous or omnivorous group contains but one family, the PTEROPINÆ, which is widely diffused throughout warm climates, and contains some of the largest species of the order. It is not improbable that the fabulous harpy may have had its origin in some of these. None of them have the tail much developed, and in many it is entirely absent. The *pteropus Javanicus* is a very characteristic example of this family. It is probably the largest of the bats—its expanded wings measuring five feet across. It is extremely abundant in the lower parts of Java, and uniformly lives in societies. They suspend themselves from trees during the day; and, from their motionless aspect and contracted bodies, they might be mistaken for parts of the tree, or for fruit suspended from its branches. When night comes, they begin to move, and go in search of food to the forests, villages, and plantations, in all of which they do great mischief, attacking indiscriminately almost any kind of fruit, of which they devour a large quantity. In their turn, they are eaten by the human inhabitants of some of the countries where they abound, who consider them as delicacies. The flesh of the common roussette of the Mauritius has been compared to that of the hare and partridge.

The Cheiroptera, inhabiting temperate climates, all remain in a torpid state during the winter. Some of them make their appearance, however, in mild days; but as casual revivals during the season of repose are injurious to them, they usually betake themselves to places of which the temperature is not readily affected by external vicissitudes. The office of this group in the economy of nature, is evidently to assist in restraining the too rapid multiplication of insects, and to keep down the luxuriance of tropical vegetation.

IV.—Insectivora.

The order Insectivora forms a group which has been considered as intermediate between the Cheiroptera and the Carnivora. Like the greater part of the first-named of these orders, the animals composing it are formed to live upon insect food; their molar teeth are beset with pointed conical tubercles, adapted to crush the hard envelopes of their prey; and they are for the most part, like the bats, nocturnal animals—like them, too, passing the winter of temperate climates in a state of torpidity. But they are completely destitute of the wing-like expansions which enable those animals to rise into the air in search of their prey; it is *their* function to seek it upon the ground, or even by burrowing beneath it. Hence, in their general organisation, they more resemble the Carnivora; but they retain the clavicle (collar-bone) of the higher orders, which, in the Carnivora, is reduced to a ligament; and this affords, in the burrowing species, a very important attachment to the powerful muscles by which their anterior members are put in action.

It is remarkable that, as far as yet known, no species of this order exist in South America or Australia. In the former continent, their place seems to be supplied by the Edentata, of which many species are similar in their food and habits; and in New Holland, they are replaced by numerous small Marsupialia, having the same general adaptation of their structure to insect food and to an underground residence.

This order may be divided into four families, which are characterised by their habits, as well as by their external form and internal structure:

1. The TALPIDÆ, of which the common English mole is a very characteristic example. The whole structure of this animal is beautifully adapted to the subterranean life which it leads, and to the mode in which it seeks its food. A very short arm, attached to a large shoulder-blade, supported by a stout clavicle, and provided with enormous muscles, sustains an extremely large hand, the palm of which is always directed either outwards or backwards. The hand comes to a sharp edge below, and though the fingers are scarcely perceptible, the nails which terminate them are long, flat, strong, and sharp. This forms a most admirable spade, by which the earth is at the same time dug away and thrown behind the animal. The sternum (breast-bone) possesses, in common with that of bats and birds, a ridge or keel, for the attachment of the large pectoral muscles which are necessary to endow the anterior member with the required power. To pierce and raise up the ground, the animal employs its pointed head, of which the muzzle is greatly prolonged, and terminated by a little bone which serves as a lever. This prolonged snout is also used as an organ of prehension, for by it the food is seized and conveyed to the mouth. The hinder part of the body is feeble, and the animal advances above ground so awkwardly, as to convey the impression of pain; but when placed in its gallery, or in a tube of the same size, it pushes itself forwards by its hind feet with great activity. The arrangement of the hairs composing the fur is such, that they will lie smooth in any direction; by which provision, the surface is prevented from offering any impediment to the motion of the animal either forwards or backwards.

The mole has been supposed to be deficient in the sense of sight, the eyes being so small, and so hidden behind the hair, that their existence was long denied; it has been ascertained, however, to be tolerably sharp-sighted. (There is a species inhabiting the south of Europe, very closely resembling the common mole, which is certainly blind; the eyelids of which are totally closed.) The sense of smell is extremely acute, and its organ largely developed; it is probably that to this almost entirely the mole is ordinarily indebted for the perception of its food, of its enemies, and of its mate. At the same time, it appears to be assisted by that of hearing, which is certainly acute, although aided by no external ear. The burrows of the mole are of a beautifully complicated construction, and are formed with the utmost art. Its food chiefly consists of earth-worms and the larvæ of beetles. When hungry, however, it will attack mice, lizards, frogs, or small birds, that may fall in its way; and it is said that if two moles are confined together, they will fight until one is vanquished, and that the victor will then devour his fellow. Besides these forms of animal matter, vegetable substances, especially the roots of plants, and the smaller roots of trees, are found in the stomach of the mole; but it may be doubted whether it eats these as food, or whether it does not simply tear them for the purpose of extracting the larvæ and worms, which may be entwined among them.

Much controversy has taken place as to whether moles are on the whole injurious or beneficial to the agriculturist; some parties maintaining that they injure crops of various kinds by the destruction of their roots, and dig up and scatter the plants in ploughing their superficial furrows, besides rendering the ground dry and sterile, by their subterranean roads; whilst others point to their destruction of earth-worms and grubs, and to the lightening of the soil produced by their operations, in proof of their beneficial character. The truth probably lies between the two extremes; the animal being neither prejudicial nor useful to the extent attributed to it by its enemies and friends respectively; but pretty certainly counterbalancing its mischief by the good it effects.

2. The SORICIDÆ, or *Shrews*, in which all the feet are formed for running. These animals are usually small, but are very numerous, and widely diffused. The fur is short, soft, and silky, and the tail long; so that the common shrew bears a strong general resemblance to a mouse, except that the snout is long and slender. The shrews, though they do not actually burrow, retreat during the winter, and for their ordinary repose, into holes; they feed, however, on the surface, or in the water, several of them being partially aquatic, diving with facility after aquatic insects, and remaining without difficulty a long time under water.

3. The ERINACEADÆ, *Urchins* or *Hedgehogs*, remarkable not only for the conversion of the hair into sharp spines, but for the great development of the muscular envelope of the body immediately beneath the skin (especially on the back), which in most other animals is scarcely perceptible. By this they are enabled to roll themselves into a ball, presenting a panoply of defensive weapons to their enemies. In its natural state the hedgehog is nocturnal, remaining coiled up in its retreat by day, and moving about all night in search of food. Its run is quick and shuffling, and as it were by starts. Insects, worms, slugs, and snails, form the usual food of the hedgehog; but it will also devour frogs, toads, mice, and even snakes, and has been known to feed on eggs and vegetable substances. It is easily rendered familiar with man and with other animals. Other species of this family connect it with the previous and succeeding groups, the spines not differing so much in size and strength from hairs, and the power of rolling up the body being absent.

4. The TUPAIDÆ, or *Banxrings*, the last family, is a very remarkable one. It is confined to the Indian Archipelago, and has not been long known to exist. Their teeth chiefly resemble those of the urchins, with a slight tendency towards the lemurs; and, like this last group, their eyes are large and prominent. They are covered with hair, which is soft and glistening, but not fine in texture, and have a long bushy tail. Contrary to the habits of other Insectivora, they ascend trees with the agility of a squirrel; from which animal, however, their pointed muzzle renders them easily distinguishable, even at a distance. They are readily tamed, running freely through the house, and coming of themselves at every meal for fruit or milk.

V.—Carnivora.

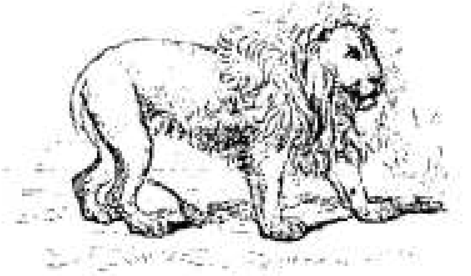
The animals composing the order Carnivora are, like the four previous orders, separated from the other Mammalia, possessing distinct fingers, by the presence of three kinds of teeth; and from these orders they are distinguished by characters which point them out as especially formed for the pursuit and destruction of large animals. They possess in the upper and lower jaw six incisor teeth; a large, strong, and pointed canine tooth on each side; and molar teeth, which are evidently formed for cutting and tearing rather than for bruising or grinding. The form of these teeth varies, however, in the different genera, in accordance with their several habits. These molars consist of three kinds: the anterior, immediately following the canines, which are always more or less pointed, and are termed *false molars*; the next class, formed especially for cutting the flesh upon which the animals feed, are termed *carnivorous teeth*; and the posterior are tuberculated, with flattened summits.

The proportion which these different classes bear to each other in number and development, accords with the degree of the carnivorous propensity of the animal, and furnishes important characters in the subdivision of the order. The more the surface of the molar teeth is raised into points and edges, and the more the action of the jaws is restricted to the scissors-like movement by which these edges are made to meet and pass each other, the more purely carnivorous is the regimen of the animal: this is well seen in the Cat tribe. On the other hand, the more the molar surfaces are flattened, and the greater the lateral grinding motion of which the jaws are susceptible, the greater is the probable admixture of vegetable food: this is seen in the bears. The general structure of the body, and especially that of the extremities, is modified in a corresponding manner, in accordance with the habits and propensities of the animal. In all, the toes are furnished with claws, which are peculiarly sharp in the cats, and are in them kept ready for use within a sheath, from which they can be projected at the will of the animal. The stomach of the Carnivora is very simple in its form, and the intestines are short, in accordance with the easily-digested character of their food.

The whole bony and muscular system exhibits a similar modification. Thus, whilst the powerful, yet active and flexible, movements of the purely carnivorous animals are adapted only to the pursuit and destruction of living prey, the more sluggish habits of most of the Bear tribe, their peculiar mode of progression, and the modified structure of the skull, teeth, and limbs, are all equally applicable to the mixed nature of their food. The difference in the conformation of the extremities, and in the mode of using them, is very striking in these two antagonised groups. In the former, the ends of the toes only touch the ground, the heel being considerably raised into the air; in this way the limbs can be used to much greater advantage in running and springing: the animals possessing this conformation are termed *digitigrade* Carnivora. In the latter, the whole foot rests on the ground—a structure more favourable to the maintenance of a firm position, but preventing great activity of progression: these are called *plantigrade* Carnivora. There is a third very remarkable variety of conformation in the extremities of this order; and this is exhibited in the Seals. Here the anterior as well as the posterior feet are formed for swimming, being spread into fin-like paddles; and the whole arrangement of their organs, as well as the general configuration of their bodies, admirably adapted to the pursuit and capture of their scaly prey.

The Carnivora may be subdivided into five families, each containing a well-known form. 1. FELIDÆ, or *Cat* tribe. In these the destructive power is most highly developed. They are characterised by their short powerful jaws, their retractile claws, and the peculiar adaptation of their teeth for cutting. They have but one small flattened molar tooth above, and no corresponding one below. 2. CANIDÆ, or *Dog* tribe. These, like the cats, are digitigrade; but their claws are not retractile; and they have two flat tuberculated molars behind the great flesh-cutter. 3. MUSTELIDÆ, or *Weasel* tribe. These are mostly semi-plantigrade, a portion of the sole touching the ground. They are distinguished by their long slender bodies, and by the presence of only one tuberculated molar. 4. URSIDÆ, or *Bear* tribe. These are the only true plantigrade Carnivora. Most of them possess several tuberculous teeth. 5. PHOCIDÆ, or *Seal* tribe. These are at once distinguished by the adaptation of their form and structure to a residence in water; and of their teeth for seizing and holding the slippery bodies of fish, and crushing them before they are swallowed.

1. The *Cat* tribe includes a large number of animals very closely resembling each other in structure and aspect—so closely, indeed, that many of the species can only be distinguished by their size, and by the markings of their skin. They all agree, too, in the mode of catching their prey, which is, to steal upon it unawares, and seize it with a sudden spring, in which they expend their energy, often slinking off when once baffled. It is very difficult to subdivide the family, on account of the strong general resemblance of its members. Most of them are sufficiently well known to render any peculiar description of them unnecessary. It may, however, be remarked, that some species are found in almost all tropical and temperate countries, and that those of different parts of the globe *represent* each other in a remarkable manner. Thus the *lion* and *tiger* are inhabitants of Africa and tropical Asia; in America they are replaced by the *puma* and *jaguar*, which are confined to that continent. In the same manner, we find the *panther* and *leopard* spread over tropical Asia and Africa; the ounce inhabiting the Asiatic mountains; the *caracal* in Turkey and Persia; and the *lynx* of Northern Europe. These are represented by the *ocelot* in South America, the *lynx* of Canada (differing from the European species), and other less known species. The Felidæ, like the noble falcons, will only eat the flesh of animals they have themselves killed, except when in a state of domestication or confinement, or when compelled by hunger.



Lion.

2. The family of CANIDÆ includes a much larger number of different forms, some of which approximate to the Cat tribe, and others to the weasels and bears. This tendency to variation from a typical form is most remarkably shown in the races of the common dog, which are believed to have all had the same origin, although the commencement of most of them is entirely unknown. The animals of this family agree in their greater or less adaptation to a mixed diet. Although animal flesh naturally constitutes the principal food of all, they do not attack living animals with a degree of boldness proportional to their strength, and many of them feed upon carrion, sometimes even when it is much putrefied. The *wolves*, *foxes*, and *jackals*, are the animals which most nearly approach the dog; and with the first of these it is regarded by many naturalists as being really identical.

The *Hyænas* constitute a group remarkably distinct from the true Canidæ, and yet bearing enough of their characters to require to be associated with them. They are more purely carnivorous than the dog tribe, and approach in the deficiency of tuberculated molars to the cats. But they differ from these not only in general aspect, which is much more nearly allied to that of the dog, but also in the absence of the retractile power of the claws, and in their propensity to feed on carrion. The teeth are peculiarly adapted for crushing bones, and their jaws are shorter than those of the dog, but longer than those of the Felidæ. In many other points of structure, the hyænas are intermediate between the two groups. They are peculiarly ferocious animals, combining the persevering *doggedness* of the one tribe with the furious bloodthirstiness of the other. Their habits are nocturnal—more so than those of most other Carnivora. Hyænas are now chiefly confined to Africa and the south of Asia; but there is no doubt, from the abundant remains of them which are preserved to us, that they must have formerly lived in large numbers in this country, and in other parts of Europe. With the Hyænas may be associated the *civets*; and the *ichneumon* of Egypt, which restrains the multiplication of crocodiles by feeding on their eggs.

3. The MUSTELIDÆ are the most *bloodthirsty* of all the Carnivora; but they are not so much adapted for devouring *flesh* as are the Felidæ. These animals, on account of the length of the body and the shortness of the limbs, which permit them to pass through very small openings, are called *vermiform*. All the members of this family are semi-plantigrade. The *weasel* of this country is a very characteristic example of the family; it is one of the most sanguinary of any, but confines itself chiefly to small animals, destroying large numbers of mice, rats, moles, &c. The *ferret*, which is an allied species, is bolder, having been known to attack man; and the *polecat* is a great enemy to the farmyard, game-preserve, and warren. All these animals have a strongly and disagreeably odorous exudation from a pouch under the tail; but it is most disgusting in the last. The *Otters* constitute an aquatic form of this family, having the same general aspect and dentition with the weasels, but being readily distinguished from all other genera of the family by their webbed toes and horizontally flattened tail. They subsist on fish.

4. The true plantigrade Carnivora, constituting the family of URSIDÆ, participate in the comparative slow motion and nocturnal life of the Insectivora; and like them, too, the species which inhabit cold countries pass the winter in a dormant state. In the *Bears*, the cartilage of the nose is elongated and movable, somewhat resembling that of the Shrews. These animals possess a great facility, from the structure of the sole, of rearing themselves up on their hind feet; and this may be especially noticed in such as are, like the bears, fruit-eaters, becoming carnivorous only from necessity; they are thus enabled to climb trees in search of food. The bears are the largest of the family; and some species of them are pretty widely diffused over the globe. The *racoons*, which resemble bears in miniature, with the exception of the greater length of the tail, are confined to the new world.

The *Badgers*, *Taxels* or Badgers of America, and the *Wolverines*, form a tribe connecting the Bears with the Mustelidæ. The *badger*, for example, is only semi-plantigrade, and has a dentition very like that of the weasels and otters, but adapted for a less carnivorous regimen. But it has the tardy gait and nocturnal habits of the other plantigrades; it does not, however, become torpid in winter. All these animals, like the weasel tribe, have the power of emitting a fetid odour at will.

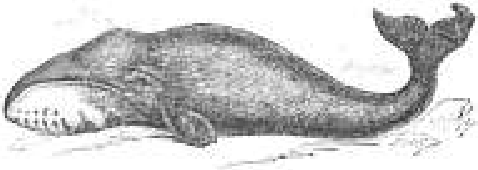
5. The last family, that of PHOCIDÆ, is sufficiently distinguished from all the rest by the peculiar adaptation of the animals composing it to a marine residence. Their feet are so short, and so enveloped in the skin, that they are of little use in progression on land. In fact, the seal employs them only when clambering, wriggling itself forwards along a plane surface by the action of the abdominal muscles. The intervals between the toes are occupied by membranes, so as to convert the feet into oars. The body is lengthened, and the spine very flexible, as in the Cetacea and Fishes; and the animals are covered with a short close fur, sitting flat upon the skin. All these adaptations combine to render them able swimmers; and they pass the greatest part of their time in the water, which they only quit to bask in the sunshine and to suckle their young.

Of the two genera, the *Seal* and the *Morse*, which this family contains, the former presents the least departure from the general type of the order, being adapted, as to its teeth and digestive organs, for animal diet; the latter group is chiefly herbivorous.

VI.—CETACEA.

In the order Cetacea, or *Whale* tribe, the adaptation of the mammiferous structure to the life of a fish is remarkably displayed. The whole body is formed for an exclusive residence in the water. The posterior extremities are no longer present, as in the seal, to assist in progression on land; nor are the toes of the anterior furnished with claws. The trunk is prolonged into a thick tail, which terminates in a horizontal cartilaginous fin, by the vertical movement of which the propulsion of the body is effected. The head is very large, and is connected with the body (as in fishes) by so short and thick a neck, that no diminution of its circumference is perceptible; and the cervical vertebræ, which are still (as in all Mammalia) seven in number, are very thin, and partly united together. The bones of the arm and fore-arm are very short; and those of the hand are flattened, and enveloped in a tendinous membrane, which reduces them to the condition of fins. Hence their whole aspect is that of fishes, except that they are not covered with scales, and that they have the tail-fin expanded in the contrary direction. The object of this last provision is to enable them more readily to come to the surface to breathe, which they are obliged frequently to do. The largest species can remain, however, for an hour under water. Their blood, like that of other Mammalia, is warm; and to prevent the animal temperature from being rapidly lowered by the conducting power of the water, they are furnished with a thick coating of fat over the whole body. There are never any external ears, nor hairs upon the body. In these general characters, some other whale-like animals, now separated from the true Cetacea, agree; but they differ in being adapted for vegetable food, whilst the true whales are all animal-feeders, and are therefore properly associated with the Carnivora, to which they make a near approach through the seal. It is evident that the want of claws should not exclude them from this division of the Mammalia, since these are rendered useless by the adaptation of the animal to an exclusively aquatic residence. Some of them, which feed upon large marine animals, seize their prey with their jaws; whilst others, which derive their support from the smaller kinds, engulf them, with a large quantity of water, in their capacious mouths.

The true Cetacea are further distinguished from those herbivorous forms which are now associated with the Pachydermata, by the remarkable conformation from which they receive the name of *Blowers*. As with their prey they necessarily take in a great volume of water, a means of getting rid of this is required, and it is accordingly transmitted through the nostrils, and expelled, by a strong muscular action, through a narrow aperture pierced at the summit of the head. It is thus that these animals produce the jets by which they are observed at a great distance. Their nostrils, being continually



Whale.

bathed in water, are not adapted to a delicate perception of odours; and their organs of hearing, being deficient in the external ear, and otherwise formed on a lower type, are also probably incapable of very acute perception of sound. But what is deficient in these respects seems to be compensated by a very high degree of sensibility of the general surface; and there is reason to believe that, by this diffused sense, whales are enabled to take cognisance of what passes in the water at a considerable distance, through the medium of the vibrations excited in the fluid.

In subdividing this order, the *dentition* does not afford much assistance, for the teeth are frequently absent altogether; and among the species which possess them, they often exhibit great differences, when the animals are closely allied. Where they exist, they are mostly small, numerous, and of a conical form, similar to each other. These animals do not chew their food, but swallow it whole. The stomach is usually of a rather complex form. The order may be divided into two families, according to the relative size of the head and body. In the first, DELPHINIDÆ, or the *Dolphin* tribe, the head is not out of the usual proportion; in the second, the BALÆNIDÆ, or *Whale* tribe, it is immoderately large.

1. The DELPHINIDÆ have teeth throughout both jaws, all simple, and nearly always conical. They are the most carnivorous, and, in proportion to their size, the most cruel of their order. The common *dolphin* has its snout prolonged into a kind of beak. It is extremely agile in its movements; and a number are often seen sporting together on the surface of the water. Nearly allied to the dolphin is the *porpoise*, which has a short muzzle. This is one of the smallest of the Cetacea, not exceeding four or five feet in length, and is very common in various parts of the Atlantic, assembling in vast herds. Allied to the porpoise is the *grampus*, which has large conical teeth, and is the most powerful of this family, attaining the length of from twenty to twenty-five feet. It is a cruel enemy to the whale, which it attacks in troops. Other species of this family are known on our coasts by the names of *white whale*, *bottle-nose*, *narwhal*, or *sea-unicorn*, &c. This last animal is remarkable for the enormous development of a single tooth or tusk, commonly reputed to be a horn, whence the name commonly given to the species. In the general form of the head and body it agrees closely with the porpoises; but it possesses no other teeth than this tusk, which projects forwards apparently from the centre of the upper jaw, to the length of ten feet. The animal really possesses, however, the germs of two tusks, of which only one is generally developed. That, on the left side usually attains its full growth, whilst the other remains permanently concealed within its socket.

2. The remaining Cetacea, constituting the family BALÆNIDÆ, have the head so very large, as to constitute one-third, or even one-half, of the entire length; but neither the cranium nor the brain participate in this disproportion, which is entirely due to an enormous development of the bones of the face. This family contains several remarkable and important animals, amongst which the following may be noticed:—The *catodon*, or spermaceti whale, receives its technical name from possessing teeth in the lower jaw only;

these are of considerable size, and lock into cavities in the upper jaw when the mouth is closed. The superior portion of the enormous head consists almost entirely of large cavities, separated and covered by cartilages, and filled with an oil that concretes in cooling, and is known by the name of spermaceti. This is commonly, but erroneously, reputed to be the brain of the animal; the cavities which contain it, however, are very distinct from the true cranial cavity, which is rather small, and lies at the posterior portion of the head. Cavities containing spermaceti are found in various parts of the body, even ramifying through the external fat or blubber, and these communicate with those in the head. This whale is extensively distributed through various seas, but chiefly abounds towards the antarctic region. It sometimes attains the length of seventy feet.

The *balæna*, or Greenland whale, equals the catodon in size and in the proportional length of the head, which is not, however, so much enlarged in front. Instead of teeth, the mouth is provided with a number of vertical plates, terminating in fringes, which are composed of a sort of fibrous horn, and may be regarded as a kind of prolongation of the gum. These fringed plates, commonly known as whalebone, serve to retain, by straining from the water, the minute animals on which these enormous beings subsist. Their food consists partly of fishes, but chiefly of soft mollusca, acalephæ, &c. The blubber is of immense thickness, and furnishes a large quantity of oil—a hundred and twenty tons being sometimes obtained from a single individual. The whalebone also is an important object of pursuit. This animal was formerly not very uncommon in our seas, but has now retired to the far north, where its number, in consequence of the attacks of man, is constantly diminishing. The *rorqual*, an allied species, attains to still greater size, having been seen of the length of a hundred feet.

VII.—Rodentia.

The order Rodentia bears a striking contrast to the last in the size as well as habits of the animals composing it, which are for the most part very diminutive; but they are very widely diffused, and are often extremely numerous. One species or another is found in every part of the world except New Holland, and sometimes their numbers are so great, as to render them very destructive to vegetation. Some of the order are the most gentle of the Mammalia, whilst others are so ferocious, that, if their size and strength were proportional, they would be extremely formidable. This order contains also some of the species most remarkable for their instincts, as the beaver. Generally speaking, the Rodentia are the most prolific of the Mammalia, the period during which they go with young being shorter, and their litters more numerous.

But though the animals differ much from one another in size and external appearance, the order is a very natural one; all the species contained in it being remarkable for the peculiar adaptation of their teeth to gnawing hard vegetable substances, and of the stomach and intestinal canal to the digestion of them. The mouth of a rodent animal is at once recognised by the two long teeth which project forwards from each jaw, working against one another, and separated from the molars by a wide interval. These are usually regarded as incisors; but they are really the canines, the direction of which has changed in consequence of the absence of the incisors. In the hare, the small true incisor teeth may be seen behind them. These gnawing teeth have enamel in front only; so that, their posterior edges being worn away faster than the anterior, they constantly retain a sloping or chisel-like edge. They continue to grow at the root as fast as they wear away at their points; so that, if either be lost or broken, its antagonist in the other jaw, having nothing to wear it down, becomes developed to an enormous extent. The mode in which the lower jaw is articulated to the skull, allows of no horizontal motion except backwards and forwards; and the flat-crowned molar teeth have enamelled ridges arranged transversely, so as to be in opposition to the horizontal movement of the jaw, and the better to assist in trituration. In a few of the genera the structure of the molars more approaches that of the Carnivora.

The form of the body of the Rodentia is generally such, that the hinder parts exceed those of the front, so that they leap rather than run. In some of them this disproportion is as excessive as in the kangaroos. The inferiority of these animals to those of the orders already considered is perceptible in many details of their organisation; the brain is less complex in structure; the fore-arm loses the power of rotation, its two bones being often united; and the eyes are directed sideways, showing their tendency to retreat from their enemies rather than to pursue them. In some, the clavicles (collar-bones) are nearly or entirely absent; the anterior extremity being then usually deficient in strength.

The Rodentia may be divided into seven families, the technical distinctions between which are founded upon minute particulars in the structure of the cranium and of the lower jaw. 1. SCIURIDÆ, or *Squirrel* tribe, comprehending a large number of light and agile animals, chiefly distinguished by their long bushy tails, and by their adaptation to a residence in trees, and to live upon their produce. 2. MURIDÆ, or *Rat* tribe. 3. CASTORIDÆ, or *Beaver* tribe, including the voles, lemmings, &c. 4. HYSTRICIDÆ, or *Porcupine* tribe. 5. CAVIDÆ, or *Guinea-pig* tribe. 6. CHINCHILLIDÆ, the *Chinchilla* tribe. 7. LEPORIDÆ, the *Hare* tribe. The rodents of the fourth, fifth, and seventh families are destitute of the clavicle, which those of the three first and the sixth possess.

1. Of the family SCIURIDÆ, the common *squirrel* of this country may be taken as a characteristic illustration; and its form and habits are sufficiently well known to render particular description unnecessary. It lives entirely upon vegetable food, in search of which it leaps with great agility from branch to branch. In taking these leaps, when it is once thrown off by an effort of its long and powerful hind-legs, it is in a measure sustained by the horizontal spreading of its limbs and bushy tail, the hairs of which are directed laterally, so as to resemble a feather. In the *pteromys*, or flying squirrel, this sustaining power is much increased by an extension of the skin of the flank between the fore and hind legs, which serves as a parachute. The *marmots* are allied to the squirrels in the number and structure of their teeth, which are partly adapted, however, to insect food. In other respects they are almost the reverse of squirrels, being heavy, with short limbs and a moderate-sized tail, and living on the ground, or even in burrows beneath it. More allied to the squirrels in the size of their tail and active habits, but differing in their dentition, are the *dormice*, the structure of whose teeth shows them to approximate with the next family. They chiefly subsist on vegetable food; but some species of them attack small birds. All the members of this family pass the winter in cold climates in a state of lethargy, which is most profound in the marmots and dormice.

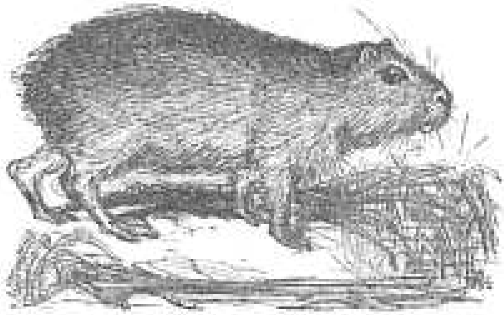
2. The family of MURIDÆ contains the smallest, and at the same time the most numerous, of the Mammalia. No undomesticated animals are better known than mice and rats. Of the common mouse, Cuvier thus concisely speaks—'known in all times and in all places.' The house *rats*, abundant in this country, are almost as universally diffused; but the time of their introduction into many parts of the globe can be distinctly traced. The *brown* (commonly, but erroneously, called the Norway) *rat* made its first appearance in Paris about the middle of the eighteenth century, and in England not many years earlier; it is believed to have originally come from Persia. The brown rat is now speedily replacing the *black* or *old English rat*, which is becoming rather a rare animal in this country, and which, from its smaller size, is an unequal match for the usurper. There is reason to believe, however, that even this is

not a native of England, and that it was introduced from France about the middle of the sixteenth century. From Europe these two rats (which infest vessels equally with houses) have been sent to America, the islands of the Pacific, and many other places, in some of which they have now become a serious inconvenience. The only strictly indigenous British species of Muridæ are the *harvest-mouse* and *long-tailed field-mouse*, both of them very beautiful little animals, and very interesting to the naturalist, although highly injurious to the agriculturist. A great number of species exist in various parts of the world, which do not differ widely from each other.

3. Of the CASTORIDÆ, the *beaver* is probably the type; but this family contains many genera having a close resemblance to the rats. The beaver is distinguished from all other rodents by its horizontally-flattened tail, which is of a nearly oval form, and covered with scales. The hind feet are webbed, by means of which and the tail these animals obtain considerable swimming powers. They chiefly subsist on bark and other hard substances, and can fell trees of considerable size, of which they use the bark and twigs as food, employing the stems in the construction of their remarkable habitations. The flattened tail is employed by them as a kind of trowel, with which they plaster the walls of their houses. The beavers are connected with the previous family by the *Arvicolæ*, or *Voles*, many of which bear a strong general resemblance to rats, but differ in their dentition. Most of them are in some degree aquatic in their habits; such is the common *water-rat* of this country, the food of which, like that of the beaver, is (contrary to the general opinion) almost exclusively herbivorous. To this group also belong the *lemmings*, or Scandinavian rats, which are remarkable for their occasional migrations in immense bodies. They are stated to advance in a straight line, regardless of rivers and mountains; and while no insurmountable obstacle impedes their progress, they devastate the country through which they pass. Most of this family lay up a winter store of food, upon which they subsist in the intervals of sleep, and do not go abroad during that season.

4. The animals which are characteristic forms of the family HYSTRICIDÆ are recognised at the first glance by the stiff and pointed quills with which they are armed, somewhat similar to those of the hedgehogs, but usually much larger. Besides the *Porcupines* and their allies, however, to which this description more particularly applies, this family contains several forms which connect it with the two preceding. The name porcupine is corrupted from the French *porc-epic*, a term expressive of the pig-like aspect and grunting voice of these animals, as well as of their spiny covering. They live in burrows, and have very much the habits of rabbits. The best-known species inhabits the south of Italy, Sicily, and Spain. It is nearly the largest of the Rodentia, measuring almost three feet in length. There is an American genus nearly allied to the true porcupine, which has a long prehensile tail, like that of the opossums, and lives in trees.

5. The next family, that of CAVIDÆ, contains the largest-sized animals of this order, although, when compared with ordinary quadrupeds, they would be termed small. They are naturally restricted to tropical America, where they replace the hares and rabbits of cold climates. But the *guinea-pig* is now extremely common in Europe, and is quite domesticated. The *capybara* is an inhabitant of the sides of nearly all the great rivers of South America, and is the largest known animal of the order, being about three feet in length, and of the size of the Siamese pig. It has a large, thick, and blunt muzzle, is destitute even of the rudiments of a tail, and is scantily covered with bristly hairs. Its semi-aquatic habits are shown by the webbing of the feet. By this structure it can both swim and dive with much activity. Upon land it makes but little progress, running badly, and generally diving in the water to avoid danger. It lives in small societies, and seems to be a nocturnal feeder. Another of the Cavidæ is the *aguti*, which is an inhabitant of the Antilles and tropical America. It is about the same size as the European hare; but in regard to its food, and its manner of feeding, it rather resembles the



Capybara.

squirrel, preferring nuts to herbage, and sitting upon its haunches whilst eating.

6. The animals of the small family CHINCHILLIDÆ were, until recently, known only by their skins, which constitute an important article of commerce. In their general organisation they seem intermediate between the cavies and rabbits, but differ from both of them in possessing clavicles. They are all natives of South America, chiefly inhabiting the range of the Andes, and they live socially, in extensive burrows.

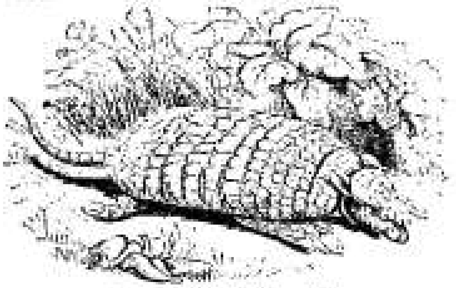
7. The LEPORIDÆ constitute the last family of the Rodentia, and are distinguished from the rest by the presence of two small incisors behind the rodent teeth. The form and habits of the typical genus, *Lepus*, are sufficiently well known in the *hare* and *rabbit* of this country. A large number of species exist in the different parts of the northern hemisphere, and some are inhabitants of the arctic regions. There is one species of this country, in which the brown fur, that forms its summer coat, changes to white at the approach of winter. The hare is a ruminating animal, though without the peculiarly complex stomach of the true Ruminantia.

VIII.—Edentata.

The animals composing the order Edentata cannot be described by any general positive characters which separate them from other groups; for there is a considerable dissimilarity in the entire structure and habits of the different species. The chief point of agreement amongst them is a negative one—the absence of incisor teeth, and the termination of the extremities in long claws. These claws are usually four in number, and partially embrace the extremities of the bones from which they are prolonged, so that each forms a kind of pointed hoof; and we have thus an approximation towards the unguiculated division of the Mammalia. The order may be separated into two distinct groups: one consisting of the EDENTATA-PROPER, and containing the Ant-eaters, Armadillos, &c. all of which are insectivorous; the other, denominated TARDIGRADA, from the slow movement of the animals composing it, and containing the Sloths.

1. The true EDENTATA are distinguished, like other insectivorous Mammalia, by their pointed muzzle. This is particularly remarkable in the *Ant-eaters*, which are peculiar to the warm and temperate regions of South America. They are destitute of any teeth; but possess a very long slender tongue, which they insinuate into ant-hills and the nests of the termites (or white ants), whence these insects are withdrawn by being entangled in the viscid saliva that covers it. Their fore-nails, strong and trenchant, enable them to tear open these nests, and also furnish them with an effective means of defence.

Most of the other true Edentata are burrowing animals, and are covered with a dense armour, composed of hard scales arranged in a *tesselated* manner, or fitted together like stones in a pavement. Between the different bands of these there are narrow rings of membrane, which allow the body to bend. They have claws adapted for digging, seven or eight cylindrical molars on each side, and a tongue but little extensible. Of these animals, the *Armadillos* are the chief, and are the forms best known. They subsist partly on vegetables, and partly on insects and carcasses. Some of them appear to prefer putrefying animal matter; and many are nocturnal feeders.



Peyou, or Six-banded Armadillo.

2. The animals belonging to the family TARDIGRADA are at once known from the EDENTATA-PROPER by the peculiar shortness of the muzzle. The name of the family is derived from that commonly applied to the animals composing it. In the *Sloths*, according to Cuvier, 'nature seems to have amused herself with producing something imperfect and grotesque.' And if we consider the peculiarities of their organisation in reference to the ordinary habits of mammiferous animals, this appears to be true. Both the fore and hind legs, by their form and proportions, and the manner in which they are joined to the body, are quite incapacitated from acting in a perpendicular direction, and of supporting the body from below; so that when the animal is placed on the floor, his belly touches the ground. Moreover, he has no soles to his feet, and his claws are very sharp, long, and curved backwards; so that he has no firm support, and can only move forwards by laying hold of some fixed object, and dragging himself on by his hooked claws. But when placed on a branch, his aspect is altogether different. In the wild state, the sloth passes his whole life on trees, and never leaves them but through force or accident, or to pass from one to the other, which, in the densely-tangled forests of South America, where alone it exists, is not frequently necessary. But though appointed to spend its whole life in trees, it is not adapted to live on the branches, like the squirrel or monkey, but *under* them. It moves suspended from them; it eats suspended from them; it sleeps suspended from them. And when its structure is considered in its adaptation to this extraordinary position, it is seen to be most admirably devised to meet the wants of the animal. The muscular system seems capable of prolonged action without effort; and this may perhaps be aided by a peculiar disposition of the arteries, such as is possessed by the lori. The sloth usually remains upon a tree until it has stripped it of every leaf, and then it proceeds to another. It has been observed that, in the more open places, where the trees are less contiguous, the sloths take advantage of windy weather to effect their transits, when the boughs are blown together and commingled. The peculiar conformation of these animals ought, therefore, no more to excite our pity and compassion, than the circumstance of fishes being destitute of legs. The perennial foliage of the tropical forest supplies them with food, and their elevated habitation removes them out of the reach of the carnivorous animals.

There have been found in South America—the country to which the existing Edentata are almost confined—remains of some enormous recently-extinct animals, belonging evidently to the same group. Of one of these, the *megatherium*, nearly the whole skeleton has now been studied, by comparing different imperfect specimens; and there can be little doubt that it belonged to a gigantic animal intermediate between the sloths and ant-eaters. Its haunches must have been more than five feet wide; and its body fourteen feet long and eight high. Its feet were a yard long, and terminated by gigantic claws. Its whole structure seems to have been adapted to digging the earth in search of the succulent roots which probably constituted great part of its food. Another extinct animal of the same description is known by little else than its claws, and fragments of bones and teeth. From the form of the claw, the *megalonyx* (as it has been named) was at first supposed to be a carnivorous animal; but Cuvier satisfactorily proved it to belong to the Edentata. It seems nearly allied to the megatherium. Remains of tesselated bony armour have also been found, which indicate the former existence of a large animal allied to the Armadillos, to which the name *glyptodon* has been given; and other remains of gigantic ant-eaters have since been discovered in the same locality.

The Edentata terminate the series of the *unguiculated* or *clawed* true Mammalia; and, as has been just seen, there are some among them with the claws so large, and so enveloping the ends of the toes, and these reduced to so small a number, as to approximate to the nature of hoofs. Nevertheless, they have still the faculty of bending their toes round various objects, and of grasping with greater or less force. The entire absence of this faculty characterises the *hoofed* animals. They use their feet only as supports, and the fore-arm has not the power of rotation, its two bones being frequently consolidated into one, or one of them greatly enlarged at the expense of the other, like those of the leg of man and of most Vertebrata. The hoofed animals in no instance possess clavicles, and they are entirely vegetable feeders. Their forms and mode of life present, therefore, much less variety than is found in the unguiculated animals, and they can hardly be divided into more than two orders—those which ruminate, and those which do not. The former constitute a very natural and easily-circumscribed group, the animals which compose it bearing a strong general resemblance to each other, and being easily distinguished from other groups; the latter contains a number of different forms, the connection of which with one another, by any very important peculiarities common to all, is not very obvious. On account of the general thickness of their skins, they are called PACHYDERMATA.

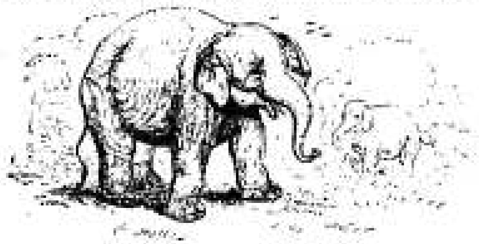
IX.—Pachydermata.

This order, consisting of hoofed animals which do not ruminate, may be divided into three groups, each of which shows a certain degree of resemblance to some other order.

1. The first group, PROBOSCIDEA, contains only one living genus, the *elephant*, to which the *mammoth*, which has become extinct within a comparatively recent period, is allied. [See GEOLOGY.] Another extinct animal of this group is the *mastodon*, which, in the conformation of its teeth, appears to have some affinity with the hippopotamus. All these animals agreed in possessing a pair of enormous tusks or front teeth, and a very elongated nose or proboscis; and it is probable that this last organ was formed, as in the elephant, to answer the purposes of a hand, laying hold of large objects by coiling itself round them, and of small by means of the finger-like organ at its extremity. The magnitude of the sockets necessary to hold the tusks, renders the upper jaw so high, that the nostrils, which are prolonged through the trunk, are placed in the skeleton near the top of the face. By means of its trunk, the elephant not only lays hold of its food, but sucks up its drink, which it makes to fill its capacious nostrils, and then discharges,

by bending its trunk, into its mouth. By this admirable organ, the shortness of the neck, rendered necessary by the weight of the head, is fully compensated. The cavity for the brain by no means corresponds with the external form of the skull; for in order, as it would seem, to give a larger surface for the attachment of the muscles of the trunk, the outer layer of bone is widely separated from the inner, and between the two are a number of large bony cells.

In none of the Proboscidea has the lower jaw of the adult any front teeth. The arrangement of the grinders differs in the various species; but in all they are composed of alternating plates of hard *enamel* and softer *bony* matter, cemented together by a third substance, which is termed the *cortical*. These grinders are in constant progress of renewal; but they succeed each other, not by rising from below upwards, as in man, but by being pushed forwards from behind, in proportion as the tooth before each is worn away. There is never more than one *perfect* molar on each side; but in proportion to the age of the animal, there may be two, three, four, or more, the front ones being the worn-down remains of those at first formed. It is stated that the molars are thus renewed eight times. The tusks, however, are only changed once; but, like the cutting teeth of the Rodents, they are constantly being renewed at the roots. Two species of elephants exist at the pre-



Elephant.

sent day, both of which inhabit tropical climates, one in Asia, the other in Africa. Their food is entirely vegetable; and in their undomesticated state, it consists chiefly of the leaves and young branches of trees, and of the long herbage of the ground, both of which it gathers with its trunk. The tusks serve not only as weapons of offence and defence, but to root up small trees, and tear down cross branches, either to obtain their leaves, or to make a passage for the bulky body of the animal through the tangled forest.

2. Of the true Pachydermata, the first family is that of SUIDÆ, the *Pig* kind. It is characterised by the peculiar thickness of the skin, and by the presence of four toes on each foot. They have three sorts of teeth in each jaw; the canines are usually long, and project forwards as tusks; the anterior molars are more or less narrow and conical; whilst the posterior are tuberculated. The food is principally vegetable, but admits of considerable variation. The domesticated pig is well known to be quite an omnivorous animal. In the true pigs, the foot has two toes furnished with large hoofs, and two much shorter ones that scarcely touch the ground. The *wild boar*, which abounds in some parts of the continent of Europe, is well known to be a very ferocious animal; and the domesticated race which is derived from it often exhibits indications of the same character. One of the most curious animals of this tribe is the *babyroussa*, a native of the Indian Archipelago; the upper canines of which are very long, and grow spirally upwards and backwards. These serve as defensive weapons of a very powerful description, inflicting, it is said, severe lacerations by an upward stroke of the head.

With the family of Suidæ is probably to be placed the *hippopotamus*, or river-horse, of which only one species is known, confined to the rivers of middle and south Africa. But for its short, thick, and very blunt muzzle, it might be compared to a gigantic pig. The body is extremely massive, and the legs so short, that the belly almost touches the ground; and it is destitute of any covering but a few weak and scattered bristles. The canine teeth are long; the upper ones straight, and the lower curved backwards, so that they rub against each other. Although ferocious, or rather courageous, when attacked, these unwieldy inhabitants of the waters are in their nature shy and retiring, and feed entirely on roots and other vegetables, seeming to prefer those which are partially decomposed by the action of the water.

3. The second family of true Pachydermata, to which the name of TAPIRIDÆ, or the *Tapir* tribe, may be given, resembles the first in the thickness of its skin, but differs in the arrangement of the toes, of which there are only three on each hind foot, and sometimes also in front, without any central cleft. There is considerable variation in regard to the teeth; but the whole family is exclusively herbivorous. No members of it exist in Europe at the present time; but fossil remains of very large species are abundant in some places. The *tapir* of America is about the size of a small ass, with a brown and almost naked skin, a short tail, and fleshy neck that forms a crest at the nape. It is common in humid places and along the rivers, and its flesh is eaten. The nose assumes the form of a short fleshy trunk—the rudiment, as it were, of that of the elephant. Other species have been recently discovered of a larger size; one of which has the bones of the nose still more elongated, approaching a very remarkable fossil genus, the *palæotherium*. This seems to have been an animal nearly allied to the tapirs. Remains of several species, varying in size from a rhinoceros to a small sheep, have been found in the gypsum quarries of Paris, and other places. [SEE GEOLOGY.]

To this family belongs the *rhinoceros*, which is remarkable for its large size, and for the kind of horn, composed of a solid fibrous substance, resembling agglutinated hairs, which is supported on an arch formed by the nasal bones. Several species exist in different parts of the tropical portion of the old world. They are naturally stupid and ferocious, frequenting marshy places, and subsisting on herbage and the branches of trees. In some species a second horn exists behind the first. The upper lip is generally elongated, and has some power of prehension. Rhinoceros' bones have been disinterred in many parts of Europe.

4. The third group of Pachydermata, the SOLIDUNGULA, contains only one family—that of the EQUIDÆ, or *Horse* tribe. Though there is only one apparent toe and single hoof to each foot, there are appendages beneath the skin which represent two lateral toes. The well-known animals of this tribe—the *horse*, *ass*, *zebra*, *quagga*, *onager*, and *dziggetai*—are commonly regarded as forming one genus. There are six incisors to each jaw, which, during youth, have their crowns furrowed by a groove, and six molars on each side, above and below, with square crowns, marked, by plates of enamel which penetrate them, with four crescents. The males have, in addition, two small canines in their upper jaw, and sometimes in both; these are always wanting in the females. Between the canines and the first molar there is a wide space, which corresponds with the angle of the lips, where the *bit* is placed, by which alone man has been enabled to subdue these powerful quadrupeds.

5. The animals associated in the family *Manatidæ*, may be considered as Pachydermata still more adapted than the hippopotamus to an aquatic residence. In their teeth and general organisation, they bear a close correspondence to this order; and the fish-like form which they exhibit, is scarcely a greater variation than is seen in the order Carnivora. The posterior extremities of those animals are entirely wanting, as in the true Cetacea. The type of this family is the *manati*, which grows to the length of fifteen feet, and frequents the mouths of the African and American rivers. It is called sea-cow, and its flesh is eaten.

This group is connected with the true Pachydermata by several fossil genera, but particularly by a very remarkable one recently discovered—the *dinotherium*, for a figure and description of which, see GEOLOGY. This must have been the largest of the Mammalia not strictly aquatic, its total length being probably eighteen feet. It blends the characters of the tapir and elephant with that of the Cetacea, having probably possessed a trunk and an enormous pair of tusks, directed downwards, though fixed in the lower jaw, and having been deficient in posterior extremities. The tusks, like those of the morse, were probably employed in raking up vegetable matter from the bottoms of the rivers and lakes it seems to have inhabited.

X.—Ruminantia.

The order Ruminantia is perhaps the most natural and best determined of the whole class, for all the species which compose it seem constructed, as it were, upon the same model, the camels alone presenting any considerable exceptions to the general characters of the group. The first of these characters is the entire absence of incisor teeth from the upper jaw; whilst the lower appears to possess eight; of these, however, the two outer ones are really canines which have taken the form of incisors, so that the number of the true incisors is six, as in the other viviparous Mammalia. The molars are almost always six in number, both above and below, and have their crowns marked with two double crescentic ridges of enamel, which aid in triturating the food. The feet are each terminated by two toes and two hoofs, which present a flat surface to each other, appearing as though a single hoof had been cleft; hence the names that have been applied to these animals, of cloven-footed, &c. Behind the hoof there are always two small spurs, which are the vestiges of lateral toes.

The name of the order intimates the singular faculty possessed by these animals of masticating their food a second time, or 'chewing the cud.' This faculty depends on the structure of their stomachs, which are four in number. The food which is cropped by the incisor teeth, is swallowed almost without mastication, and is moistened in the stomach; and after being compressed into little pellets or *cuds*, is returned to the mouth to be rechewed while the animal is at rest. When this operation has been performed, the food is transmitted to the true digestive stomach, as already explained under ANIMAL PHYSIOLOGY.

The Ruminantia are exclusively herbivorous animals. As a group, they are timid and innocent, and destitute of powerful means of defence. With this character their structure corresponds. Their legs are long in proportion to their body, and the spinal column is very flexible; both which conditions are favourable to great activity of motion. They are endowed with a very acute sense of smell, which seems to be their guide in the selection of their food. Their ears are placed far back, and are very movable; and these are well adapted to catch sounds from behind, so as to warn the animals of danger whilst feeding. The eyes are placed at the sides of the head, and the pupil is in the form of a horizontal oblong; so that the range of vision along the surface of the earth is very great, and the animals can easily look behind them when pursued. Their means of defence consist in the use of their horns to gore the enemy, and of their hind feet to kick it; but it is only when peculiarly courageous that single animals of this species will act on the offensive, or stand on the defensive, against others of proportional size and strength.

The Ruminants, of all animals, are those which are most useful to man. They supply him with a large proportion of his animal food. Some serve him as beasts of burden; others furnish him with their milk, their tallow, leather, horns, and other useful products.

The great resemblance which exists among the very numerous members of this order, renders the distribution of them into families, each characterised by some important peculiarity, a matter of some difficulty. These subdivisions are, probably, best erected upon the character of the horns, which are possessed by the males of all the species in their natural state, excepting such as (like the camel) connect this order with other groups. The horns are essentially bony prominences from the fore part of the skull. In some Ruminants, commonly termed *cattle*, such as oxen, sheep, goats, and antelopes, these prominences are covered with an elastic sheath, formed as it were of agglutinated hair, which continues to increase by layers during life. It is to the substance of this sheath that the name of *horn* is commonly applied, whilst the bony support is termed the *core*; this grows during life, and never falls. In the *giraffe*, again, the bony prominences are covered with a hairy skin, which is continuous with that of the head; and here, too, the bony part of the horn is permanent. But in the *deer*, these prominences, which are covered for a while with a hairy skin (commonly termed the *velvet*), like the other parts of the head, have at their base a ring of bony tubercles, which periodically enlarge, and compress the nutritive vessels of the horns. These accordingly die, and fall from the skull; and the animal remains defenceless. Others, however, are reproduced, generally larger than before, which are destined to undergo the same fate. These horns, periodically renewed, are usually styled *antlers*.

The Ruminants with horny sheaths to the bony prominences may be divided into three families. ANTELOPIDÆ, or *Antelope* tribe, characterised by the light-

Spring-bok Antelope.

ness of their forms and the activity of their movements, and by the solidity of the bony core. CAPRIDÆ, or *Goat* tribe: in these the bony core is partly occupied with cells, and the general form approaches that of the Ox tribe; but the horns are directed upwards and backwards. BOVIDÆ, or *Ox* tribe: these have the horns directed upwards and forwards; the form is robust, and the movements heavy. The division of the Ruminants in which the horns are periodically cast off, constitutes only one family, that of CERVIDÆ, the *Stag* tribe. Another family, including only the giraffes, and named CAMELOPARDÆ, is characterised by the shortness and permanence of the horns, which are covered with a skin. Of the Ruminants without horns there are two distinct families—the MOSCHIDÆ, or *Musk-deer*, which are remarkable for their elegance and lightness, and differ but little from the rest of the order save in the absence of horns; and the CAMELIDÆ, or *Camel* tribe, which in their dentition, and in the structure of the extremities, exhibit a transition to the Pachydermata.

1. The family ANTELOPIDÆ, remarkable for the slenderness of form and swiftness of foot of the animals composing it, contains above seventy well-ascertained species, bearing a strong general resemblance to each other. Most of these are natives of Africa; a few species, however, inhabit Asia; a still smaller number exist in America; and one only, the *chamois*, now remains in Europe. Among these numerous species we meet with forms that remind us of the other families of the Ruminantia—the ox, goat, stag, &c. They generally associate in large herds, which migrate together in search of pastures. A species well known to the colonists of South Africa is the *spring-bok*, which occasionally visits their cultivated lands, during seasons

of drought, in innumerable herds, causing devastation wherever they pass. The antelopes may probably be regarded as the types of the Ruminantia, exhibiting the peculiar characters of the order in the most remarkable degree. They are extremely vigilant and timid; and the speed of the swiftest species surpasses that of every other mammiferous animal. Those which are adapted to live on rocks and mountains exhibit the most remarkable agility, and fearlessness of those dangers which their habits would seem to involve; they walk with perfect composure along the giddy brinks of the most awful precipices, climb and descend with wonderful care and precision, and leap up or down to the smallest surface that will contain their collected feet, with perfect firmness; and yet they are so fearful of any supposed enemy, that it is difficult to get within gunshot of them.

2. The family of Capridæ is connected with the last by many antelopes which, like the chamois, approach the goats in form. It includes only the *goats* and *sheep*. The original stock of the domestic breeds of the former appears to be indigenous to Persia, where it inhabits the mountains in large troops. The goats of Angora, Thibet, &c. celebrated for the fine quality of their hair, are no more than varieties of the common species. The *ibex*, which inhabits the mountains of the old world, and especially the Caucasian chain, is distinguished by the size and strength of its horns. It is said that this animal fearlessly precipitates itself down precipices, always falling on its horns, the elasticity of which secures it from injury. The *sheep* appear to have extremely little real difference from the goats: a large number of races exist, the relation of which to each other is uncertain; and there is doubt as to the original stock of the whole. Of the domestication of this animal we have an earlier record than of any other.

3. The species of the Bovidæ, or *Ox* tribe, are comparatively few. They are all rather large animals, with a broad muzzle, heavy and massive body, and stout limbs. Of the original stock of the domestic ox we have no certainty, since, as in the case of horses, the existing races of wild cattle are probably all descended from those which have been at some period subservient to man. Of all the animals which have been reduced to his service, the ox is, without exception, that to which he is most indebted, for the extent and variety of its means of usefulness. The universal utility of the animal appears to have been very soon detected; and we find, consequently, that its domestication soon followed that of sheep, and that it is mentioned in the most ancient records as a servant of man, long before either the horse or dog are noticed.

Cape Buffalo.

Amongst the undomesticated species of this family, which have all a strong general resemblance to each other, and are the most powerful and savage animals of the whole order, may be noticed the European *bison*, which was formerly spread over Europe, but is now restricted to Lithuania and the Caucasian region; the American bison, commonly called *buffalo*, which inhabits all the temperate parts of North America; the *Indian buffalo*, of which there are several different races (in one, the horns include a space of ten feet from tip to tip), of which some have been domesticated; the *Cape buffalo*, an extremely ferocious animal, with large horns, first directed downwards, so as nearly to cover the forehead, inhabiting the woods of Caffraria; and the *musk-ox*, a species inhabiting the coldest regions of North America, with short legs, and long hair reaching the ground, which diffuses more strongly than the rest the musky odour common to the whole genus, and which is particularly noticeable in the European bison.

4. The Cervidæ, or *Stag* tribe, includes, like that of antelopes, a considerable number of species, differing but little from each other, very widely diffused over the earth's surface, and easily separated from others by the character of the horns. With the exception of the reindeer, however, the female is destitute of horns, save in a few rare individual cases, analogous to those in which the hen assumes the plumage of the cock bird. The substance of the horns, when completely developed, is that of a dense bone, without pores or internal cavity; their figure varies greatly according to the species, and even in the same individual at different ages. These animals are extremely fleet, and live mostly in forests, where they feed on grass, the leaves and buds of trees, &c. They may be subdivided into sections, according to the form of the antlers. In some, these are wholly or partially flattened, as in the *elk*, one of the largest existing species, which lives in troops in the marshy forests of the north of both continents. It is as large as a horse, and sometimes larger. The antlers of the male, at first dagger-shaped, and then divided into narrow slips, assume, at the age of five years, the form of a triangular blade, with tooth-like projections on its outer edge. These increase with age; so that the horns have at last fourteen branches proceeding from each expanded portion, and weigh fifty or sixty pounds. To this group also belongs the *reindeer*, so serviceable to the Laplanders, which is the only species properly domesticated, though others are doubtless susceptible of being so. The *fallow-deer*, now naturalised in this country, but probably introduced from the south of Europe, is another species of this group. The remains of a gigantic species of deer, belonging to the same section, are frequently found in peat bogs, and other recent deposits in this country, and more especially in Ireland, whence the name *Irish elk* has been given to it.

The species with round antlers are more numerous; those of temperate climates change colour, more or less, with the seasons. The common stag, or *red deer*, is the best known of these, being indigenous to the forests of all Europe and of the temperate parts of Asia. The Canadian stag, or *wapiti*, the elk of the Anglo-Americans, is a fourth larger. A great number of species are indigenous in Central and Southern Asia.

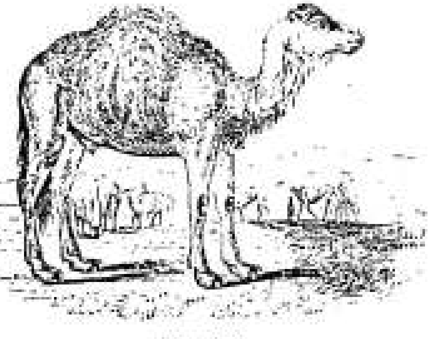
5. Of the family Camelopardidæ, only one species was for a long time known to exist; but there are probably two, or even three, kinds of giraffe, all of which are natives of Africa, frequenting chiefly the borders of the deserts. Its remarkable form, depending chiefly on the great length of its neck and fore legs, is familiar to every one. In its general structure, however, it closely resembles the deer; differing from them in the permanence of the horns. It has also some points of affinity to the camels; especially in the length of its neck, the existence of callosities, or hard surfaces, on the breast and knees, and the absence of the small spurious hoofs. It is the tallest of all animals; its head being frequently raised eighteen feet from the ground. Its disposition is gentle, and it feeds on leaves; browsing upon the young branches at a height much above that which any other animal can reach, and drawing them towards its mouth by its prehensile tongue. It lives in small troops of five or six individuals, and is

very timid, although capable of powerfully defending itself by kicking. Notwithstanding the length of its neck, the number of vertebræ which this part contains is no greater than in other Mammalia.

6. The MOSCHIDÆ, or *Musk-deer*, are completely intermediate between the true *Deer* and the *Camel* tribe, which last connects the Ruminantia with the Pachydermata. They resemble the ordinary Ruminants in the lightness and elegance of their forms, and in the nimbleness of their movements; and differ chiefly in the absence of horns, and in the projection of the canine tooth on each side of the upper jaw, as in the camels. The name of this group has been derived from the common Musk, the males of which secrete the odoriferous substance so called. This species is almost without tail; and the hairs, which completely cover it, are so coarse and brittle, that they might almost be called spines. It is confined to the mountainous region between Siberia, China, and Thibet, from which most of the Asiatic rivers descend. Its habits are nocturnal and solitary, and its timidity extreme. The other musk-deer inhabit the warmer parts of Asia and the eastern Archipelago; they have no musk pouch. They are the smallest and most elegant of the Ruminantia, and are active and gentle in their habits.

7. The CAMELIDÆ, or *Camel* tribe, approximate to the preceding order, and especially to the whole-hoofed division of it constituting the Horse tribe, more than do any other Ruminants—to such a degree, indeed, that some naturalists prefer associating them with that group. They have always canines in both jaws, and two of the incisors have also the same pointed shape. The animals of this family are much less elegant in form and graceful in action than the other Ruminants; but their organisation is, equally with theirs, most perfectly adapted to the circumstances in which they exist. The family contains two groups—the *Camels* and *Llamas*; the former are restricted to the old world, and the latter correspond to them in the new.

In the true *Camels*, the two toes are united below by a kind of horny sole, almost to their points, which terminate in small hoofs; and there is a soft cushion beneath the foot, by which it bears upon the sandy surface over which it is formed to move. Two species are known, one called the *Bactrian*, or *two-humped camel*, and the other the *Arabian*, or *one-humped*. Both are completely domesticated. The first is employed chiefly in Central Asia, the latter in Arabia, North Africa, Syria, Persia, &c. The two-humped camel is the larger and stronger, being capable of sustaining above one thousand pounds' weight, and is best adapted for rugged ground; the other is the most abstemious, and the best



Dromedary.

fitted for the sandy desert. The *dromedary* is merely a lighter variety of it, possessed of greater fleetness and power of endurance. The flesh and milk of the camel serve as food, and the hair for the manufacture of cloth, to the people who possess it. Their humps, principally composed of fat, are provisions of superabundant nutriment, which are gradually absorbed and disappear on the occasion of a scarcity of other food, as is observed at the end of a long journey. By resting on their callosities, they are enabled to repose on a scorching surface, and their stomachs are adapted to contain a supply of water sufficient for several days.

The *Llamas* of South America are much smaller than the preceding; they have the two toes quite separate, and are without humps. They were the only beasts of burden possessed by the Peruvians at the time of the conquest. They can only make short journeys, and the largest of the four species known cannot sustain more than one hundred and fifty pounds. Remains of a fossil species have been lately found, which must have equalled the camel in stature.

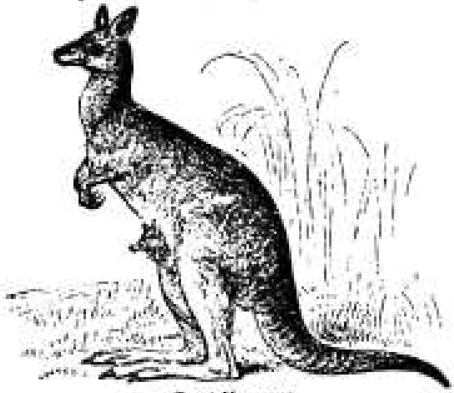
XI.—Marsupialia.

The two remaining orders of Mammalia, the Marsupialia and Monotremata, are now usually regarded as constituting a distinct sub-class, termed *Ovo-vivipara*, intermediate between the truly viviparous Mammalia and the oviparous Birds and Reptiles. Their most obvious peculiarity is the production of their young at a very early period of development, resembling the half-formed chick in an egg which has been but a few days incubated. In accordance with the lower grade of this important function, we find a general inferiority of the whole organisation to that of the truly viviparous Mammalia. The skeleton, the nervous system, the arrangement of the large blood-vessels, and the larger number of the incisor teeth (which in the higher subclass never exceed six), all show indications of this approximation; and this is also indicated in the deficiency of intelligence, which is manifest in their physiognomy as well as in their actions.

Of these two orders, that of Marsupialia is the one which exhibits the least departure from the general type of the Mammalia; and it is that, too, in which the provision for the continued nourishment of the young by its parent is the most remarkable. The new-born imperfect offspring attaches itself to the teats of the parent, and remains fixed there until it has acquired a degree of development comparable to that with which other animals are born. The skin of the abdomen of the parent is so disposed as to form a pouch, in which these imperfect young are protected, and into which, long after they can walk, they retire for shelter on the apprehension of danger. It is from the pouch (*marsupium*) that the order takes its name, this being its distinguishing peculiarity. It is remarkable that, notwithstanding the general and usually very striking resemblance of the species to each other, they differ so much in the teeth, the digestive organs, and the feet, that, if we rigidly adhere to these characters, we should find it necessary to separate them into distinct orders.

The geographic range of this order is extremely peculiar. With the exception of the Opossum group, which inhabits America, its species are at present almost confined to Australia and the neighbouring countries, where they constitute, with the Monotremata, almost the only mammaliferous animals.

The Marsupials may be divided into families according to the nature of their food. Some of those inhabiting Australia (*dasyurus*) are carnivorous, and display considerable ferocity. The *Opossums* have a mixed diet; and are remarkable for possessing an opposable thumb, like that of Quadrumana. Another group is more formed to live in trees, where they feed upon insects and fruit; to this belongs the *petaurus*, or flying opossum, which is formed upon the same plan with the flying lemur. The *Kangaroos*, of which several species exist, resemble the Ruminantia in food and habits. They are remarkable for the enormous length of their hinder feet, whence their generic name, *Macropus* (long-footed), is derived. The hind legs and tail are also very largely developed; whilst the fore legs and feet are very small. From this great inequality in the size of the limbs, they advance on all-fours very slowly; but they can make immense leaps with the hind legs, the tail probably assisting them. These are furnished with one large nail, almost like a hoof, which is a powerful weapon of offence and defence; for, supporting itself upon one leg and its tail, the animal can inflict a very severe blow with the leg which is at liberty. It will sometimes grasp its enemy with its fore paws, whilst it kicks it with its hind foot; but this it will only do when attacked, for it



Great Kangaroo.

is naturally a very gentle animal. The largest species is sometimes six feet in height, having the bulk of a sheep, and weighing 140 lbs. Its flesh is used as food by the New Hollanders, and is described as being like venison. The members of the last family, which includes the *Wombats*, are root-eaters, and in the structure of the teeth and alimentary canal are true Rodents.

XII.—Monotremata.

The order Monotremata contains but two species—the *echidna*, or spiny ant-eater, and the *ornithorhyncus*, or duck-billed platypus; and these are found nowhere else than in New Holland and Van Diemen's Land. These were included by Cuvier (who regarded the absence of teeth as the chief character) amongst his Edentata; but zoologists have now generally agreed that the peculiarities of their structure and physiology fully entitle them to rank as a distinct order, even more dissimilar to the other Mammalia than are the marsupial quadrupeds just considered. Until recently, indeed, it was much doubted by many, whether they could be included among the class Mammalia at all, since their organisation did not appear at all adapted for the nourishment of the young by suckling, which is the essential character of the group. The lips of both animals, in adult age, are of horny consistence, resembling the bills of birds; in the echidna they are prolonged into a narrow beak, and in the ornithorhyncus they form a wide flat bill like that of a duck. Moreover, the presence of glands for the secretion of milk appeared doubtful. But the late researches of Mr Owen have shown that the lips, in the young state of these animals, are much softer and more flexible, and that mammary glands certainly exist; so that the question may now be regarded as decided.

The name and character of the order are derived from the fact of the excretory openings at the posterior part of the body being united into one, as in birds; and this is a point of very remarkable affinity with that class, which is borne out by their *general* organisation. There is a sort of clavicle (collar-bone) common to both shoulders, placed before the ordinary clavicle, and analogous to the *furcula* (merry-thought) of birds. Each foot possesses five claws; and, besides these, the males have a peculiar spur on the hinder ones, like that of a cock. The young ornithorhynci are produced in an extremely imperfect state; the fur being totally wanting, and the place of the eyes scarcely discernible. The tongue, which in the adult is lodged far back in the mouth, advances in the young close to the lower mandible; and this disproportionate development, viewed in connection with the flexibility of the bill, is evidently designed to enable it to derive its nourishment by suction. The young echidna has not yet been discovered.

The *Echidna* is characterised by the slenderness of the prolonged muzzle or bill, which contains an extensible tongue, like that of the ant-eater. The feet are short, very robust, and adapted for digging. The whole upper part of the body is covered with spines, bearing some resemblance to those of the hedgehog; and when apprehensive of danger, and unable to escape from it by burrowing, the animal can erect its spines, and roll itself into a ball. The habits of the *Echidna* are but little known; for they do not exist in any large number; and they burrow so rapidly in the ground, that even when one is discovered, it is not easily got hold of. To lift it from the ground requires more force than would be supposed; for it firmly fixes itself to the earth in an instant, and but a few moments elapse before it is so far down, that its back is level with the surface. It feeds upon insects, principally ants, which it captures by its long extensile tongue; and this appears to be furnished with a glutinous secretion which causes them to adhere to it.

The muzzle of the *Ornithorhyncus*, as already stated, bears a close resemblance in form to the bill of a duck. The jaws contain no true teeth; but there are two pairs of horny ridges on each side, which may be considered as representing them. The fore feet are furnished with a membranous web, which not only connects the toes, but extends beyond the claws. The under surface or palm of this is concave, so that it can strike the water with great effect; but when the animal burrows, it falls back behind the claws. The hind feet are directed backwards when the animal is swimming, and somewhat resemble a fin; the membranous web does not extend on them, however, beyond the roots of the claws. The tail is broad and flat. The body is covered with two kinds of hair, like those found in the seal and the otter; the one fine, long, and thick; the other a still finer, short, and very soft fur. The whole organisation of the animal adapts it for seeking its food in the water, and for chiefly inhabiting that element. It burrows in the banks of rivers, and seeks its food in precisely the same manner as the duck. River insects, small shell-fish, and water-plants, appear to constitute its nourishment. The animal is very timorous; and if alarmed whilst at the surface of the water, dives down head foremost, and does not ascend at the same spot. In captivity, it is said to be harmless and playful; but it moves with great difficulty over the surface of the ground.

Such is the class Mammalia; a class the members of which are of the highest importance to man, not only from their occupying the chief grade in vital development, and therefore in some measure partaking of the characteristics of his own being, but from their supplying him directly or indirectly with much that is necessary to the comfort of his existence. The horse, ass, ox, reindeer, elephant, camel, llama, and dog, in their respective countries, assist materially in lessening the amount of his drudgery and toil; these and others, with their skins, hair, fur, and wool, furnish him with his finest, warmest, and most durable clothing; the flesh and milk of many are principal elements in the food of most nations; while the horns, teeth, bones, bristles, &c. of others, are fashioned into numerous articles of utility or ornament. Viewing them, therefore, as fellow-creatures exhibiting structural adaptations, instincts, and propensities somewhat akin to our own, as contributing economically to our well-being and comfort, and as partakers of the same common bounty, we should ever treat them, and all other animated forms, however humble, with considerate kindness. Even the most bloodthirsty and destructive are indispensable parts of the great scheme of creation; and while reason may dictate their suppression for our own safety and advantage, it as sternly forbids every approach to wanton massacre and cruelty.

CLASS II.—BIRDS.

Birds take their place as a class immediately after Mammalia, in consideration of their possessing, like them, a complete double circulation and warm blood; while, on the other hand, they approach the Reptiles in being oviparous. There is a more striking conformity in the entire class of Birds to one general type than is seen in any other group of equal extent in the Animal Kingdom. All are remarkable for the arrangements made in their organisation for lightness in proportion to bulk, a provision necessary for the aërial life which they generally lead. They are divided into orders, with the usual regard chiefly to external peculiarities and obvious habits—namely, INSESSORES, Perching-Birds; RAPTORES, Birds of Prey; SCANSORES, Climbing-Birds; RASORES, Scrapers; CURSORES, Runners; GRALLATORES, Waders; NATATORES, Swimmers.

I.—INSESSORES.

This is an extensive group of birds, presenting no very marked differences among its members. The principal character in which all agree, is the slenderness and shortness of the legs, with a form of foot (three toes in front and one behind, furnished with long and slightly-curved claws) adapting them to *rest* on the branches of trees; hence the name of the order. Their food is various, but in general mixed, consisting of insects, fruit, and grain; a few are almost as predacious as the regular birds of prey. In general, the females are smaller and less brilliant in their plumage than the male: they always live in pairs, build in trees, and display the greatest art in the construction of their nests. The young come forth from the egg in a blind and naked state, and are wholly dependent for subsistence, during a considerable period, upon parental care. The *larynx*, or organ of voice, is always of complex structure in the members of this order, which contains all that are commonly known as singing-birds. There are few that do not either sing, or utter some peculiar note or chatter analogous to song, during the season of courtship; and even of those which in general utter only monotonous cries, or of which the notes are harsh, some are frequently capable of being taught to speak, to whistle airs, or to imitate other sounds.

The families composing the order may be distributed under four large groups or assemblages, characterised by the respective forms of their bills. The CONIROSTRES have a stout beak, more or less conical, and with regular edges. The DENTIROSTRES have the upper mandible notched, as in the Raptores, towards the point; but this notch only exists in the horny covering, and not in the bone. The FISSIROSTRES have a short, broad, horizontally-depressed beak, so formed, that the gape of the mouth is extremely wide; it is slightly hooked, but without any tooth at the edge. The TENUIROSTRES have the bill very slender and elongated; sometimes straight, and sometimes curved.

1. The CONIROSTRES are to be regarded as containing the types of the order, the species belonging to it having the most varied faculties. They feed indiscriminately upon insects and vegetables, and are therefore termed omnivorous. Their feet are so constructed, that they can walk upon the ground with nearly the same facility as they perch upon branches. The families included in this tribe are the CORVIDÆ, or Crows; STURNIDÆ, Starlings; FRINGILLIDÆ, Finches; BUCERIDÆ, Hornbills; and LOXIADÆ, Crossbills:—

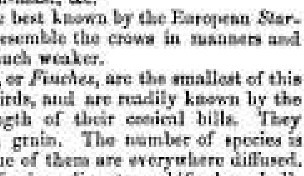
Of the family CORVIDÆ, the common *Crows* are the most characteristic examples, and may be regarded as combining the general features of the class in a greater degree than any other birds. In every climate habitable by man these birds are found: they are constructed for powerful and continued flight, as well as for walking firmly upon the earth; they feed indiscriminately on animals or vegetables, and, when pressed by hunger, do not refuse carrion: their smell is remarkably acute. They are bold, but wary, live in common societies, and possess great courage: when domesticated, they possess a power of imitating the human voice nearly equal to that of the parrot; and, like it, show signs of greater intelligence than is found in the rest of the class. Under the general term *Crow* are included the raven, which is the largest of European perching-birds, and which is bold enough occasionally to carry off poultry; the corby crow, which is very destructive to eggs and young game; the rook, which chiefly feeds on insects, and especially devours the grubs of the Coleoptera, though it occasionally eats grain, if its proper food be scarce; the hooded crow; and the jackdaw. The *magpies* are nearly allied to the crows; as are also the *jays*, which live principally, however, in woods, and feed on acorns, beech-mast, &c.

The STURNIDÆ are best known by the European *Starling;* they greatly resemble the crows in manners and structure, but are much weaker.

The FRINGILLIDÆ, or *Finches*, are the smallest of this group of perching-birds, and are readily known by the shortness and strength of their conical bills. They subsist generally on grain. The number of species is very great; and some of them are everywhere diffused. The sparrows, chaffinches, linnets, goldfinches, bullfinches, and larks, are those best known in Britain.

The BUCERIDÆ, or *Hornbills*, are readily distinguished at first sight by the enormous size of their bills, which are swollen or enlarged at the base into protuberances resembling horns or knobs, which are sometimes as large as the beak itself. The form of this excrescence varies much with age; and in very young individuals there is no trace of it perceptible. It is not solid, except in one species, but composed of a fragile network of bony fibres. The use of this curious appendage is unknown. The Hornbills are gregarious noisy birds, of large size, and are peculiar to the old world. They subsist on all sorts of food—devouring fruits, chasing mice, small birds, and reptiles, without disdaining carrion. They breed in the clefts of lofty trees.

The LOXIADÆ, or *Crossbill* tribe, contains a large number of genera, of which the common crossbill can scarcely be regarded as a characteristic illustration, the peculiarity from which it takes its name not being possessed by more than a few other species. This peculiarity consists in the strong curvature of the mandibles, so that their tips pass each other, and not always on the same side. By this extraordinary bill, the bird is enabled to extract the seeds from pine-cones with astonishing facility, and it is confined to localities in which these are to be obtained. The species common in Western Europe has of late years become more abundant in the British Isles, where it was previously known as an occasional straggler.

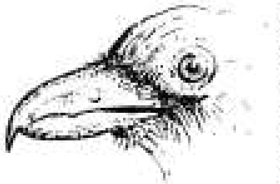


Beak of Crossbill: *a* and *b*, muscles which move it.

2. The DENTIROSTRES are the most allied of all the Insessores to the Birds of Prey. As the name imports, the species it includes are distinguished by a distinctly notched bill; and they are the greatest destroyers of insects among the Perchers. With very few exceptions, they either live entirely on insects, or resort to fruit only when insufficiently supplied with their favourite nourishment. The mouth is protected on each side by bristles, which defend the soft parts during the struggles of the prey; and the feet are generally adapted more for perching than for walking. The form of the beak varies in different species; in the shrikes, for example, it is stout and compressed, whilst it is flattened or depressed in the fly-catchers, which lead towards the Swallow tribe. The group includes the following families:—LANIADÆ, or Shrikes, which most prominently manifest the peculiarities of

the section; MERULIDÆ, Thrushes, in which there is less restriction to peculiar kinds of food; SYLVIADÆ, or Warblers, chiefly peculiar for the small size, delicate structure, and vocal powers of the species it contains; AMPELIDÆ, or Chatterers, distinguished by the enormous width of their gape; MUSCICAPIDÆ, Fly-catchers, which are more exclusively insectivorous than the rest of the tribe, and have small and weak legs.

The analogy between the LANIADÆ, or *Shrike* tribe, and the rapacious birds, is extremely evident. In the most characteristic specimens of the family, the bill, which is in all short and strong, is abruptly hooked at the point, and the notch so deep, as to form a small tooth, more or less prominent on each side: by this conformation, the bird is enabled to take a firm grasp of its food, and to tear it in pieces. The claws, also, are usually strong and sharp. Like many of the falcons, the shrikes will sit for hours watching for their prey, which consists of small birds, and, in the less powerful species, of insects; and will suddenly dart down upon such as come within their reach, seize it with their feet, and carry it home to be devoured at leisure. They not only pursue small birds, but successfully defend themselves against larger ones, even attacking them when they intrude in the vicinity of their nests. Many species feed also upon frogs, and other small terrestrial animals. The family contains a large number of species, distributed through all quarters of the globe.



Bill of Shrike.

The MERULIDÆ, or *Thrushes*, have an arched and narrow beak, but the point is not hooked, and the lateral tooth is not so marked as in the shrikes. Nevertheless, the transition from one form to the other is very gradual. This family is inferior to the shrikes, therefore, in the peculiar organisation adapted to rapacious habits, but they possess a greater variety of powers. It is in this family that we find the birds most distinguished for the sweetness, compass, and versatility of their song. They are not confined to animal food, but live much on fruits and berries. The common *thrush*, the *blackbird*, and *fieldfare*, are well known and also characteristic examples. These, as well as the *missel-thrush*, *redwing*, *ring-thrush*, &c. are closely allied species of the same genus, of which the other members are distributed over the whole globe. The *mocking-birds*, on the other hand, which probably stand unrivalled for their powers of voice, are restricted to America: some of them approximate to the shrikes in their habits. A few species of the family have somewhat aquatic habits.

The chief peculiarity which runs through the numerous family of SYLVIADÆ, or *Warblers*, is the very small size and delicate structure of the species which compose it. Excepting the Humming-Birds, we find among these elegant little creatures the smallest birds in creation. The diminutive golden crests, the nightingale, the white-throat, and the wood-wren, are examples of this family well known to the British naturalist; as are also the robins, stone-chats, wagtails, tit-larks, and tit-mice. Its different groups are spread over all the habitable regions of the globe, and appear to have a peculiar function in the economy of nature, being specially designed to keep down the multiplication of the innumerable minute insects which lurk within the buds, the foliage, or the flowers of plants. The Sylviadæ are for the most part migratory birds; appearing in spring, when the insect world is called into life and activity by the renewal of vegetation, and disappearing in the autumn, when their supply of food diminishes.

Of the AMPELIDÆ, or *Chatterers*, the most characteristic examples belong to tropical America, and only one is found in Europe—the *Bohemian wax-wing*. The Chatterers are distinguished from all the other Dentirostres by the enormous width of their gape, which in many extends beyond the eye, and in some is nearly as wide as in the goatsucker. They subsist almost entirely on soft berries and small fruits, which they swallow whole.

The MUSCICAPIDÆ, or *Fly-catchers*, are a family hardly less numerous than that of the Warblers; and are composed, like that group, entirely of small birds. They are more purely insectivorous than any other of the order, few of them ever partaking of fruits. They are distributed through the temperate and tropical portions of the old world, and the temperate latitudes of the new.

3. The FISSIROSTRES form a comparatively small group; but it is very distinct from all others in the beak, which is short, broad, horizontally depressed, slightly hooked, and deeply cleft, so that the gape is extremely wide. The birds possessing this kind of bill are adapted for capturing insects on the wing, receiving their prey in full flight into their mouths, which remain open for that purpose; and the victim is secured by a gluey exudation within, and a strong fence of bristles on the outside, which also serves to protect the soft parts of the head from its struggles. Although such is the typical or characteristic form of the bill in the group, it is not always seen. In some species, the bill is stronger and longer; and these also are distinguished by having the external toe nearly as long as the middle one, and attached to it until nearly its end; to these the name of *Syndactyli* was given by Cuvier, who associated them into a separate group. The Fissirostres, as a whole, are peculiarly distinguished by having the powers of flight developed to the highest degree. All the energies of their nature seem concentrated in this one perfection; for their feet are always very short and weak, and serve but for little else than to rest the body after flight.

This group may be divided into the five following families:—HIRUNDINIDÆ, or Swallow tribe; CAPRIMULGIDÆ, or Goat-suckers—both these present, in a remarkable degree, the organisation which has been described as characteristic of the order; the remaining families have a longer and narrower bill, and are syndactylous—MEROPIDÆ, or Bee-eaters; HALCYONIDÆ, or Kingfishers; TODIDÆ, or Todies.

The HIRUNDINIDÆ, containing the swifts and swallows, are diurnal birds, remarkable, like the diurnal Raptores, for their close plumage, the extreme length of their wings, and the rapidity of their flight. The *swifts* possess these characters in the highest degree, and surpass all other birds in the power of sustaining a rapid flight for a long time. They are distinguished from the swallows by having the hind toe directed very much forwards; and all four toes are armed with strong crooked claws, which give to the bird such a firm grasp, that it can sustain itself by the side of perpendicular rocks or buildings with great facility. In some species, the tail feathers are very stiff, as in the woodpeckers, and serve as an additional support. They spend their time almost entirely in the air, and pursue insects in flocks, sometimes at a great height, uttering discordant screams. They nestle in the holes of walls and rocks. The *swallows* are less capable of sustaining a continued flight than the swifts. Several species exist in Europe, and many more in the warmer parts of the world. Among them may be mentioned a small species inhabiting the Indian Archipelago, which forms its nest of a species of sea-weed, which it macerates in its stomach, and then arranges in layers. These *edible birds'-nests*, as they are commonly termed, are highly prized as delicacies in China, and constitute an important article of traffic with that country.

The CAPRIMULGIDÆ, or *Goat-suckers*, are nocturnal birds, and have the same light soft plumage which characterises the owls. Their eyes are large, and their gape still wider than that of the swallows, so as to be capable of engulfing the largest insects. They come forth in the twilight, and return to rest before morning; but in their other habits they much resemble the swifts, with which, indeed, they are closely connected by intervening species; for whilst there are some which fly by day, skimming over the surface of ponds in small flocks, precisely in the manner of swallows, there is also a swift which only flies at night.

The family of MEROPIDÆ, or *Bee-eaters*, is confined to the warm regions of the old world; only one species being known as having occasionally strayed to Britain. They have long and pointed wings and short feet, and fly in the manner of swallows. The European Bee-eater annually visits Italy, in flocks of twenty or thirty, and may be seen skimming over the vineyards and olive plantations, especially pursuing bees and wasps. It is remarkable that they are never stung by these insects, which they seize and at once crush by a snap of their powerfully-compressive beaks.

The HALCYONIDÆ, or *King-fishers*, are remarkable for the great length of the bill, and the extreme shortness of the feet. Their habits are sedentary, much resembling those of the fly-catchers; but their food is more various. The common British species partly lives on small fish, which it takes by precipitating itself into the water, either from the branch on which it had perched, or by suddenly arresting itself during rapid flight, poising for an instant, and then plunging. It returns to its perch to gulp its prey, first killing it by repeatedly beating it against a bough.

The TODIDÆ, or *Todies*, are small American birds, resembling the king-fishers in their general form, and may be regarded as representing them in the new world.

4. The TENUIROSTRES, it has been well remarked, 'are among the most interesting of the animal world. Deriving their subsistence, for the most part, from the nectar of flowers, we never fail to associate them in our idea with that more beautiful and perfect part of the vegetable creation with which, in their delicacy and fragility of form, their variety and brilliancy of hues, not less than by their extracting their nourishment from vegetable juices, they appear to have so many relations.' This tribe is confined exclusively to the torrid zone and southern hemisphere. The length and slenderness of the bill are its distinguishing characteristics. It is not by this, however, but by the long filamentous tongue, that the juices of flowers are sucked up; and to protect this important organ, the peculiar conformation of the bill seems chiefly intended. The tongue is often simply forked; but is sometimes divided into so many slender filaments, as to resemble a painter's brush. The feet are very short and delicate.

The TROCHILIDÆ, or *Humming-Bird* tribe, so celebrated for the metallic lustre of their plumage, and particularly for the gem-like brilliancy of some of their feathers, have, within their long slender beak, a tongue capable of protrusion like that of the woodpeckers, and divided almost to the base into two filaments. These filaments are *not* tubular, as they are sometimes described, but are flattened. It is not improbable that the tongue may serve for catching insects, as well as for sucking the juices of flowers; since it is unquestionable that, like others of the order, the humming-birds are partly insectivorous. When hovering over flowers, these birds balance themselves in the air by a rapid motion of the wings, like many flies; and it is by this movement that the *humming* sound is produced from which they take their name. The family is exclusively confined to America; and, with few exceptions, to the southern part of that continent and the adjacent West Indian islands. About two hundred species are at present known; and others are constantly being discovered. The smallest of them, when plucked, is less than a large humble-bee; and one only, which is much larger than any others as yet known, nearly equals the common swift in size.

The CINNYRIDÆ, or *Sun-Birds*, represent the humming birds in the eastern continent. They are closely allied to the Trochilidæ in general structure, and in the mode of obtaining their food, but their tongue is not so deeply divided. They are small birds, and the males have the most brilliant colours, rivalling those of the humming-birds during the breeding season; but the garb of the female, and of the male at other times of the year, is much more dull. The PROMEROPIDÆ, or *Hoopoes*, are also restricted to the old world; one species, the common hoopoe, annually visits Europe, in company with the bee-eaters and other swallow-like families.

The PARADISIDÆ, or *Birds-of-paradise*, are among the largest of the order, and live, like the rest, chiefly upon soft vegetable substances. They are confined to New Guinea and the neighbouring islands. The extraordinary development of their feathery appendages is well known; but of the purpose these serve in their economy, no plausible account has been given.

The MELIPHAGIDÆ, or *Honey-suckers*, are distinguished from all the preceding families by their notched bill; their tongue is terminated by a bunch of delicate filaments, and the hind toe is so strong and robust, that it serves as a support to the bird during the process of feeding. This group is chiefly confined to Australia, where its members abound in great variety of form, and where they find a never-failing support in the luxuriant vegetation of that country.

The members of the family CERTHIADÆ, which consists of the Tree-creepers, Nuthatches, &c. strongly resemble the scansorial birds in their habits; but they more closely approximate to the Tenuirostres, and especially the Meliphagidæ, in general structure. Like these, they are of small size; the foot has three of the toes directed forwards, and the bill is more slender and delicate than that of the woodpeckers. The *Tree-creepers* bore into trees, however, and rest upon their tail in climbing, much as do the woodpeckers; but they rather seek for their food in the natural chinks of the trees, or among the mosses and lichens which cover the branches. The *Nuthatches* have a stronger bill, which is straight and pointed, like that of the woodpeckers. They use it, however, rather to scale off the bark than to perforate it, and they do not support themselves upon the tail. They feed not only upon insects, but upon various seeds, and are celebrated for the instinct of fixing a nut in a chink while they pierce it with the bill, swinging the whole body as upon a pivot, to give effect to each stroke.

II.—Raptores.

The rapacious birds constitute a well-marked group, which may be compared with that of the Carnivora among Mammalia. In comparison with the Insessores, their number is but few; had it been otherwise, they would soon have extirpated the whole race. They usually breed but slowly, leading solitary lives, and never appearing in numerous flocks. Most of them are large and powerful birds; and, what is an exception to the general rule, the female is larger than the male, but her plumage is usually of a duller aspect. There are few of this family which do not show great strength of wing; but the power and swiftness of flight which are possessed by the different species, vary with their habits. They are all remarkable for their strong hooked bill and large acute talons. The force of these is indicated by the size of the muscles of the legs and thighs; and the foot is usually but of moderate length, that its power may not be lost by being diffused over too large a space. It is by the talons that the prey is usually struck first; and, when secured by the feet, it is torn open by the bill.

The FALCONIDÆ, or *Falcon*, exhibit the perfection of the order, and correspond very closely in their general habits, and the adaptations of structure to them, with the Feline tribe among the Carnivora. Their bodies are of moderate size; their forms light, but powerful; their flight graceful; and their courage very great. They are technically distinguished from the vultures, to which (being both diurnal birds of prey) they are most nearly allied, by the bill being toothed or notched, as well as shorter and sharper; and by the acuteness and strong curve of their talons, which, like those of the Cat tribe, are retractile. The members of this family are almost universally diffused over the earth's surface, some species of them existing wherever there is a sufficient expanse of land. They are less abundant in islands, for a considerable extent of country is necessary to supply them with food. Their plumage is destitute of a bright assemblage of colours, but is nevertheless in several instances peculiarly elegant. The Falconidæ have been commonly divided into the *noble* and *ignoble;* the latter not being susceptible of being trained to the (so-called) noble sport of falconry. The noble division comprehends the *Falcons-proper*, which are distinguished from the rest by the size of the tooth on the mandible, and by the power of their wings, which are long and pointed. They are the most courageous of all the family, in proportion to their size, and are specially adapted to pursue and bring down their prey whilst it is on the wing. The *Eagles* may be considered as ranking next to the falcons. They are the largest and most powerful of the whole group, and pursue and destroy quadrupeds as well as birds. They are distinguished from all other Raptores by having the legs and feet feathered quite down to the toes. They usually build their nests in lofty and secluded situations, and resist with great courage any attack upon their young. The *Hawks*, *Kites*, and *Ospreys*, are well-known forms of this family.

The birds of the VULTURIDÆ, or *Vulture* tribe, are, on the whole, much larger than those of the previous family, but they are much less courageous. The beak is lengthened, and curved only at the end, and it is not in the least toothed. The power of their talons by no means corresponds with the stature of these birds, and they make more use of their beak than of their claws. Hence they are not adapted for a contest with a courageous victim, and rather seek carrion already decomposing, to which they are attracted—whether by the sight or by the smell, is still a disputed question. The vultures are most abundant in hot climates, where they perform important services, by removing decomposing carcasses, which would otherwise be a source of offensive and noxious exhalations. They are sparingly scattered over the south of Europe; in Egypt they are more numerous; and in tropical America, although the species are fewer, the individuals are much more plentiful.

The STRIGIDÆ, or *Owl* tribe, including all the nocturnal birds of prey, is characterised by the large proportion of the head to the body, and by the

Barn Owl.

size of the eyes, which are surrounded by a fringe of feathers. Their soft downy plumage, too, may at once be distinguished from the firm and sharply-cut feathers of the diurnal Raptores. All these peculiarities have reference to their habits. The size of the eyes has an evident relation to the small amount of light in which they are usually to be employed; the pupils are so large, that the birds are dazzled in full day; hence in part arises the stupid appearance which they exhibit. The fringe which surrounds them probably has for its object to prevent the interference of light from the sides above or below, and to enable them to concentrate their whole power of sight upon the object directly before them—as when we look through the hand contracted into a tube at some object which we desire to see more distinctly. This fringe is most remarkable in the *Barn Owl* and its *allies*. In the owls which are partly diurnal in their habits, this circular fringe is hardly perceptible. The owls seek their prey, not by power of flight, but by stealing upon it unawares; hence the movement of their wings should be as noiseless as possible; and this object is peculiarly answered by the downy character of the whole plumage, and by a particular arrangement of the barbs of the feathers at the edge of the wings. Their food is wholly animal; consisting of mice, frogs, small birds, fish in some instances, and insects.

III.—Scansores.

The peculiar disposition of the toes in the birds of this order—two being placed behind, and all four arising nearly on the same level—gives them great facility in climbing the branches of trees, but proportionally impedes their progression on level ground. By this character they may be readily distinguished from all other birds, notwithstanding many and striking variations in the form of the bill and wings. Their nests are generally less skilfully constructed than those of the Insessores; and they often employ for this purpose the clefts and hollows in decayed trees: one family is remarkable for depositing its eggs in the nests of other birds. Their flight is ordinarily but moderate. Their nourishment consists of insects and fruits; and the species feeding upon each may be distinguished by the greater or less robustness of the beak. They may be divided into the four following families:—

1. PICIDÆ, or *Woodpeckers*, chiefly characterised by their long, straight, angular bill, the end of which is compressed into a wedge, adapted to perforate the bark of trees. The tongue is also of peculiar conformation, being worm-like in its shape, barbed at its point, and capable of being suddenly thrust out to a great length. By this mechanism the bird can introduce it into holes and crevices, or even under the loose bark of trees infested by those peculiar insects which it is its province to destroy; and these they obtain, not only by transfixing them with the barbed point, but by causing them to adhere to it by means of a viscid glue with which it is covered. The feet of these birds are short, but very strong; the nails are broad and crooked. As an additional and powerful support in their rapid and perpendicular ascent up the trunks of trees, their tail-feathers are very firm, and terminate in points; so that this member, being pressed against the bark, is of assistance to the bird in maintaining its perpendicular attitude.

2. CUCULIDÆ, or *Cuckoos*, a numerous and diversified race, spread over all the temperate regions of the globe. They are principally distinguished by the short and slender make of the feet, of which one of the back toes can be occasionally brought forwards. The beak is of mean length, slightly arched, and compressed at its sides. Most of this family are migratory, and scarcely any build nests of their own. They fly rapidly, and subsist upon insects and fruits. The common cuckoo has long been celebrated for its habit of depositing its eggs in the nests of other birds, generally insectivorous species; and, what is more extraordinary, the foster parents, often of species inferior in size, bestow as much care upon the young cuckoo as upon their own proper nestlings, even though the rearing of this involves the destruction of their own young; for, if other eggs are hatched with that of the young cuckoo, the latter speedily ejects the rightful tenants from the nest, and receives all the attention of their parents. If it were not for this, it must speedily perish for want, from the frequency and urgency of its demands for food, and its long incapability of assisting itself.

3. RAMPHASTIDÆ, or *Toucans*, easily recognised by

the enormous size of the bill, which is nearly as large and long as the body itself, but internally very light and cellular; its edges are toothed, and both mandibles are arched towards the tip. The tongue is narrow and elongated, and laterally barbed like a feather. Their feet are formed more for grasping than climbing; accordingly, they always live among trees, and proceed by hopping from branch to branch. So light and elegant are their movements, that in the living bird, in its natural situation, the disproportionateness of the bill does not attract observation. Its large size is to give a more extensive distribution to the nerves of smell, for the purpose of enabling the birds to discover their food, which consists chiefly of the eggs and young of other birds, and also to enable them to obtain it, by dipping it into the deep hanging nests which abound in their natural abodes, for which purpose its surface is endowed with considerable sensibility, enabling it to feel the contents of these nests. Toucans are mostly large-sized birds, and clothed with brilliant plumage. They are peculiar to the warm regions of America, where they live in small flocks, different species often associating together.

4. Psittacidæ, or *Parrots*, a family which is very widely diffused through the torrid zone in both new and old continents, and is scarcely found beyond it. It contains a large number of species, each of which has its peculiar locality, the short wings of these birds not enabling them to traverse large tracts of sea. They correspond with the other Scansores in little else than the structure of the foot, and this is formed rather for grasping than for climbing. It is also used for conveying food to the mouth, a peculiarity nowhere else seen but in the goat-suckers. Their beak is stout, hard, and solid, curved and pointed, and serves to assist them in climbing. They subsist upon vegetable food, and have a peculiar provision for supplying their young, analogous to that which will be described as possessed by the pigeons. Their jaws are set in motion by a greater variety of muscles than are found in other birds. Their tongue is thick, fleshy, and rounded; and their larynx, or organ of voice, is more complicated than in other birds—by which peculiarities they gain their facility of imitating the human voice as well as other sounds. Their voice, in a state of nature, however, is loud and harsh. They use their crooked bills in clambering upon trees, where they feed, nestle, and spend almost the whole of their time.

IV.—Rasores.

This order, corresponding with the *Gallinaceæ*, or poultry tribes, consists of birds with bulky bodies, and essentially formed to live upon dry ground. They are the most easily domesticated of the whole class; they furnish man with a considerable amount of savoury and wholesome food, and their fecundity is very great. The majority of them are at once known by their strong thick legs, long necks, short wings, and large ample tails; and the heads of many, especially of the males, are ornamented with elegant crests. The form of the bill is well seen in the common cock; the upper mandible is vaulted, and at the same time destitute of any notch; the whole is short and strong, having a peculiarly horny appearance. The wings are muscular, but their feathers have rounded ends; and the breast-bone presents a much smaller surface for the attachment of the muscles than in the previous orders, so that the power of flight is comparatively small. Their food, with few exceptions, is entirely vegetable, and their chief support is derived from the seeds and grains of various plants. Many of them eat also the green portions, and are in this respect nearly peculiar among birds. Almost all of them have a large crop and an extremely muscular gizzard.

The Rasores are mostly social birds, and are readily domesticable. In general, they deposit and hatch their eggs on the ground, in a rudely-constructed nest of straw; but some of them, which reside in forests, build in trees. Each male usually associates with many females; he takes no part in the construction of the nest or in rearing the young, and these are generally numerous, and able to run about and provide for themselves the moment they quit the shell. When this is the case, the male is larger and more gaily-coloured than the female. But in the few species which associate in pairs, as the ptarmigan and partridge, the sexes nearly resemble each other both in size and colour.

From the strong resemblance which subsists among all the members of this order, the division of them into families is difficult. The following may be regarded as the most natural distribution:—1. Phasianidæ, *Pheasant* and *Fowl* tribe, distinguished by the shortness of the hind toe, the presence of spurs on the legs, and the beautiful development of the tail. 2. Cracidæ, *Curassows*, the legs of which are destitute of spurs, and the hind toe so much developed, as to give considerable power of perching. 3. Tetraonidæ, *Partridge* tribe, having a short hind toe, and also very short tails. 4. Columbidæ, the *Pigeon* tribe, which are much isolated from the rest, and may be regarded as in some respects allied to the Insessores. From the well-known character of most of these birds, a detailed description of the families is unnecessary.

1. The whole of the Phasianidæ, with the exception of the turkey, are restricted to the old world. The characters by which they are known from the other families, are those which peculiarly distinguish the order; hence there can be no hesitation in regarding this family as its type. It is in the hotter parts of Asia that the most brilliantly-coloured birds of this family present themselves in the greatest numbers. The *peacock*, for example, abounds in the forests of India; and the wild specimens even surpass the domestic ones in brilliancy. The *turkeys* are the only representatives of this group in the new world, whence they were brought by the early discoverers, and are now quite naturalised in Europe. The *guinea-fowl* is originally a native of Africa, where it lives in large flocks, in the neighbourhood of marshes. Of our common fowls, the original stock, like that of most domesticated races, is obscure; but it was probably a species of *gallus*, inhabiting Java or Sumatra. The *pheasants* were originally brought from the banks of the Phasis in Asia Minor: several very handsome species abound in different parts of Asia.

2. The Cracidæ, or *Curassows*, which are restricted to America, offer a remarkable contrast, in their plain colours, to the brilliant plumage of the Asiatic races which occur in nearly the same parallels of latitude. They are equally capable of domestication with the fowls; and their flesh is of excellent quality.

3. The Tetraonidæ, or *Grouse* tribe, also differ strongly from the Phasianidæ, in the comparative dulness of their plumage, as well as in the extreme shortness of the tail. The *grouse* are formed to inhabit cold climates, and are found in Europe, Asia, and North America. The largest species, commonly known as the capercailzie, is the largest of the true poultry, surpassing the turkey in size. It particularly feeds on pine shoots. These birds strut with outspread tail, in the manner of the turkeys; and are polygamous. The *ptarmigan* live in pairs, and do not strut in this manner; the more generally-diffused species become white in winter; there is one species peculiar to Britain, however—the moorfowl or red grouse—which does not change. Nearly all the grouse have the toes and legs more or less covered with soft feathers; a character which disappears in the *Partridges*, an extensive group, scattered in nearly all parts of the old world, but unknown in the new. In the *Quails*, we have the miniature resemblance of partridges, but the tail is so short, as to be nearly imperceptible.

4. The family of Columbidæ, containing a large number of elegant and lovely birds, appears as much isolated from the rest as the Parrots are from the Scansores. Although it is particularly numerous, and spread over every part of the world, there is no difficulty in distinguishing its members from all other birds.

One of their chief peculiarities is the *double* dilatation of the crop, which expands on each side of the gullet; and the young are fed with grain disgorged from this receptacle by the parent, and impregnated with a secretion which it forms. These birds live invariably in pairs; they nestle in trees, or in the holes of rocks, and lay but few eggs, though they breed often. This family includes the whole of the well-known tribe of *Pigeons and Doves*. Some of the tropical species are of considerable size, and of very rich plumage.

V.—Cursores.

This order contains a small number of species, differing so considerably from one another, that almost every one may be regarded as belonging to a different family, and yet all agreeing in one characteristic—the non-development of the wings, and the enormous size and power of their legs—by which they seem justly separated from all other orders of birds. They may be regarded as in many respects intermediate between the Rasores and Grallatores; but they also present many remarkable points of approximation to the Mammalia. The most obvious of these are the loss of the powers of flight, and the dependence on the legs alone for locomotion; and the deficiency (most conspicuous in the cassowary) of barbs upon the feathers, so that they much resemble hair. In their internal structure, moreover, similar approximations exist: thus the ostrich has the rudiment both of a diaphragm and urinary bladder, organs which are wanting in all other birds. Although destitute of the powers of flight, wings exist in an undeveloped or rudimentary state; and it has been observed that, when the ostrich is running, its small anterior members execute analogous motions, which seem to assist it. Their muscles, however, requiring but little strength, the sternum has no prominent keel, but is flat as in man; whilst, on the other hand, the muscles of the posterior extremities are of enormous size and power. Only five genera are at present known to exist in this order:—

The *struthio*, or ostrich, is a well-known bird in the tropical parts of the eastern hemisphere; its feathers do not differ so widely from those of other birds as do those of the cassowary, being furnished with barbs; but these do not adhere to one another, so that no continuous resisting surface is formed. Still, the wings present sufficient expanse to assist the bird in running; which movement it executes so swiftly, that scarcely any animal can overtake it. The *rhea*, or South American ostrich, is about half the size of the African ostrich, and more thinly covered with feathers. Two species, or rather varieties, exist, one inhabiting the central parts of South America, where it is as abundant in some localities as the ostrich in Africa; and the other in Patagonia, where it is rare.

The *casuarius*, or cassowary, has wings shorter than those of the ostrich, and quite useless in aiding progression. Besides the peculiarity of the feather, which has been already mentioned as giving it the appearance of hair, there is another, consisting in the great development of the *accessory plume*, so that two or even three equal stems appear to grow from the same quill. In its general aspect and size it much resembles the ostrich, but differs in the structure of its digestive organs. The head is surmounted by a bony prominence, covered with horn. The skin of the head and neck is bare of feathers, and of a bright-blue and flame colour; it is furnished with wattles, like those of the turkey-cock, which change colour under the same circumstances. It lives on fruit and eggs, but not on grain; and is an inhabitant of the Indian Archipelago.

The *dromaius*, or emu, is a native of New Holland, and is closely allied to the cassowary; but its plumage is more dense, from its feathers being more barbed.

The *apteryx* of New Zealand appears, of all birds, to have the wings reduced to the most simple rudiments; and it presents, at the same time, many points of approximation to the Mammalia. It has a complete diaphragm, and no air-cells exist in its abdomen; nor are any of its bones hollow. The bill is long and slender; the rudiments of wings are terminated by a sharp hook, which seems to be an important organ of defence; the feet have three toes in front; and the rudiment of a fourth behind, the claw of which is alone externally visible. The size of this bird is about that of a domestic fowl, and its colour a deep brown. It runs with rapidity, and defends itself vigorously with its feet. It is nocturnal in its habits, and subsists on insects.

With this group is probably to be associated the *dodo*, now known to us only by some very imperfect remains, and by the paintings and descriptions of naturalists nearly two centuries since, when it seems to have existed in the islands on the eastern coast of Africa, especially Madagascar; though no traces of it can now be found there. Another recently-extinct bird of the same group is the *Dinornis* (from *deinos*, terrible; and *ornis*, a bird), bones of which have been found in the river-mud of New Zealand, indicating a size nearly twice that of the ostrich.

VI.—Grallatores.

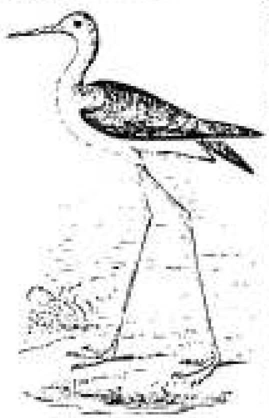
The Grallatores, Waders or Stilt-birds, derive their name from their habits and conformation. Their long legs raise up their bodies, as it were, upon stilts; and thus elevated, they frequent the banks of rivers and lakes, marshes, the shores of estuaries; and, whilst resting with their feet upon the land, derive their nourishment chiefly from the water—some feeding exclusively upon small fishes, aquatic mollusca, worms, small reptiles, and water insects—whilst others are of more terrestrial habits and food. Such as are more especially aquatic have a short web to their toes. Their wings are long, affording them the power of changing their habitation with the seasons, which most of them enjoy. During flight, they stretch out their long legs behind, to counterbalance their long necks; and the tail is always extremely short, its function as a rudder being transferred to the legs. They mostly construct or choose their nests upon the ground; and the young are enabled to run about as soon as hatched, except in those species which live in pairs. They are remarkable for their power of preserving a motionless position upon one leg for a considerable time.

The Waders may be grouped together under four families, principally characterised by the form of the beak:—1. Ardeidæ, the *Heron* tribe, in which the beak is long, thick, and stout, and has usually cutting edges, as well as a point. 2. Scolopacidæ, the *Snipe* and *Woodcock* tribe, in which the bill is long, slender, and feeble. 3. Rallidæ, the *Rail* and *Coot* tribe, in which the bill is less slender; but the chief character is derived from the extreme length of the toes. 4. The Charadriadæ, or *Plover* tribe, in which the bill is of moderate size, and the back toe either entirely absent, or not long enough to reach the ground.

1. The family of Ardeidæ includes the Cranes and Storks besides the true Herons. Nearly all the *Cranes* are large birds, with short powerless wings; their necks long, and frequently naked, and their habits more terrestrial than those of any of their congeners. They feed almost exclusively upon vegetables; and have a muscular gizzard. Most of them live in warm latitudes; and those which frequent Europe, migrate southwards in the autumn, and return in the spring. The *Herons* differ from the Cranes in being decidedly carnivorous; they are known by a larger and more pointed bill, and by the greater length of their legs. Their stomach is a large undivided sac, but slightly muscular. As a whole, they are the most beautiful of all the Waders; not so much, however, on account of the colours of their plumage, as from the elegant crests and prolonged feathers which ornament nearly all the species. They build in societies, usually in trees in the neighbourhood of banks of rivers; but generally feed and live solitarily. They are chiefly supported by fish, for which they watch in some concealed situation, transfixing them as they pass with their long and sharp bills. The *Storks* are less aquatic in their habits than the rest

of the family, nestling, by preference, on towers and chimney-stacks; each pair returning, for many successive seasons, to the same place in the spring, after having passed the winter in Africa.

2. The SCOLOPACIDÆ, or *Snipe* tribe, characterised by their long, slender, and feeble bill, which only enables them to bore in the mud in search of worms and small insects, have all nearly the same conformation, the same habits, and the same distribution of colours; so that it is difficult to distinguish amongst them. They are also remarkable for the delicacy of their legs, and the smallness of the hinder toe. They run with vast celerity, and have considerable powers of flight; and they have also the faculty, in part, both of swimming and diving. The females are usually larger than the males, and lay their eggs on the ground, in little or no nest. Their geographic dispersion is as wide as their locomotive powers are great. The shores of every part of the world abound with *sandpipers* and *curlews*; whilst snipes, woodcocks, &c. frequent the inland waters and marshy grounds. The *stilts* surpass all the rest of this family, and probably therefore all other birds, in the length and slenderness of their legs.



Stilt.

3. The RALLIDÆ, or *Rail* tribe, are furnished with very long toes, for traversing aquatic herbage; and they are even useful in swimming, especially in some species in which their surface is extended by a border of membrane. They are also distinguished by the form of the body, which is very thin and narrow—a structure adapted to their habits and mode of life, since they live for the most part in the thick and tangled recesses of the reeds and aquatic vegetables which clothe the sides of rivers and morasses. Their wings are short, or of moderate length, and their flight feeble; but they run with considerable swiftness. They are for the most part solitary and timid birds, hiding themselves at the least approach of danger, but quitting their semi-aquatic retreats morning and evening, to feed in more open spots. The flesh of these birds is delicate; and, as they live chiefly upon aquatic seeds and vegetable aliment, they may be regarded as aquatic Gallinaceæ. The *rails*, *coots*, and *crakes*, are the chief British species of this family, and are sufficiently characteristic.

Under the *Rail* tribe are placed two remarkable birds, the place of which is rather doubtful. One is the *jacana*, which is distinguished from all other stilt-birds by the length of its toes and claws, which enable it to walk with facility on the floating leaves of aquatic plants. The other is the *flamingo*, which is perhaps rather to be considered as one of the duck tribe, with an inordinately long neck and legs. The front toes are webbed to their ends, and the hind toe is extremely short. The mandibles are suddenly bent downwards, about the middle of their length; and they are roughened at the edges, like those of the ducks, to which the fleshiness of the tongue also shows an alliance. It feeds on mollusca, insects, the spawn of fishes, &c. The flamingoes construct their nests in marshy situations, placing themselves astride of them during the act of incubation, being incapacitated by the length of their legs from sitting on them in the usual manner.

4. The CHARADRIADÆ, or *Plover* tribe, are less aquatic than most of the other families. The legs are long, and the back toe is either quite absent, or so short as not to reach the ground. They live only on sandy and unsheltered shores, or on exposed commons, congregating in flocks, and running with great swiftness. The bill is usually of moderate strength, enabling these birds to penetrate the ground in search of worms, to obtain which they have the habit of patting with their feet, which causes the worms to rise. The species in which the bill is more feeble, frequent meadows and newly-ploughed land, where this food can be obtained with greater ease; those which have stronger bills, subsist additionally on grain, herbage, &c. Of the plovers, several species exist in Britain; and others are distributed through most other countries. Some chiefly frequent the sea-coast, and others the upland moors. The *Lapwings* are nearly allied to the plovers, and, like them, are migratory, passing the winter in warm latitudes: they are peculiar to the eastern hemisphere. They are very noisy birds, screaming at every sound they hear, and defending themselves with courage against birds of prey.

Three other genera of this family are worthy of notice. The *Bustards* connect the Grallatores with the Rasores, in the heaviness of their bodies, the small membrane at the base of their toes, and some other characters. They have, however, the long naked legs of this order, and the flavour of their flesh resembles that of the wading-birds. They fly little, scarcely ever using their wings, except (like the ostriches) to assist them in running. They feed equally on grain, herbage, worms, and insects. The great bustard is the largest of the European birds, and is one of the finest kinds of game: it has been nearly extirpated in Great Britain. The *Turnstone* is at once recognised by a short stout bill, turned slightly upwards: the name is derived from the habit it possesses of turning up stones on the sea-shore, to feed upon the marine animals concealed beneath. The *Oyster-catcher* has a long, straight, wedge-shaped beak, strong enough to force open the bivalve shells of the mollusca upon which it feeds.

VII.—Natatores.

The Swimmers are, of all the orders of birds, the most easily recognisable by the structure and position of their oar-like feet. This peculiarity, which occasions that awkwardness of gait on land which every one may observe in ducks and geese, is extremely favourable to those birds whose 'business is in the great waters.' The body is boat-shaped, and the neck very long in proportion, for the purpose of reaching prey beneath the water when the bird is floating on the surface. The thick downy covering is rendered impervious to water by the abundant application of an oily secretion. The bones of these birds are not hollow, like those of the rest of the class, but are filled with an oily marrow. In this, and in other points, their structure approximates to that of reptiles. Their circulation is less energetic than that of the other orders, and is capable of being considerably retarded, by the obstruction of the respiration, without injury. As the water is the element on which these birds are formed to move, so does it also supply them with food. Some of them live on aquatic plants and submarine insects; but the greater proportion prey upon fish, and those innumerable swimming and creeping things which subsist in the sea, and cover its shores. In general, several females associate with one male, and the young are hatched in a condition which renders the co-operation of both parents for their support unnecessary, being able to take to the water, and swim about in search of food, the instant they are liberated from the egg-coverings.

This order may be divided into five families—1. The ANATIDÆ, or *Duck* tribe; 2. The LARIDÆ, or *Gulls*; 3. The PELICANIDÆ, or *Pelicans*; 4. The COLYMBIDÆ, or *Divers*; 5. The ALCIDÆ, or *Penguins*. The three first are distinguished by the length of their wings, which enables them to fly well; while in the two latter, these members are so short, that they seem perfectly useless for any other purpose than that of fins.

1. The ANATIDÆ are distinguished by a thick bill,

which is horny only at its extremity; the remainder of the mandibles being invested with a soft skin, which in other birds is found only at their hinder part. This skin, in the ducks, is extremely sensitive, and by it the animals take cognisance of the food contained in the mud into which they plunge their bills. The edges of the bill are roughened, either by plates or small teeth arising from it; and the tongue is large and fleshy. These birds live more in fresh waters than in the sea; and many of them (such as geese and swans) are exclusively vegetable-feeders. The ducks, on the other hand, subsist in part upon animal diet; and one tribe of them, the mergansers, feed almost exclusively upon fish. Under the general designation of *ducks*, *geese*, and *swans*, all the birds of this family may be arranged; and as those typical forms are so well known, it is unnecessary to dwell longer on it, although the habits of many species are extremely interesting.

2. The LARIDÆ, or *Gull* tribe, resemble the higher orders of birds in their general structure. The wings are very long, and their powers of flight considerable. The feet, although webbed, are so constructed as to enable them to walk with ease along the shore in search of food; the legs are slender, and sometimes so long, as to resemble those of the waders; the hind toe is very small, and sometimes wanting. Many of the birds of this tribe have a tendency to associate in flocks. In consequence of their capability of protracted flight, they are met with at a greater distance from land than most others: many species are almost constantly on the wing, and brave the most violent storms. They seem to devour almost every description of animal and vegetable food. This family includes, with the *Gulls*, the *Skuas*, *Terns*, *Petrels*, and also the *Albatross* of the Southern Seas, which is the largest of all aquatic birds, and in its general habits may be described as a sort of marine vulture. It is extremely voracious, and devours almost anything that falls in its way.

3. The PELICANIDÆ, or *Pelican* tribe, are characterised by having the hind toe united to the rest by one continuous membrane: notwithstanding this conformation, which renders their feet perfect oars, they are almost the only Natatores which perch upon trees. All of them fly well, and have short legs. They are a large, voracious, and wandering tribe, living for the most part on the ocean, and seldom approaching land but at the season of incubation. The *Pelicans* themselves are remarkable for the length of the bill, which is armed with an abrupt hook at the end; the width of the gape is excessive; and the skin hanging from the lower jaw, and forming the throat, is so extensible, as to dilate into a pouch capable of holding a large quantity of fish. The *Cormorants* are remarkable for being not only voracious, but docile, so that they have been trained for fishing, as hawks for fowling.

4. The COLYMBIDÆ, or *Divers*, may perhaps be regarded as intermediate in structure between the Duck tribe and the next family. They are all marine birds, with a lengthened, strong, straight bill. The wings are in general remarkably short; and the feet placed so far behind the point of equilibrium of the body, that they will not allow the birds to walk upon land even so well as ducks; but they can pursue the fishes upon which they feed, even beneath the water, with great swiftness. They are few in number, and are chiefly confined to the seas of northern regions.

5. The ALCIDÆ, or *Auk* tribe, exhibit the most remarkable adaptation of the structure of the bird to an aquatic life with which the entire order presents us. This is best seen in the *Penguins*, whose wings are very small, and covered with mere vestiges of feathers, which resemble scales; so that they serve as admirable fins or paddles, but are totally useless for flight. The feet are placed very far back, so that, when upon land, the bird stands nearly erect. Having no power of flight, and not being able to run, the penguin may be overtaken with ease upon land; but once in the water, it distances its pursuers, swimming with the ease and rapidity of a fish.

CLASS III.—REPTILES.

The Reptiles, which constitute the class next to be considered, presents us with more diversity of form amongst its separate orders than any other division of the vertebrated sub-kingdom. Scarcely any animals are more unlike in external aspect than tortoises and serpents; yet we find that these extreme forms are connected with each other by a gradual series; and the internal differences are not so great as to prevent their association into one class, distinguished by characters which are common to all. These characters are—their low power of maintaining heat, or cold-bloodedness, arising from the imperfect aëration of their blood, of which only a portion is sent to the lungs at each impulse of the heart (see ANIMAL PHYSIOLOGY); their oviparous reproduction, and the protection of the skin by hard scales or plates.

The deficiency in the oxygenation of the blood, combined with the slowness and feebleness of the circulation, is connected with general inactivity of the nutritive functions, as well as with obtuseness of sensation and sluggishness of locomotion. It is a curious result of the feeble exercise of these functions, that they may be suspended for a considerable time without apparent injury to the animal; and that parts separated from the body, retain for a long period much of that low degree of vitality which they usually exhibit in connection with it. Although, at present, Reptiles appear to perform a comparatively insignificant part in the economy of nature, especially in temperate climates, where their numbers are few, and their powers feeble, we learn from the records of geology that there was a period, long antecedent to the creation of Birds and Mammalia, when gigantic animals of this class constituted the chief tenants of the earth.

I.—Chelonia.

The order Chelonia differs the most of any from the general form of the class. The shell in which the body is enclosed, and into which, in some species, the head, legs, and tail can be completely withdrawn, would seem a perfectly new organ, to which nothing correspondent exists among vertebrated animals. And the fin-like extremities of the aquatic species remind us more of fish than of other reptiles. The shell, however, is composed of the usual bones of the skeleton, modified only in their form. The upper piece, termed the *carapace*, is usually more or less arched, and is composed of a bony expansion of the ribs, which are consolidated into a firm structure, adhering to each other along their edges, and covered with horny plates, secreted from the skin like hair or nails. The lower plate, or *plastron*, is formed by a peculiar development of the sternum or breast-bone, which, instead of being prolonged forwards into a keel, to give attachment to large muscles, as in birds, is extended laterally for the protection of the subjacent parts.

Most of the Chelonia possess no weapons of offence, being destitute of teeth, claws, or other sharp instruments. The jaws are covered with a horny substance, resembling that of the bills of birds; but their surfaces are usually rounded, so as to be more adapted to bruise than to bite. The shell, however, serves as a most effectual means of passive resistance. In the land species it is usually high-arched, and firmly united, so as to bear a very great weight without injury; and the feebleness of the power of motion in these animals is thus compensated. But in the aquatic species it is generally more flattened, so as to oppose less resistance to the water. Some of these have the power of swimming with considerable rapidity, and are altogether more active in their habits than the rest of the order. In these, the shell affords a much less complete protection to the body, and its parts are more loosely united, so that it possesses some degree of flexibility.

Among the families into which the Chelonia are subdivided, it will be convenient to notice first the CHELONIDÆ, or *Turtles*. These are distinguished by the incompleteness of their shelly covering, and by the peculiar modification of the feet for swimming. The ribs, by the union of which the carapace is formed, are separate from one another around its margin, and the pieces which compose the plastron do not form a continuous plate, but leave great intervals, which are occupied only by cartilage. All the feet are much elongated, particularly the anterior pair, and are flattened, so as to serve for oars or paddles. The toes are seldom at all separated, the whole foot being enveloped in the same skin, closely set with hard plates. They live almost entirely at sea, feeding chiefly upon marine plants, and they only come to the shore to deposit their eggs.

The EMYDÆ, *Fresh-water Turtles*, or *Mud Tortoises*, are intermediate in form between the family just described and the Land Tortoises. The character by which they may be most constantly separated from the marine Turtles, is the distinctness of their toes, which are terminated by claws; but a web still exists between the toes, which assists them in swimming, and also prevents the feet from sinking into mud. Rivers, ponds, and running streams are the haunts of these animals, of which one species is common in the south and east of Europe, and is fattened for food in Germany and Russia, where it is considered a delicacy. The food of the Emydæ consists of mollusca, aquatic insects, small fish, carrion, and vegetables.

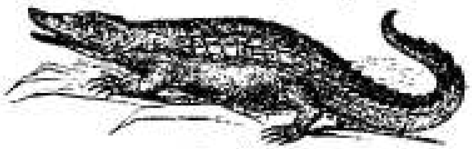
The family of TESTUDINIDÆ, or *Land Tortoises*, is distinguished by the highly-arched carapace, and still more by the short clubby feet, of the animals composing it. Their armour is harder and thicker in proportion to their size, and also more firmly united together, than that of the aquatic species. The neck and legs are short, and capable of being drawn entirely within the shell; so that the whole structure of the animal is adapted for passive resistance. The feet, shaped very much like those of the elephant, are adapted for walking on firm ground only, as the surface they present is very small. They are subdivided into toes, of which there are five on the fore feet and four on the hind; and these are furnished with short conical claws, well adapted for digging. These creatures are of the most inoffensive character possible. They feed only upon roots and vegetables, and upon the worms and slugs that infest these: during the summer they live in woods, or among herbage; and they pass the winter, in cold climates, beneath the earth, where they burrow and sleep. They are generally dispersed in all the warm and temperate latitudes; but they do not naturally extend to Great Britain, although individuals that have been introduced have lived to a great age.

II.—Enaliosauria.

The order Enaliosauria has been founded upon two extraordinary fossil genera—the *Ichthyosaurus* and the *Plesiosaurus*, for an account of which, see GEOLOGY.

III.—Loricata.

The order Loricata includes the Crocodiles, Alligators, and Gavials. The body is enclosed in a sort of plate-armour, of which the separate portions are closely fitted together, and are capable of great resistance. This order includes the most bulky reptiles at present known to exist. Some of them attain the length of thirty feet, and a circumference of seven or eight. Although capable of moving on land, the greater number of them prefer the water, and show their chief activity in it. Besides the expansion of the foot, they are adapted for swimming by the lateral compression of the tail, which thus acts as a large and powerful fin. The crocodiles and their allies are all inhabitants of the rivers and fresh waters of warm climates; and they are all purely carnivorous. They destroy their prey by holding it beneath the surface of the water until it is drowned; the position of their nostrils, and the arrangement of the air-passages, being such that they are themselves enabled to breathe during the process. They cannot swallow under water, however, and their habit is to hide their prey in holes on the bank, until it has become putrid, and then to devour it at leisure. The group may be divided into—the *Crocodiles*, chiefly inhabiting the Nile and other African rivers; the *Gavials*, found in the Ganges and other Asiatic rivers; and the *Caymans* or *Alligators*, confined to the new world. The characteristic differences of these three divisions are best marked in the form of the head. The *Gavials* have the muzzle exceedingly prolonged and narrow, somewhat resembling in form the beak of the spoonbill. In the true *Crocodiles* it gradually widens from



Crocodile.

the point towards the eyes; and in the *Caymans* the snout is much more rounded, and the head is broader in proportion to its length. These last appear less adapted to aquatic habits than the Crocodiles and Gavials, for the feet are not webbed to nearly the same extent as in the latter, and the ridge which increases the surface of their hind legs is wanting in the Alligators. With these exceptions, the general conformation of all, as well as their mode of life, is very similar.

IV.—Sauria.

The order Sauria comprehends all the animals commonly known as Lizards. They are intermediate between the Loricata and Serpents, for they have a lengthened body, terminating in a tail, like the former; but this, instead of being enclosed in large shields or plates, is covered with small scales, as in the latter. Moreover, they have usually four legs; but in some species one pair disappears, and in others they are all concealed beneath the skin, so that the body presents a snake-like aspect. In this group are found some of the most active, and certainly the most beautiful, of the Reptile class. Many of them are tinctured with the most brilliant colours, and as they are called into the greatest activity in the bright sunshine, nothing can surpass the splendour of their ever-changing hues. These colours bear an interesting relation to the habits of the animal, having a general resemblance to that of the places they frequent; thus tree-lizards are almost always of bright colours, in which green predominates; ground-lizards, brown, more or less speckled; and those which live in stony places are of a grayish hue.

The majority of the Sauria are carnivorous, feeding upon other animals of inferior size and strength to themselves, and almost always preferring living prey. Many of them pursue nothing but insects; others lie in wait for small birds. The Iguanas, however, feed almost wholly upon vegetables. Many of them are possessed of very great agility upon land; some of them can ascend perpendicular walls, and even run along the ceiling with their backs downwards; none of them are inhabitants of the water, though a few occasionally resort to it. The activity of the smaller insectivorous lizards, when in pursuit of their food, is exceedingly curious and interesting. They watch with all the caution of a cat, and dart upon their prey with the quickness of lightning. Their movements are effected chiefly by means of their feet, and in the higher tribes exclusively so; but in those species in which the legs are short, and the feet very small, in proportion to the length of the body, progression is greatly assisted by the lateral motion of the trunk, which works its way along somewhat in the manner of that of the serpents.

The order is usually subdivided into five families—1. The LACERTINIDÆ, characterised by the small head and thick neck, but particularly by the very long slender forked tongues of the animals composing it. This group includes the common lizards of this country, and most of the Saurians whose habits are peculiarly active. 2. The IGUANIDÆ, having the same general form, but short thick tongues, and including some of the largest of the Sauroid type, both recent and fossil. Among these may be noticed the genus *Draco*, the animals included in which are distinguished at the first glance from all other Saurians, by the possession of a pair of wing-like appendages to the sides of the body. These are formed by extensions of the skin, supported by the false ribs, which are much prolonged, and serve as a kind of parachute, on which this little dragon, not many inches long, flutters from branch to branch in search of its insect prey; and also as a support to it when shooting, like the flying-squirrel, from tree to tree. These animals, the only living representatives of the fabulous dragons of the olden time, are found in the woods of tropical Africa and Asia, especially in the Indian Archipelago. 3. The GECKOTIDÆ, which are nocturnal in their habits. These have not the attenuated form of the previous families, but are flattened, especially on the head. Their legs are short, and their movements comparatively tardy. Their colour is usually very sombre; and they are reputed, but without foundation, to be venomous. 4. The CHAMÆLEONIDÆ, whose tongue is of immense length, but obtuse at its point. The feet and tail are both peculiarly adapted for climbing; the former having two of the toes opposable to the rest, and the latter being round and prehensile. Their movements are very slow, except when the tongue is darted out to secure its insect prey. 5. The SCINCOIDÆ, or Serpent-lizards, which are recognised by the shortness of the feet, the non-extensibility of the tongue, and the equality of the tile-like scales which cover the whole body and tail.

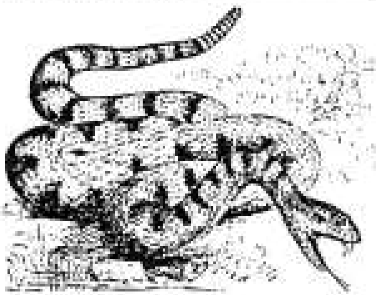
V.—Ophidia.

The animals composing this order are at once distinguished not only from all other Reptiles, but from all other Vertebrata (except certain fishes of the *eel* kind), by the entire absence of members or appendages for locomotion. Although no trace of these is ever perceptible externally, there are some species bordering upon the Saurians in which rudimentary legs can be detected; and these approximate, therefore, towards the lizards in their own tribe, just as the two-legged long-tailed lizards approach the serpent in theirs. Although apparently so different from other reptiles, Serpents are to be distinguished from lizards by little but the absence of extremities; since, in the possession of teeth, and in the scaly covering of their bodies, as well as in their general interior organisation, they closely correspond with them. They pass the coldest part of the year in a state of torpidity; on emerging from which, they slough or cast their skin. Their progression is accomplished in two ways: sometimes the whole body creeps along the ground, the scales on its under side serving (like the minute bristles of the earthworm) as so many points of resistance to a backward movement, when the trunk is elongated, after being contracted; and sometimes it is bent upwards into a series of arches, by which the tail is brought near the head; and when these are straightened, the head is thereby projected forwards. In crawling along the ground, they are much assisted by the points of the ribs, which do not meet again in a sternum, but bear upon the ground, and serve as so many short feet, having a certain power of movement in themselves by means of the intercostal muscles. Most serpents can swim when placed in the water; and there is one group which is pre-eminently aquatic, and is distinguished by its vertically-flattened tail. So closely do the members of this group resemble certain species of the eel tribe, that it is not always easy to determine to which a specimen belongs, until its respiratory organs have been examined. The great flexibility of the body is partly due to the very large number of vertebræ (from 200 to 300) composing the spinal column, each of which is united to those before and behind it by a very beautiful ball-and-socket joint. A large group of serpents is distinguished by the possession of venomous teeth, or *poison fangs*, in addition to the ordinary teeth. (See fig. of rattlesnake.) These are sharp, long, and tubular, and are connected at their roots with a gland by which the poison is secreted; and this is instilled into the wound through the tube in the tooth.

As in the case of other reptiles, we find that serpents only attain their full development in warm climates, having very little proper heat of their own. The species inhabiting the temperate zone are not nearly so remarkable either for size, brilliancy of colour, or poisonous properties, as those which exist between the tropics. The order may be divided into five families—1. The COLUBRIDÆ, consisting of the *Boas*, *Pythons*, *Colubers*, and other non-venomous snakes not belonging to the subsequent orders; 2. The CROTALIDÆ, containing the *Rattlesnake*, *Viper*, and all the venomous species; 3. The HYDROPHIDÆ, or *Water-snakes*; 4. The AMPHISBÆNIDÆ, or *Double-walkers*; 5. The ANGUINIDÆ, or *Slow-worms*.

The COLUBRIDÆ are particularly distinguished by the power of dilating the opening of the jaws to an enormous extent, so as to permit of animals being swallowed which are much larger than the diameter of the serpent itself. This is accomplished by the separation of the jaw-bones into various pieces, which are very movable on one another and on the skull. The most remarkable species of this family, which is the most numerous of the order, are the *Boa Constrictors* of the new world and the *Pythons* of the old; these, when full grown, attain the length of from thirty to forty feet, and in thickness nearly equal a man's body. They do not fear to attack any animal; and if they can once coil themselves round it, crush it by the enormous combined power of their muscles, in spite of all its means of resistance and defence. Their power is much increased by coiling the tail round a tree, so as to give a point of support from which the muscles may act more efficiently; and it is in this manner that they commonly wait for their prey. When they have seized and entirely destroyed it by crushing, in which process all the principal bones are broken, they begin to swallow it. The process of digestion takes some days, or even weeks, for its performance, according to the size of the prey; and during that time the monster lies in a very inactive state, only issuing forth to seek a new victim when the digestion of the last has been for some time finished. The hair, horns, and other least digestible parts are usually disgorged during the process. The Boas are distinguished from other serpents by the presence of two projecting bones near the vent, which are called *claspers*, and which may be regarded as the rudiments of posterior extremities. The *Colubers*, strictly so called, are of comparatively small size; but their habits are the same in proportion.

The CROTALIDÆ, or *Venomous Serpents*, do not differ much in external characters from the preceding family; but the character of their teeth is quite sufficient to distinguish them. The poisonous properties of the different species vary considerably; in general, they are more severe in the serpents of warm climates than in those of temperate regions. Cases of death from the bite of the British viper are very rare, and are generally to be attributed in part to some previously-existing derangement of the system. There are many serpents in the torrid zone, however, whose bite is fatal to man and to other large animals in a few hours. This family contains two principal sections—the *Rattlesnakes* and the *Vipers*. The former are generally regarded, but probably incorrectly, as the most venomous of all serpents. The rattle at the end of the tail, which is their distinguishing characteristic, is formed of several separate pieces of a dry horny substance, one of which is received within another. They are quite loose, and receive no nourishment after they are once formed. A new piece is said to be added every time the skin is cast, which usually takes place twice a-year. The sound made by the rattle is not great in the ordinary motion of the serpent, and cannot be heard at more than two or three yards' distance. Several species of *Crotalus* are described, varying in length from four to eight feet. They are all natives of America. Their ordinary food consists of birds, squirrels, and other small animals. It was once supposed that they possessed the power of charming or fascinating these animals: this is certainly an error; but it is equally certain that most animals are so terrified at the sight of the rattlesnake, as to lose the power of escape, and so become an easy prey.



Rattlesnake.

The *Vipers*, being destitute of the peculiar characteristic of the Rattlesnakes, are more like the Colubers; their forms, however, are less elegant, their colours less splendid, and their movements less active. In general, they are remarkable for the dark lurid tints of their covering. The most deadly species of this group is the *cobra di capello*, or *spectacle-snake* of the East Indies. Its first name, given to it by the Portuguese, signifies hooded snake, and is derived from the power of dilating the skin behind the head, when irritated, so as to give the appearance of a hood. The English appellation is bestowed in consequence of a mark, in the shape of a pair of spectacles, behind its head.

The Hydrophidæ, or *Water Serpents*, are comparatively few, and are limited in their geographical range. They are mostly found in the seas and rivers of the East Indies.

The Amphisbænidæ, or *Double-Walkers*, are a still smaller group, intermediate in some respects between the true serpents and the slow-worms. They derive their name from the power of moving either backwards or forwards with equal facility. The two extremities of the body are so much alike, that they would not be distinguished by a superficial observer, the eyes being so very small, as sometimes to appear wanting: the whole body is of nearly equal diameter. They are restricted to the warmest parts of South America: and notwithstanding the common idea of their venomous properties, are quite harmless.

The Anguinidæ may almost be called either lizards or serpents, so remarkably do they combine the characters of the two orders. In one species, the rudiments of hind legs form a visible projection near the vent; and in another, the anterior ribs are connected by a cartilage which is the rudiment of a sternum. The common *slow-worm* or *blind-worm* of this country has received its second name from the supposed absence of eyes; this is an absurd error, however, as the eyes, though small, are very brilliant. It is a perfectly harmless animal, feeding on insects, slugs, &c.

VI.—Amphibia.

The general peculiarities of the Amphibia may be thus stated:—Their skin is soft and naked, being destitute of scales or plates. Most of them undergo a metamorphosis which has reference to a change of condition, from the form of a water-breathing fish to an air-breathing reptile. In many species, however, little change is seen from the time that the animal emerges from the egg to its adult stage. With the exception of the frogs, they have much the form of lizards, and have generally four feet and a lengthened tail.

The order, which contains but a small number of different genera, may be best subdivided according to the degree to which the metamorphosis proceeds. Thus, in the first, Anoura, embracing the *Frogs* and *Toads*, the gills are entirely lost in the perfect state, and the tail also disappears. In the Urodela, including the *Salamanders*, *Water-Newts*, &c. the gills disappear in the perfect state, but the tail is retained. The Amphipneusta, to which the *Proteus* and *Siren* belong, retain their gills during the whole of life; the tail continues to form a large part of the body, and in some instances only two legs are developed. In the Abranchia, a group which consists only of two little-known genera, no gills have been found at any period of life, but the body and tail are evidently formed for swimming. And in the Apoda, including only one genus, the *Cœcilia*, the body is altogether destitute of feet, and has a serpent-like form.

The principal subdivisions of the first group are the Ranidæ, or *Frogs*, and the Bufonidæ, or *Toads*. The former frequent water, and are adapted for swimming in it; the latter are usually found at a distance from water, and are much less adapted for active movements of any kind. The metamorphosis of both these is attended with the same general phenomena. It is one very easily observed, for, by obtaining a little water containing young tadpoles, the whole process may be made to go on under our eyes, and the young naturalist is earnestly recommended to watch it for himself. The spawn, soon after its deposition in pools, consists of a transparent gelatinous mass, enveloping a number of little black dots, which are regularly distributed through it, and which are the eggs. These are abundantly found in stagnant pools in the month of April, being usually deposited (in this country) at the end of March, and hatched about a month afterwards. When the tadpole first emerges, it presents, in every respect, the appearance of a fish. It has a large oval head, and an elongated tail, flattened vertically, by the vibrations of which it swims actively through the water. The gills are found hanging in tufts on each side of the head; and if examined with a microscope, the motion of the blood through them may be very beautifully seen. The circulation may be observed also with great facility in the fin-like expansion on the upper and under edge of the tail. Very soon, however, the gills are withdrawn, as it were, into the head, being covered over by a fold of skin analogous to the operculum, or gill-plate of fishes. The little creature, which at first seemed to derive its subsistence from the fluid absorbed within the body, and on its surface, now seeks its food amidst softened or decomposing vegetable matter; and, to give greater power of movement, the surface of the tail is considerably increased. It now undergoes but little change in external form for a considerable time, but increases rapidly in bulk. The first appearance of limbs is seen in a tubercle or knob which projects at the back of the head; this is the rudiment of the hind leg. It soon acquires somewhat the form of the perfect limb, the toes budding, as it were, at the extremity; but it still continues very short, even in proportion to the diminutive size of the animal. Meanwhile, the fore legs are also budding out in the same manner, and gradually assume their distinct and ultimate form. During this process, the development of the body advances at the expense of the tail, which is gradually removed by absorption. The gills disappear by a similar process. The little animal has now undergone its complete development, and having, at the same time, become capable of respiring air by true lungs, and of moving freely on land by means of its hinder legs, it comes to the shore to feed on small insects and worms, which are henceforward to constitute its nutriment. Such multitudes of these little beings are often found in damp weather enjoying their new scene of existence, as to have given rise to stories of showers of frogs, which are still believed in some parts of the country. They now grow with great rapidity during the rest of the year; but on the approach of winter, retire to the mud at the bottom of the water, where they congregate in large masses, remaining torpid until the return of spring.

The BUFONIDÆ, or *Toads*, are a perfectly harmless and inoffensive race, although certainly not inviting in their general aspect. The idea of their venomous character is altogether unfounded. The body is of a dull hue, its shape awkward, and its movements appear difficult; but it is by no means deserving of that disgust which it has inspired in some naturalists, as well as in the popular mind. It issues forth from its concealment at twilight in search of food, which consists of insects, worms, slugs, &c. When about to feed, it remains motionless, with its eyes turned directly forwards upon the object, and the head inclined towards it; and in this attitude it remains until the animal moves, when, by a stroke like lightning, the tongue is thrown forward upon the victim, which is instantly drawn into the mouth. So rapid is this movement, that it requires some little practice, as well as close observation, to distinguish the different motions of the tongue. This organ is folded back upon itself, as in the frog; and the under surface of the tip is imbued with a viscid secretion, which adheres to the prey. The toad, like the other Amphibia, becomes torpid in winter; but instead of returning to the water, like the frog, it chooses for its retreat some sheltered hole, or a space amongst loose stones.

The members of the section URODELA bear so strong a general resemblance to lizards, that they were united with that group by *Linnæus*, and are still popularly regarded as such. The *Salamanders* and their allies, however, are easily distinguished by the smoothness and softness of their skin, which is entirely destitute of those scales which all lizards possess. Moreover, they undergo a metamorphosis similar to that of the frogs, except that the change of form does not proceed to the same extent. Like the Anoura, this group may be subdivided into two families, of which one—the TRITONS—is of aquatic habits even in the adult state; whilst the other—the true SALAMANDERS—bears more analogy with the toads in its aspect and habits.

Of the TRITONS, several species exist in this country, and are known under the names of *Evat, Eft, Newt, &c.* The largest is about six inches in length: it is not at all uncommon in ponds and large ditches, where it lives upon aquatic insects and other small living animals: it even devours the smaller species of newt. The *Salamander* is a land animal, of the same general character with the water-newt, but possessing a rounded instead of a flattened tail, and a surface somewhat warty, like that of the toad. It discharges, when alarmed, an acrid secretion from the tubercles in the skin, which is said to be poisonous to small animals. In other respects it is quite harmless, and is not possessed of any remarkable properties.

The members of the section AMPHIPNEUSTA exactly resemble salamanders, the development of which has been checked just at the period of their transformation from aquatic to air-breathing animals. They retain their gills during their whole life, and acquire lungs in addition by the partial metamorphosis they undergo. The legs bear but a very small proportion, in their degree of development, to the tail; and in some instances only one pair is formed. The first-discovered animal of this order was the *proteus*, an inhabitant of the underground lakes of Carniola and Styria, and of the passages between them. So strongly does this resemble the larva of a salamander, that it was at first believed by naturalists to be such; and it was only after the discovery of others of the same character, that its true nature was understood. Unlike most other animals, it appears to suffer injuriously from light; for not only does it prefer dark places, but even dies if it be exposed to open day for any length of time without the power of hiding itself. The *siren* is an animal of similar character, inhabiting the North American rivers, where it feeds upon earthworms, aquatic insects, &c. in search of which it burrows in the mud. Only the anterior pair of feet is developed, and there is no rudiment of the others.

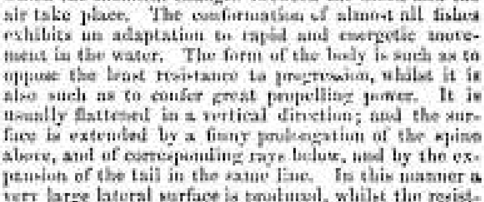
The group ABRANCHIA contains only two genera, and these both peculiar to North America—the *menopoma* and the *amphiuma*. They are not known to undergo any metamorphosis, but breathe by lungs during the whole period of life, and have never been seen destitute of legs. These are, however, very short, and seem almost useless appendages to the body, which is shaped like that of an eel.

The APODA present but one genus, the *Cæcilia*, blindnewt, or naked serpent. Its name was conferred by Linnæus, on account of its supposed blindness. The eyes are exceedingly small, and are nearly hidden under the skin, and it is believed that, in some species, these organs are altogether wanting. These animals frequent the rivers and marshy grounds of many tropical countries: further information in regard to them is much needed. They are said to burrow in the ground, and to live very much in the manner of earthworms.

CLASS IV.—FISHES.

The animals of this class are the only Vertebrata which, in their adult state, are formed for respiring beneath the surface of the water they inhabit. In them, as in the Mollusca, the blood receives its necessary purification by being exposed to the air contained in the surrounding fluid. This is done by its transmission to a series of delicate filaments, constituting the *gills*, each of which consists of two minute blood-vessels (one to convey the blood from the heart, and the other to return it), enclosed in a delicate membrane, through which the chemical changes between the blood and the air take place. The conformation of almost all fishes exhibits an adaptation to rapid and energetic movement in the water. The form of the body is such as to oppose the least resistance to progression, whilst it is also such as to confer great propelling power. It is usually flattened in a vertical direction; and the surface is extended by a finny prolongation of the spine above, and of corresponding rays below, and by the expansion of the tail in the same line. In this manner a very large lateral surface is produced, whilst the resistance to forward movement is very small. The propulsion of the fish is chiefly effected by the movement of the whole body and tail from side to side, which operates in precisely the same manner as the oar of the sculler; and this is facilitated by the great flexibility of the spine, the bones of which are so united together as to move with the slightest possible effort.

The propulsion is usually aided by lateral fins, which answer to the legs and arms or wings of higher Vertebrata. Besides the fins on the central line of the body, above and below (of which the one running along the back is called the *dorsal* fin, and the one under the body the *anal*), there are generally found two *pairs*, of which one, corresponding to the anterior extremities of other Vertebrata, is always situated near the head, and is called the *pectoral*; whilst the position of the other,



a, dorsal fin; *b*, pectoral fin of one side; *c*, ventral fins; *d*, anal fin; *e*, caudal fin or tail.

corresponding with the posterior extremities of land animals, and called the *ventral*, is extremely variable. Sometimes the ventral fins are placed far back, in the usual position of hind legs; and sometimes they are fixed far forwards, even anteriorly to the pectoral. It is chiefly by the vibrations of the pectoral fins that the animal is raised or depressed in the water; and they also assist in changing its direction from side to side. The forward position of the ventral fins is chiefly noticed in those species whose habits involve a considerable variation of their depth in water. Sometimes one, and sometimes both pairs of these fins are absent; in the latter case the fish is said to be *apodal*, or footless. In other instances, the pectoral fins are enormously developed, like the wings of birds, and even enable the animal to rise out of the water, and to skim for a short time along its surface.

The surface of the body is generally covered with numerous scales, which vary considerably in form and size in different species. Each scale is attached to the skin of the fish by its anterior edge, which is covered by those in front of it, whilst its posterior edge overlaps the scales behind it. This arrangement is not universal, however; for the scaly covering is sometimes formed by a series of bony or even enamel plates, united to each other by their entire edges. Such an arrangement was very common in the fishes existing at the time of the coal formation (see GEOLOGY), but is now much more rare.

When we consider that more than two-thirds of the earth's surface is covered with water, often to a very great depth, and that, as far as is known, the whole of this element is habitable by fishes, little doubt can be entertained that they form the most numerous class of vertebrated animals. Their numbers are kept up by their extreme fertility. The cod-fish has been ascertained to lay not much fewer than four millions of eggs at a single deposit; and in other species the number may even be greater. Their voracity is also extreme. Almost all of them are adapted to devour and digest animal food, some of them living chiefly on crustacea, mollusca, and other invertebrate inhabitants of the ocean; and others having it for their especial function to keep down the inordinate multiplication of their own kind. Some attain a considerable size. The pike has been found nineteen feet long. The sun-fish has reached the length of twenty-five feet; and some rays and sharks have exceeded forty feet.

The primary division of the class is into the *Osseous* and *Cartilaginous* Fishes, the former having a hard bony skeleton, and the latter having one of less firm consistence, possessing but little calcareous matter. The former group is divided into six orders, which are principally characterised by the structure and arrangement of the fin rays. These are distinguished as either consisting of a single piece—in which case, whether stiff or flexible, they are said to be *spinous*—or as consisting of a number of jointed pieces, divided at their extremities, when they are called *soft* or *articulated*.

DIVISION I.—OSSEOUS FISHES.

I.—Acanthopterygii.

The Acanthopterygii, or Spiny-finned Fishes, are divided by Cuvier into fifteen families, the most important of which will be noticed:—

PERCIDÆ, the *Perch* tribe. These are very numerous in the waters of all warm climates, some species inhabiting the rivers, and others the open sea. Their bodies are oblong, and covered with hard or rough scales; and the gill-covers are toothed at the margin. They are mostly *thoracic*, or have the ventral fins under the pectoral. Their teeth are very minute, and set close together in numerous rows. Their flesh is in general agreeable and wholesome. This family includes all the fish known as Perches, of which some species are found in almost all the rivers in the world, and a large number of marine fishes used as food on different shores.

TRIGLIDÆ, the *Gurnard* tribe. These bear a general resemblance to the Perches, but have the head peculiarly armed with spines or hard scaly plates. In several species the pectoral fins are very much extended; but in none, except the flying-fish, are they sufficiently powerful to raise the animal out of the water. Many species of this tribe are found in the temperate seas. The most interesting of all is the *dactylopterus* or *flying-fish*, which has a kind of supplementary pectoral fin on each side, formed of a membrane stretched over finger-like processes, which in the gurnards are unconnected. By the impulse of these on the surface of the water, the flying-fish can raise themselves to the height of several feet into the air, and can suspend themselves above the surface for a few seconds, often skimming lightly over it for a considerable distance; but they cannot sustain themselves in the atmosphere for any length of time. They are gregarious; and it is when a shoal of them is chased by the *coryphæna* (commonly, but erroneously, termed *dolphin*), or some similar enemy, that the most remarkable leaps are taken. They not unfrequently fall upon the deck of a large vessel that may be passing amongst them.

The family SQUAMIPENNES is so named because the soft, and even the spinous parts of their dorsal fins are so covered with scales, as not to be distinguished from the rest of their bodies. The most interesting genus is the *Chætodon*, of which several species, remarkable for the beauty of their colours, abound in tropical seas. One of these, the *C. rostratus*, which has a very prolonged snout, has the faculty of shooting insects with drops of water projected from the mouth, and it then seizes them as they fall. This power is the more extraordinary, as, according to the laws of the refraction of light, the place of the insect will appear to the fish different from the reality, the rays passing from a rarer to a denser medium; and the drop must not, therefore, be projected in the line in which the insect *appears* to be, but somewhat below it. This little fish, which is a native of India, is often kept in glass vases by the residents there, as gold-fish are in this country, for the purpose of affording amusement by its dexterity.

The next family, SCOMBERIDÆ, or the *Mackerel* tribe, is one of very great importance to man. It comprises a large number of genera, a vast collection of species, and numberless individuals. The aspect of the common *mackerel*, with its spindle-shaped, beautifully-coloured, smooth, and small-scaled body, is well known. It very rapidly dies out of water, and soon becomes tainted. Mackerel has been supposed to be migratory, on account of its appearing on our shores, in immense shoals, at particular epochs. The fact is, that it passes most of the year in the open sea, and its object in approaching the shore is to deposit its spawn; after which, those that have escaped being entrapped by the ingenuity of man, return to their former quarters. The extent and importance of the mackerel fishery of Britain, especially in the south and east, are well known. The *tunny* is an allied species, attaining a much greater size, and also valuable as an article of food. This frequents the Mediterranean, and is occasionally seen on our own shores. It sometimes attains the length of fifteen or even eighteen feet. To this order belongs also the *xiphias*, or *sword-fish*, distinguished by its long pointed beak. This is a most powerful offensive weapon, and with it this fish attacks the largest inhabitants of the ocean. By its high dorsal fin and expanded tail, it is able to impel itself forwards with great force; and when attacking a large animal, it makes a violent dart against it, quite transfixing it with its sword. It has been known in this manner to drive its beak into the timbers of a ship, and not being able to withdraw it, to break it off and leave it. The sword-fish abounds in the Mediterranean, but is less frequent in the Atlantic. It is very palatable as food; and often attains the length of fifteen feet. The *dory*, of which one species is highly prized by epicures, is another fish of the same family. It is remarkable for the filamentary prolongations from its dorsal fins. And lastly may be mentioned the *coryphæna*, commonly known as the *dolphin*. This is a large and splendidly-coloured fish, which darts through the water like a radiant meteor, exhibiting an extraordinary play of colours when brilliantly illuminated. It has long been celebrated for its change of colour when dying. It swims with great rapidity, and is very voracious, committing great havoc among the flying-fish and others of like size.

The fishes of the family PHARYNGINÆ LABYRINTHIFORMÆ, are characterised by a very peculiar structure, from which they derive their designation. The membranes of the pharynx (or back of the mouth) are divided into small irregular leaves, containing cells among them, which the fish can at pleasure fill with water; and, by ejecting a portion of this water, it moistens its gills, and may thus continue its respiration out of its proper element. By means of this apparatus, which resembles that possessed by the land crabs, these fishes are enabled to quit the pool or rivulet which constitutes their usual element, and move to a considerable distance over land. Such a provision is especially desirable in tropical climates, where shallow lakes are often dried up by a continued drought, and their inhabitants must perish if not enabled to migrate. The people of India, who often witness the appearance of these fishes where they were known not to exist, believe that they fall from heaven. Some of them are able not only to traverse plane grounds, but can climb steep banks, or even trees, in the course of their journeys. Of these, the most curious is the *anabas*, commonly known as the *climbing perch* of Tranquebar, which climbs bushes and trees in search of its prey, a species of land crab, by means of the spines on its back and gill-covers.

The members of the family GOBIIDÆ, or *Goby* tribe, are known by the thinness and flexibility of their dorsal spines. Many of them are remarkable for producing their young alive, the eggs being hatched within the body of the parent. This is the case with the *blenny*, of which several species frequent the British shores, living in small troops among the rocks. They are remarkably tenacious of life, being capable of being kept a good many days in moist grass or moss, but they are of little value as articles of food. The true *gobies* are chiefly remarkable for the *nest* which they construct among the sea-weed for the protection of their young, which was observed by the ancients. They prefer a clayey bottom, in which they excavate canals, and in these they pass the winter.

The next family, PECTORALES PEDUNCULATI, derives its name from the peculiar structure of the pectoral fins, which have a kind of wrist formed by the elongation of the bones to which they are attached. This conformation gives these fishes a very strange appearance, and enables them to leap suddenly up in the water in pursuit of their prey, and even to leap over the mud. In many of them the skeleton is demi-cartilaginous. One of the most curious is the *lophius*, or *fishing-frog*, of the British seas, which is met with chiefly on muddy shores. It derives its name in part from its wide gaping mouth, and in part from the peculiar manner in which it angles for its prey. It has some curious appendages to its head, which terminate in long, round, and rather brilliant filaments, having a resemblance to worms. The animal lurks in the mud, and puts these appendages in vibration; they are mistaken for worms by small fishes, which they attract, and these are gulped down the capacious swallow of the lophius. To such an extent is this voracity carried, that the *angler* (as it is sometimes called) is often an article of value for the live fish which it has in its stomach, although its own flesh is worth but little. There is an allied genus, the *chironectes*, of which a species abounds on the north coast of Australia. When the tide ebbs far back in the dry season, these frog-fishes are so abundant, and capable of taking such vigorous leaps, that those who have visited these places have taken them at first sight for birds. The fishes of this genus can inflate their large stomachs with air, in the manner of the Tetrodons.

II.—Malacopterygii Abdominales.

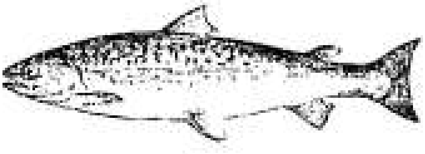
This order, consisting of Soft-spined Fishes which have the ventral fins under the abdomen, contains five families, all of which are highly interesting to the naturalist.

1. The CYPRINIDÆ, or *Carp* tribe, are all fresh-water fishes. They have the mouth shallow, the jaws feeble, and very often without teeth, but the pharynx is strongly toothed. They are among the least carnivorous of fishes, feeding chiefly on seeds, the roots of plants, and decomposing vegetable matter. The common *carp* is imported into England from the warmer parts of Europe; it thrives better in ponds or lakes than in rivers, it feeds on insects and worms, as well as on vegetables, and it is very tenacious of life, so that it is easily transported from place to place.

2. The ESOCIDÆ, or *Pike* tribe, contains the most voracious fresh-water fishes, as well as several important marine species. The *pike* is very destructive of the smaller fishes in the ponds and rivers in which it exists, and sometimes attains a considerable size, weighing between thirty and forty pounds. The *gar-fish*, or *sea-pike*, is an allied species, frequenting the British shores, and stretching into the arctic regions. Some of this kind have been known to attain the length of eight feet, and to bite very severely; hence they may be considered as the sharks of northern seas.

3. The SILURIDÆ are distinguished from all the rest of the order by the want of true scales; having only a naked skin, or large bony plates. The fishes of the genus *Silurus* inhabit the rivers of warm countries: they have a strong spine in front of the dorsal fin, which can be laid flat on the shoulder, or perpendicularly erected, so as to become a formidable weapon; and the ragged wounds inflicted by it are reputed (but probably erroneously) to be poisonous. One species, belonging to the sub-genus *Malapterurus*, an inhabitant of the Nile, and of the rivers of Central Africa, has electric properties, similar to those of the gymnotus.

4. The fishes of the order SALMONIDÆ, known as *salmons* and *trouts*, are very extensively, indeed almost universally, diffused over the globe, some of them being confined to fresh water, and others passing a part of their lives in the sea, but resorting to rivers to deposit their eggs. They are distinguished by the fatty deposition in the dorsal fin, from part of which the spines often disappear. All of this family are clouded with dusky patches when young, and many remain permanently spotted. The flesh of most of them is esteemed as food. The *salmon* inhabits the seas of comparatively



Salmon.

cold regions, ascending the rivers for the purpose of spawning at seasons varying with the climate. The efforts which they make to overcome difficulties in the ascent are very great: they will not only swim against powerful streams, but will leap up cascades of considerable elevation, and find their way to the brooks and small lakes of lofty mountains. They return to the sea after this operation is accomplished, and are followed by the young produced from the eggs they have deposited. These, in their turn, ascend the rivers for the same purpose, and are understood to resort to those in which they were produced. The *trout* appears to vary much in size and colour, according to the conditions of its residence, so that it is difficult to distinguish species from mere varieties.

5. The CLUPEIDÆ, or *Herrings*, form one of the most important families in the whole class, for the amount of food it supplies to man. The fishes belonging to it resemble the Salmonidæ in many characters, but differ in having no fatty matter in the dorsal fin. They chiefly inhabit the seas of the temperate zone.

The *herring*, which periodically visits our shores in such immense shoals, was formerly supposed to migrate from arctic seas; but this is now ascertained to be a mistake, the fish being almost unknown there, and often appearing on the southern coast of Britain before the northern. The fact is rather that the herring, like the mackerel and many other fish, usually lives in the open ocean, and resorts periodically to the nearest coast to deposit its spawn.

III.—Malacopterygii Sub-Brachiati.

The Soft-rayed Fishes, which have the ventral fins brought forwards beneath, or even in advance of, the pectoral, are divided into three families:—

1. Gadidæ, the *Cod* tribe. The fishes of this genus are easily known by the softness of all their fins, and by having the ventrals inserted under the throat, and pointed. The greater number live in cold or temperate seas, and furnish a most important article of food, their flesh being wholesome, easy of digestion, and agreeable to the palate, and their numbers (owing to their extraordinary reproductive power) extremely abundant. The *cod* is nearly the largest of the family, but is usually surpassed by the *ling*, which is commonly from three to four feet long: both these are especially valuable for their excellence when salted. The *haddock* is a smaller species, nearly allied to the cod; for, eating in the fresh state, it is perhaps the most delicate of the whole family. Many other species are useful to man, occurring in large numbers in particular localities. Such are the *whiting*, the *coal-fish*, the *pollock*, the *hake* (of which some species frequent high southern latitudes), the *burbot* (which ascends rivers), the *rockling*, and many others. Besides their use as food, these fish are valuable on account of the oil obtained from their large livers, which is very serviceable in the arts.

2. The second family is that of Pleuronectidæ, the *Flat-fish* or *Flounder* tribe. The form of these fish is peculiar, not only for the extreme flattening of the body, but for its deficiency in symmetry. The two flat surfaces—one of which (in the ordinary position of the fish during life) is above, and the other below—are in reality the two *sides* of the fish, differing in several important respects. Both the eyes are placed on the upper side; and its colour is usually much deeper than the other. The body, from the head backwards, partakes a little of the same peculiarity. The two sides of the mouth are not equal, and the pectoral fins rarely so. On the other hand, the dorsal fin, which runs along one of the lateral edges, corresponds with the anal, which occupies the other, and with which the ventrals are sometimes united; so that, when we look at the fish in its usual position, its body appears more symmetrical than it really is. These fishes are destitute of air-bladder, and they frequent the bottom of the sea, from which they seldom rise far. The colour of their upper surface usually corresponds closely with that of the ground on which they lie; and thus they escape the observation of their enemies, and are unnoticed by the small fishes on which they prey. Individuals are occasionally found, however, in which both sides are alike; these are called 'doubles:' it is usually the dark side which is doubled. The fishes of this family are found along the shores of almost all countries, and are, generally speaking, wholesome and agreeable as food. The form and aspect of the different species exhibit little variation. The *flounder*, *turbot*, *brill*, *plaice*, *dab*, and *sole*, are the chief species of our own coasts: the *halibut* is a very large species, attaining the length of six or seven feet, and weighing 500 lbs., occasionally taken in the British seas; and other species inhabit the Mediterranean.

3. The Discoboli, so named from having their ventral fins formed into a sucker or disk, are the last family of this order. By this curious provision, these fishes have the power of attaching themselves to rocks and other hard substances, and thus remain and find their food in situations where every other species would be swept away by the current of water.

IV.—Malacopterygii Apoda.

The fishes in which the ventral fins are wanting form but one natural family—the Murænidæ, or *Eel* tribe. They are all lengthened in form, have the spine extremely flexible, the skin thick and soft, and the scales almost invisible. In most of them, the external gill-apertures are very small, and open very far back; by which arrangement they are enabled to keep the gills moist for a long time when out of water, whilst the roundness and flexibility of their bodies facilitate their motion upon land. Many of them inhabit rivers, whilst others are exclusively marine. The *eel* is the kind most abundant in Britain. The *conger* is a marine eel, frequenting the European seas; it is one of the largest of the family, being from four to six feet long, and as thick as a man's leg. The *gymnotus*, or *electric eel*, is a native of the South American rivers. It attains the length of five or six feet, and communicates shocks so powerful, that men and horses have been stunned by them. This power seems voluntary, and can be sent in a particular direction, or even through the water, the fish in which are killed or stunned by its shocks. By giving these, it is greatly exhausted, and requires rest and nourishment before it can renew them.

V.—Lophobranchii.

This order is a very small one, containing but one family, of which the genera are few. Their appearance is very peculiar. The tufted gills are covered by a large operculum; but this is bound down by membranes on all sides, so that there is only one small hole for the water to escape. The body is covered, not with small scales, but with shields or plates, which often give it an angular form. In general, they are of small size, and almost without flesh. The *syngnathus* possesses a long tubular snout; it is peculiar for the protection which it affords to its young, which resembles that provided in the marsupial Mammalia. The eggs are conveyed into a sort of pouch under the body of the male, and are hatched there, the young fry afterwards finding their way out. Some of these are found in the British seas, as are also the *hippocampi*, commonly called sea-horses, from the resemblance of the upper part of the body (especially when the dead specimen bends in drying) to the head and neck of a horse in miniature. Their tail is prehensile, and they climb or hold on to the stalks of marine plants by its means. Some of this family are almost destitute of fins, having none but the dorsal.

VI.—Plectognathi.

This order, the last of the Osseous Fishes, approaches the cartilaginous in many points of its organisation; principally, however, in the slow ossification of the skeleton, and the imperfect structure of the mouth. They derive their name, as already stated, from the union of the upper jaw to the skull; so that its motion is obtained, not from a distinct joint, but by the mere flexibility of the half-ossified cartilages. The gill-lid is concealed under the thick skin, with only a small opening; the ribs are scarcely developed; and there are no true ventral fins. The order contains two families.

1. The Gymnodontes, or Naked-toothed Fishes, are distinguished by having the jaws covered with a substance resembling ivory, arranged in small plates (which are reproduced as soon as destroyed by use), and really representing united teeth. The most remarkable species are the spinous globe-fishes, *diodon* and *tetraodon*, which have the power of blowing themselves up like balloons, by filling with air a large sac which nearly surrounds the abdomen. When thus inflated, they roll over with the belly upwards, and lose all power of directing their course; but they are remarkably defended by spines over their whole surface, which are erected as they are inflated. They are mostly inhabitants of warm seas, but a specimen is occasionally drifted to our coasts. The *sun-fish* has a body of somewhat similar form, but incapable of inflation: the tail

is so short, that it looks like the anterior half of a fish cut in two in the middle. Some species attain an immense size; one which is occasionally taken on the British coast has been known to weigh 300 lbs.

2. The second family, SCLERODERMI, contains fishes which are remarkable for their very hard and granulated skins. They have a prolonged muzzle, with distinct teeth. Their skin is covered with scales in some species, and in others very rough, like a file; whence they are commonly termed *file-fishes*. They are principally inhabitants of warm seas, living near rocks, or on the surface of the water, their brilliant colours sparkling in the sunshine like those of the Chætodons.

DIVISION II.—CARTILAGINOUS FISHES.

The skeleton of these fishes is not entirely devoid of calcareous matter, but this is disposed in separate grains, and does not form fibres or plates; hence the hardest portions of the framework remain quite flexible. This division contains two subordinate groups: in the first, the gills are attached by one edge only, hanging in fringes, as in the osseous fishes; in the second, they are so attached to the skin by the second edges, that the water cannot escape from their intervals except by holes in the surface. Accordingly, instead of having a single pair of large apertures, with a valve-like cover, or *operculum*, behind the head, they have as many apertures on each side as there are arches of gills. The first group contains but one order, the second two.

VII.—Chondropterygii Branchiis Liberis.

This order contains only one family, the STURIONES, or *Sturgeons*. In many of its characters, as well as in the disposition of the gills, it is intermediate between the Osseous Fishes and the Sharks, which may be regarded as the types of the Cartilaginous division. Sturgeons are chiefly river fish, and from their large size, vast numbers, and the quantity of food and other important products they afford, are extremely valuable to man. The common *sturgeon* of the British shores is about six feet long, and its flesh is somewhat like veal. The rivers falling into the Black and Caspian Seas, however, produce several other species, of which the largest not unfrequently attains the length of fifteen feet, one individual being recorded as having weighed 3000 lbs. The roe of the sturgeon furnishes the caviar so much esteemed in Russia; and from its air-bladder is manufactured the isinglass of commerce.

The section of CHONDROPTERYGII BRANCHIIS FIXIS is divided into two orders—the first having teeth, and the second having the mouth formed into a sucker:—

VIII.—Selachii.

This order only comprises one family, that of *Sharks* and *Rays*. A great metamorphosis here takes place in the condition of the bones of the mouth, those which are commonly termed the jaws, in which the teeth are fixed, being very different in position and character in osseous fishes, and the true jaw-bones not being here developed. This tribe is distinguished from other fishes by many peculiarities: in several members of it, the young are produced alive, the eggs being hatched within the body of the parent; and in others the eggs are enclosed in a peculiar horny casing, which has often long tendril-like appendages, that coil round and attach them to other bodies. This is the case with the eggs of the common *dog-fish* of our coasts, vulgarly known as *sea-purses*. The sharks much resemble ordinary fishes in their form, having the gill-openings on the sides of the neck, and the eyes on the sides of the head, in both of which respects they differ from the rays. The dog-fish differs but slightly from the true sharks, and is, in its way, equally voracious.

The *white shark* is the most celebrated species of the tribe, being, from its size and voracity, the terror of mariners in the seas it inhabits. It frequents warm latitudes, but has occasionally visited the British shores. It has been known to attain a length of thirty feet; and the opening of the jaws in the largest individuals is sufficient to admit with ease the body of a man. The mouth is placed on the under surface of the head, from which circumstance the fish cannot bite whilst in the act of swimming forwards; so that a dexterous person has been known to defend himself from its attack. The *blue shark*, which frequents the Mediterranean, the *fox shark*, or thresher, so called from the use which it makes of its powerful tail, and the *porbeagle*, are other species of this tribe which occasionally visit our shores. A remarkable genus, allied to the Sharks, is the *zygæna*, or *hammer-headed shark*, so named from the projection of the head at each side in the form of a double-headed hammer, with an eye in the middle of each extremity. The *pristis*, or saw-fish, is another interesting genus. Its general form and character are like that of the sharks, but the snout is extended like the blade of a sword, with strong and cutting tooth-like spines on both edges. With this formidable weapon, the fish, which sometimes attains the length of fifteen feet, will attack the largest whales, and inflict dreadful wounds.

The *Rays* are less numerous than the Sharks, and abound rather in temperate than in tropical seas. They are characterised by the extreme horizontal flattening of the body, in which, however, there is not (as in the Pleuronectidæ) any want of lateral symmetry. The two sides are expanded horizontally, and unite with the expanded and fleshy pectoral fins to form one continuous surface. The eyes are placed on the back or upper surface; whilst the mouth, nostrils, and gill-openings are below. To this group belong the *rays* and *skates*, *thornbacks*, and other species; but the most interesting of all is the *torpedo*, or electric ray, sometimes found on the Channel coast of England, but more abundant in the Mediterranean. The electric apparatus is of very similar structure with that of the *gymnotus*; and it is disposed in the space between the pectorals and the head and gills. The shocks given by this fish, though smart, are not so benumbing as those of the gymnotus; their use in its economy are not apparent, as the animal can obtain its prey without them. The flesh of the rays is wholesome, and that of most species agreeable as food. The skin of some is employed for polishing, and from that of others shagreen is prepared.

IX.—Cyclostomata.

The third order of the Cartilaginous Fishes, and the last of the class, is one which contains comparatively few species, and these exhibiting but a very low degree of organisation. They take their name from the adaptation of the mouth to the purposes of suction, by its transformation into a round fleshy disk, having the oral opening in the centre, and the margin supported by a ring composed of the cartilaginous jaws united together. The spinal column loses its distinct division into vertebræ, the space elsewhere occupied by these bones being traversed from end to end by a cylindrical membranous tube filled with a mucilaginous fluid; and this, in the higher species, presents cartilaginous rings at intervals, which are the rudiments of vertebræ; whilst in the lower, there is no vestige of these bodies, and the whole structure is reduced to the level of that of the Annelida. The pectoral as well as the ventral fins are absent; and the skin is soft and mucous, with scarcely a vestige of scales. This order contains but a single family. The *lampreys* are the most allied to other fishes in their general organisation; they possess teeth within the ring, and with these they tear the bodies of the animals to which they attach themselves. There is a marine species two or three feet long, and other smaller ones which inhabit rivers. The *myxine*, or *hag*, is destitute of eyes, and is altogether of lower organisation than the lamprey; but the species that differs most in its general characters from the rest of the class, is the *amphioxus*, or *lancelet*. This is a very small animal, about an inch long, sometimes found lurking under stones in pools left by the ebbing tide. It is destitute of almost every one of the characters which have been mentioned as peculiar to vertebrated animals; and, nevertheless, can scarcely be classed anywhere else than with this family.

ARTICULATA.

From the Vertebrata we might pass, in the descending scale, either to the Mollusca or the Articulata, both of which exhibit some points of approximation to that series. In both we meet, as in the Vertebrata, with very highly-organised, as well as very simply-constructed beings; in both we find animals much superior to the lowest Vertebrata; and in both, also, we find species which are in many respects below the highest Radiata. It is the necessary consequence of a *natural* classification, which aims at grouping together the different forms of living beings according to the type or plan on which they are constructed, that such should be the case. Neither of these two sub-kingdoms can be regarded as in all respects superior to the other. The high development of the locomotive power in the Articulata, strikingly contrasts with its usually slight possession by the Mollusca. On the other hand, the digestive and nutritive systems in the Mollusca are much more complex, and attain a higher organisation; so that the heart, for example, of a tunicated mollusc, is as powerful in its action on the circulating fluid as that of the highest Articulata. On the whole, however, the Articulata should be regarded as ranking above Mollusca in the animal scale, since it is in the *animal* powers that the former have the superiority.

The leading character of the series is the jointed or *articulated* form of the skeleton or hard portion of the structure, and the enclosure of the body within this. Nothing can be found in the Molluscs at all approaching in character to the shell of a lobster or the horny case of the beetle. It is the peculiarity of the skeleton in the Articulata, that it not merely encloses the body, but is prolonged over the appendages for locomotion, where they exist; and the portions of it which cover these are also jointed, for the sake of conferring upon them the requisite flexibility. This structure is more apparent, however, in some cases than in others. In the lowest members of the series, where there are no appendages for locomotion, and where all movements are effected by the body itself, this is endowed with great flexibility, and the whole envelope is so soft, that the division into segments can scarcely be recognised. This is the case, for example, in the leech and earthworm. The articulated character is most apparent in the Centipede tribe, where the segments are all of nearly equal size, and where each possesses a pair of short legs, which are themselves also articulated. But in the highest classes of the sub-kingdom we again lose the appearance of the division into segments, from an opposite cause—the consolidation of several rings into one piece. In proportion as the locomotive power is more intrusted to the extremities, so does it become unnecessary that the trunk should possess much flexibility; and in the same proportion does it become necessary that the portion of it from which arise the muscles of those extremities should be very firmly framed. Accordingly, the part of the body behind the head, which is called the *thorax*, and from which the legs and wings of Insects, and the principal walking legs of Crustacea, have their origin, very commonly appears as if composed of one piece, although it is really made up of three or more segments, each of which gives rise to a pair of external members.

The Articulata are almost invariably of small size; and the bulk of their bodies is made up, not by their digestive and nutritive apparatus, but by the muscles which move it. It is only in those which approach the Molluscs in the vegetative nature of their existence, that we find any considerable dimensions attained. As the Mollusca are an essentially aquatic group, so are the Articulata principally adapted to atmospheric respiration; and the most active among them can even quit the surface of the ground, and mount up into the air. We find their respiratory apparatus constructed, therefore, upon an opposite plan. Instead of the blood being sent into external prolongations of the surface—gills—to meet the air contained in the surrounding fluid, the air is introduced into the body to meet the blood, this being distributed on the sides of cavities or tubes into which it enters. In Insects, these tubes have a very complex and beautiful distribution through the body. The series also exhibits a peculiarity in the nervous system, which often enables us to detect the real character of doubtful animals. A double cord runs along the centre of the *lower* surface of the body, studded with knots or *ganglia* at regular intervals, which are so many centres from which the nerves pass off to the different segments. The head, also, has its ganglia, in which the double cord terminates anteriorly. Where the members, however, are not uniformly distributed along the whole body, but are concentrated to one part, as in Insects, Arachnida, and the higher Crustacea, we observe a corresponding concentration of the ganglia in that region. The degree of concentration indicates the elevation of the animal in the series.

The following classes may be arranged, in the *ascending* order, under the articulated sub-kingdom, though in some of them the characteristic structure is very indistinct:—

Annelida, or *Worm* tribe. In these the body is prolonged, without any distinct appendages for locomotion. The habitation is usually aquatic, though sometimes terrestrial. The division into segments is not very distinct, the entire skin being soft.

Myriapoda, or *Centipede* tribe. These have also a prolonged body, but are provided with legs; and the articulation of the covering, both of the body and legs, is very distinct.

Insecta, which are distinguished in their perfect state by the possession of one or two pairs of wings; by the restriction of the legs, which are never more than six in number, to the thorax; and by the division of the trunk into three portions—the head, thorax, and abdomen—which are usually very distinct from one another. They are also distinguished by their remarkable metamorphosis, commencing from a form which resembles that of the Annelida.

Arachnida, the *Spider* and *Scorpion* tribe, the members of which differ from insects in having the head and thorax united, in undergoing no metamorphosis, and in having eight or more legs.

Crustacea, which have a hard envelope, principally composed of earthy matter, and which are adapted for aquatic respiration. Many of them have the form of insects; but their legs are never fewer than ten.

The foregoing constitute a tolerably regular series, into which we must also introduce the Entozoa, that seem to exhibit the characters of the Worm tribe in their most degraded condition, and the animals composing which are parasitic upon or within others; the Rotifera, or *Wheel-Animalcule* tribe, of which some approach the Polypifera and Polygastrica, whilst others approximate the Crustacea; and the Cirrhopoda, or *Barnacle* tribe, that bear a strong general resemblance to the Molluscs, but unquestionably belong to this sub-kingdom, which will therefore embrace—

1. Crustacea.	3. Insecta.	5. Annelida.	7. Rotifera.
2. Arachnida.	4. Myriapoda.	6. Cirripoda.	8. Entozoa.

CLASS V.—INSECTS.

We begin with the Insects, which, though not the highest in point of general organisation, are the most typical of the series, and therefore afford the best standard for comparative description. As a class, they are perhaps the most interesting in the whole Animal Kingdom, both in regard to the number, variety, beauty, and complexity of the forms which it contains, the vast assemblages of individuals of the same species which not unfrequently make their appearance together, and their consequent importance in the economy of nature.

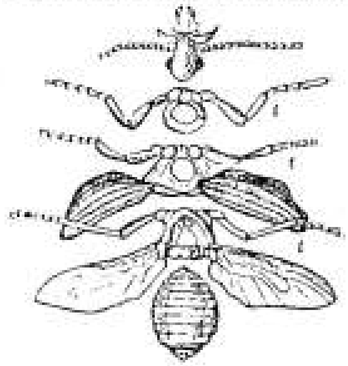
The true Insects are distinguished from the Crustacea by their peculiar apparatus for atmospheric respiration; from the Arachnida by having but six legs (eight being the number in that class), and by the division of the body into three parts; and from the Myriapoda by the limited number of legs and segments, the latter seldom exceeding thirteen. In the perfect insect, it is sometimes difficult to distinguish the division into segments; they may generally be seen, however, on the lower side of the body, especially on the abdomen. But in the larva or caterpillar state, they are never obscure, and their number is very constant, being almost always thirteen, one forming the head. Of the twelve segments of the body, three in the perfect insect form the thorax, or division succeeding the head, whilst the remaining nine constitute the abdomen. It is more common for one or two segments to be apparently deficient (being consolidated with the rest), than for any increased number to be present.

The *metamorphosis*, or complete change of form, which may be seen in the greater number of insects during their development, has attracted much attention from the earliest ages to the present time. The *larva*, which afterwards changes to a beetle, a butterfly, or a wasp, bears no resemblance whatever to the perfect or *imago* form, and is in fact allied, in almost every particular of its conformation, to a class far beneath. Moreover, it has to go through an intermediate form—if anything, still more remarkable—that of the *pupa*, or *chrysalis*, in which there is an almost complete cessation of activity, but in which preparation is being made for the exit of the perfect insect at its final change. The alteration of the entire character of the animal is no less remarkable than its change of form. In the *larva* condition, its whole energies seem to be concentrated upon the nutritive functions—the voracity being extreme, and the increase in the weight of the body very rapid; whilst, in the perfect insect, the body undergoes little increase of size, but is provided with powers of active movement, which are principally destined to enable it to seek its mate, for the purpose of propagation.

The *larva*, when it first emerges from the egg, bears but a very small proportion to its subsequent bulk. According to Lyonnet, the comparative weight of a full-grown caterpillar of the goat-moth to that of the young one just escaped from the egg, is as 72,000 to 1. During its increase, it throws off its skin several times, like the Crustacea. The larvæ in the different tribes vary extremely as to the degree of their development: in some orders they are very imperfect, not even possessing legs; whilst in others they correspond with the perfect insect in almost every particular except the presence of wings.

After attaining its full growth in the larva condition (in which the bulk of the body often much exceeds that of the imago), the insect undergoes a very remarkable change, ceasing to take food, and apparently losing all appearance of vitality. In this state it is termed the *pupa*, or chrysalis. Many larvæ enclose themselves in a silken cocoon, or in some other kind of envelope, before undergoing this change; and remain in it during the whole period of inactivity, which is sometimes many months in duration. Some bury themselves in the ground; and others, again, suspend themselves in the air. The pupæ of different orders of insects vary, like the larvæ, both in form and in degree of torpor. Some have the whole body enclosed in a horny case, without vestige of members, and are totally inactive, except when disturbed; others present the general form of the perfect insect, but appear as if the body and limbs were separately bandaged, and laid in close apposition; whilst others retain all their limbs free, and suffer no diminution in their locomotive powers or in their appetite for food. These, indeed, can scarcely be said to pass into the pupa state at all, their condition being only indicated by the gradual development of the wings—a development equally taking place beneath the envelope of the pupæ which are enclosed and inactive.

The perfect insect, or imago, when it emerges from its pupa case, exhibits in all respects the *form* which is characteristic of the species, and, in general, the size also; few growing much after they have attained this condition, and many scarcely eating at all. As already mentioned, the twelve segments forming the body of the larva may still be recognised here, but very much changed in their character. The three anterior ones are often soldered, as it were, together; forming but one strong sheath for that portion of the body from which the wings and legs proceed—and this sheath affords firm attachment for the powerful muscles which move these organs. Those which constitute the abdomen, however, retain much more of their original aspect. The head is now quite distinct from the body, and connected with it by a neck, which is often very slender. From each of the segments of the thorax a pair of legs proceeds; and the second and third usually give origin to a pair of wings each. Where, however, only one pair of these organs exists, they proceed from the second segment. The segments of the abdomen never show any vestige of legs. The accompanying diagram represents the chief parts of the perfect insect:



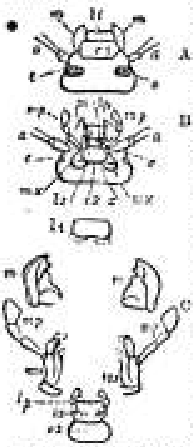
Segments of Insect.

the three segments of the thorax (*t t t*) are separated from each other to show the organs attached to them. The especial function of the perfect insect is the continuance of the species; and the wings enable it to seek its mate, and to obtain a situation fit for the deposition of its eggs, which are always laid in the neighbourhood of whatever substances will supply the larvæ with nourishment, although it most commonly happens that the image itself does not feed upon them. Many insects, such as the *silkworm* moth, and the *ephemera* or May-fly, die soon after having fulfilled this object.

However extraordinary the metamorphosis of insects, it is by no means *unique*, as was formerly supposed. The change of the tadpole into a frog is an exact parallel to it; for the tadpole is for the time a fish, resembling that class in its entire organisation, just as the maggot is for the time a worm. Moreover, we shall hereafter see, in some of the lower classes, a change which is fully as remarkable. When the larva is very imperfect, and the pupa inactive, so that its change to the form of the imago is very striking, the metamorphosis is said to be *complete*; but if the larva is more advanced, and the pupa differs little from it, and from the ultimate form of the perfect insect, the metamorphosis is termed *incomplete*.

Insects, in their perfect state, are distinguished beyond all other animals for their power of locomotion, and for the perfection of their instinctive actions. In estimating their power of locomotion, the space traversed is of course compared with the length of the body; and thus it is seen that, rapid as is the flight of many birds, that of most insects far surpasses it. The senses of insects appear likewise to be acute. They have generally large eyes, formed, in fact, by the union of a great number of small ones—often several thousand; and although these are fixed, yet, from their being directed, like the facets of a jewel, at various angles to each other, an extensive range of vision is obtained. It is believed that insects possess the power of hearing, and also of smell; though no distinct organs for receiving such impressions have been satisfactorily determined. That they have a delicate sense of touch in some part of the body, even where the general envelope is firm, cannot be questioned; and, from observations made upon the social genera, such as bees and ants, there is reason to believe that they communicate with each other chiefly by this sense.

The different organs on the head of insects furnish, by their varieties of conformation, important characters in classification. It will therefore be necessary to describe these in some detail. The most important characters, upon which, in fact, the primary subdivision of the class is founded, are drawn from the structure of the mouth: in one large group it is furnished with *mandibles*, or jaws, adapted for biting and bruising; whilst in the other, it is provided with a *haustellum*, or proboscis, adapted for suction: hence the first group is termed MANDIBULATA, and the second HAUSTELLATA. These organs are, however, but different modifications of the same primary elements.

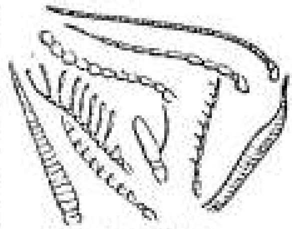


Different parts of the mouth of a beetle.*

In the mouth of the Mandibulata, six principal pieces may be readily distinguished. Of these, four are arranged in two pairs, which work against each other laterally; a fifth piece is above the upper pair, and a sixth below the lower. The two lateral pairs are the jaws; of which the upper pair is distinguished by the name of *mandibles*, and the lower by that of *maxillæ*. The mandibles are usually the largest, and are very powerful organs: sometimes they are provided with sharp or toothed edges, working against each other like those of a pair of scissors; and sometimes with hooked points, more formidable, for the size of the animal, than the teeth of the tiger. These are the principal organs by which the food, of whatever description, is usually obtained; but in the bees and wasps, of which some species are adapted to obtain their nourishment by suction, they are the instruments by which their curious edifices are built up. In a word, as has been well remarked, they supply the place of trowels, spades, pickaxes, saws, scissors, and knives, as necessity may require. The *maxillæ*, or under pair of jaws, are of similar construction, but usually smaller and less powerful. The pieces which are applied above and below to the spaces left between the jaws are termed *lips;* the upper being designated the *labrum*, and the lower the *labium*.

Various modifications of these parts are seen in the different orders of insects, but their existence may always be detected under some form or other. The most remarkable alteration in the structure of the mouth is that which we find in the Lepidoptera, or Butterfly tribe. Instead of cutting jaws, we observe a tubular appendage, or trunk, which is often of considerable length, and coiled spirally beneath the head, but capable of being unrolled when its point is required to descend into the corollæ of flowers. This tube is composed of two long narrow filaments, which are, in fact, the *maxillæ* excessively drawn out; these filaments are channelled on the sides at which they approach one another; and by the adhesion of the edges of these channels, which lock together by means of minute teeth, a complete tube is formed. In this mouth, therefore, all the parts except the maxillæ would seem at first sight to be wanting; but they may be detected by a careful examination, and the rudiments of the upper lip, of the mandibles, and of the lower lip, as well as of the *palpi* (organs to be presently described), may be distinctly demonstrated. In other instances, an entirely different modification of the same parts may be observed, which will be noticed in the proper place.

The head of the perfect insect is usually furnished with three pairs of jointed appendages, all of which are probably instruments of sensation. The first of these are termed *antennæ*; they are affixed to the sides of the head, and usually between the eyes and the mouth. The number of joints in them, and the forms they present, vary in the different tribes of insects, as also does their size, within very wide limits. Occasionally, they are three or four times as long as the whole body, and sometimes they are scarcely to be perceived: in some cases they are simple thread-like organs, gradually tapering from the base to the point; in others they swell out towards the extremity; and often they possess side branches or appendages of various forms. These different characters are extremely useful in classification. The *palpi* are organs which are not dissimilar in general character, but are usually of much smaller size, consisting of seldom more than six joints; of these, one pair is attached to the *maxillæ*, and the other to the *labium*, and are respectively called *maxillary* and *labial* palpi. The uses of these appendages are involved in some obscurity. There is good reason to believe that all of them are organs of touch; and this sense is probably sometimes most acute in the antennæ, and sometimes in the palpi. There is also reason to believe that the sense of hearing is in some way connected with the antennæ; and a curious modification of the joint at the base seems to be particularly appropriated to this function. It has been further surmised that the antennæ minister to the sense of smell.



Variously formed Antennæ.

The *wings* of insects are the organs most peculiar to them; nothing at all analogous being developed in other articulated animals. They consist of a double layer of membrane, prolonged from the skin which covers the body, and partaking of its characters. This membrane is supported by a framework of harder structure, composed of ribs, which go by the name of *veins*, or *nerves*. These terms must not be supposed to imply any analogy of structure with the organs they designate in higher animals; they are rather drawn from the analogous parts in the leaves of plants.

There is scarcely any organised substance upon which insects are not adapted to prey. In regard to the food of individual tribes, it may here be stated in general terms, that some are purely carnivorous, devouring only prey which they have themselves killed; others eat carrion, and even keep it until its decomposition is advanced. Many are herbivorous — some feeding only upon particular species of plants, whilst others are not restricted, but feed upon almost any vegetable substance. Others, again, are omnivorous, and will attack anything that falls in their way. The excessive multiplication of insects, which would result from the enormous number of their eggs, and from their rapid growth, is prevented by the influence of other tribes of animals, as well as by the wars of their own tribes against each other. The destruction of the larvæ of some species by those of others is often enormous, and far exceeds in proportion the diminution in their numbers effected by higher classes. There is no class of animals formed to exist on land, however, of which part do not derive a great proportion of their

* A, upper side; B, under side; C, parts separated: *a a*, antennæ; *e e*, eyes; *l* 1, upper lip; *m m*, mandibles; *m x*, maxillæ; *m p*, maxillary palpi; *l* 2, labium; *l p*, labial palpi; *c* 2, chin, or mentum.

food from insects; and thus, if man does not interfere with the economy of nature, a balance is maintained which is rarely disturbed. But if these higher tribes be destroyed (as, for example, if a rookery be dispersed), insects will then multiply inordinately, and will become a pest to the district.

Insects are distributed abundantly over every portion of the globe. Even in the coldest regions which man has yet explored, they present themselves to his notice during the brief summer; and no severity of the winter appears capable of destroying their vitality, although it reduces them to a state of complete torpidity. It is in tropical regions, however, that the largest and most brilliant species are found.

The subdivision of the class into orders is chiefly founded on the character of the wings; since it is found that the structure of these organs affords a good general index to that of the body. But it cannot be trusted to alone. For whilst certain orders may be included under the general designation *Aptera*, or Wingless, and another be termed *Diptera*, or Two-winged, we find wingless and two-winged insects in all the other orders.

WINGED INSECTS.

Winged insects may be distributed amongst the eight following orders, of which the first four are MANDIBULATE, whilst the rest possess a mouth formed for suction, and are termed HAUSTELLATE:—

1. COLEOPTERA (*Beetles*). In these the two anterior wings are converted into a horny or leathery substance, and enclose the posterior when folded.

2. ORTHOPTERA (*Grasshopper, Cockroach*). In these the anterior pair of wings is composed of a substance more resembling membrane.

3. NEUROPTERA (*Dragon-Fly, Termite*). Both pairs of wings are membranous, and the nerves form a close network by their interlacement.

4. HYMENOPTERA (*Bee, Wasp, Saw-Fly*). Both pairs of wings are here also membranous; but the veins have larger areas between them.

5. HOMOPTERA (*Cicada, Lantern-Fly*). In this order the four wings are of the same consistence, often somewhat like parchment; and, when folded, they incline at an angle, like the roof of a house.

6. HETEROPTERA (*Bugs*). The anterior pair of wings is horny, or leathery, but generally tipped with membrane; both pairs are horizontal, or nearly so.

7. LEPIDOPTERA (*Butterflies* and *Moths*). These have four membranous wings, covered with minute scales, which give them a downy appearance.

8. DIPTERA (*Gnat, Fly*). These have but two wings, and are in many respects parallel to the fourth order.

Besides these, there are some small orders intermediate between the principal groups. Thus a separate order, TRICHOPTERA, has been formed to include the *case-worm-flies*, which are intermediate between LEPIDOPTERA and NEUROPTERA. The order STREPSIPTERA, again, comprehends a small group termed *wasp-flies*, intermediate between the LEPIDOPTERA and DIPTERA.

I.—Coleoptera.

This order comprehends all insects which have the anterior pair of wings converted into wing-cases, or *elytra*, and which undergo a complete metamorphosis. These wing-cases are of horny consistency, and are opaque, or nearly so. When expanded, they are of little or no use in flight; and when closed, they meet along the back, in a straight line, which is called the suture. The second pair of wings constitute the true organs of flight; they are of large size, and of membranous texture; and when unemployed, they are shut up in several transverse folds, and are entirely concealed beneath the elytra. The mouth is formed for mastication, and possesses two horny mandibles. The head is provided with two antennæ, of variable form, and of which the number of joints is usually eleven; these often differ considerably in the two sexes. The eyes are large and protuberant, especially in the carnivorous species, and in these, the slowness of whose habits makes quick powers of sight necessary for the purpose of avoiding their enemies.

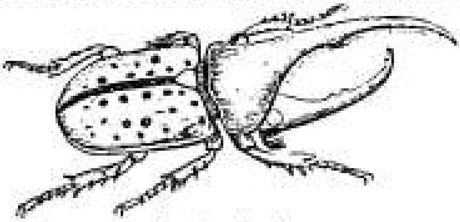
Although these characters are applicable to by far the greater number of insects included in this order, nearly all of them are subject to exceptions. Thus there are some species in which the organs of flight are altogether wanting, as in the female of the glow-worm; others which have elytra, but no wings; some, in which the elytra adhere together along the suture; others, in which they overlap; others, again, in which they do not meet; and some, in which the wings are longitudinally folded. It is well for the student to be aware that such exceptions exist in almost every large natural group, however definite its characters may generally be. In none of these instances is there an exception as to more than one or two of the characters; the remainder conform to the usual type. The most universal is that of the metamorphosis, which, being *complete*, distinguishes this order from others approaching it, either in the structure of the mouth, or in the character of the wings.

The coleopterous order comprehends an immense number of species, which have been classified, first in genera, then in tribes, and finally in sections, with a regard to the number of joints in the tarsus or divisions of the foot. Some are wholly carnivorous, others herbivorous, and some take both kinds of food. Some, again, are aquatic, while a much larger number live on land. The habits of the various families—of which we can only notice a few of the more interesting—are, upon the whole, obscure and foul.

The SERRICORNES are distinguished by the toothed or serrated structure of the antennæ. Some of this family, having the body of solid consistence, and oval in form, have the head buried, as it were, in the thorax, which advances on its two sides nearly as far as the mouth. In this way are formed the *Buprestis*, distinguished for the splendour of its colours, many of its species having spots of golden hue upon an emerald ground, whilst in others azure glitters upon the gold. These brilliant species belong to tropical climates, which these insects appear especially formed to inhabit, our native species flying with the greatest activity in warm weather. They live among trees; and if an effort be made to seize them, they counterfeit death, and fall to the ground. The beetles belonging to the allied genus *Elater*, are commonly called 'skip-jacks;' for, when laid on their backs, being unable to raise themselves on account of the shortness of their feet, they spring perpendicularly into the air, so as to alight upon their feet. This is effected by a violent backward blow of the head against the surface on which they are lying. The larva of an English species is known to the farmer as the *wire-worm*, which does much injury by devouring the roots of the corn. A species of elater inhabiting the West Indies and South America, has two brilliantly luminous spots upon the front of the thorax; and a portion of its abdomen, which is uncovered during flight, is also illuminated. Another interesting genus is the *Lampyris*, to which belong the common glow-worm, and some of the fire-flies of warmer regions. The body of these insects is very soft, especially the abdomen; and it is from the two or three last segments of this part that the phosphorescent light for which they are so remarkable is emitted. Its intensity is evidently dependent in a great degree upon the state of the animal: if the insect be irritated, it is increased; but if its powers are depressed or exhausted, it is lessened. It seems to be sometimes withdrawn simply at the will of the animal. In the glow-worm (*L. noctiluca*), it is only the female that is luminous; and she is destitute of wings and elytra, which the male possesses. They are only active by night; and as the male is known to be attracted, like moths, by lights in houses, it is probable that the phosphorescence of the female is given for the purpose of signalising her place.

The CLAVICORNES, characterised by the club-shaped form of the extremities of the antennæ, are partly terrestrial and partly aquatic; they feed for the most part on animal matter, at least in the larva state. The terrestrial ones seem to prefer substances which are in a state of decay; they creep slowly, and are mostly of a dark colour—black or bronzed. One of the most interesting genera is the *Necrophorus*, or burying-beetle, so named from its habit of excavating the ground beneath the dead bodies of small quadrupeds, such as mice or moles. Having thus interred a carcase, they deposit their eggs in it, and the larvæ, when hatched, feed upon the flesh.

The Lamellicornes is a family of very great extent, and one of the most striking of the whole Beetle tribe, in respect to the size of the body, and the variety in the form of the head and thorax in the different sexes; and often, also, in those species which in their perfect state live upon vegetable substances, in respect to the brilliancy of the metallic colours with which they are ornamented. All have wings, and they crawl but slowly along the ground. None of them are aquatic. Their food consists of dung, manure, tan, and particularly (in some species) of the roots of vegetables; whence these insects, especially in their larva state, often occasion great loss to the cultivator. This family receives its name from the peculiar conformation of the antennæ, which terminate in a mass formed of the three last joints; these are flattened into plates or lamellæ—sometimes arranged like a fan or the leaves of a book, frequently in the manner of a comb, and sometimes enclosing each other. The family is distributed into two principal sections—the *Scarabæi* and the *Lucani*. Of the Scarabæi, one subdivision, including the sacred beetle of Egypt, feed principally upon the excrements of various animals. A most remarkably formed species is the *Dynastes Hercules*, a native of



Dynastes Hercules.

Brazil, which attains the length of five inches, and of which the male possesses an enormous horn projecting from the head, which is opposed by a corresponding protuberance from the thorax. To this group also belongs the *Melolontha vulgaris*, or common cockchafer, which is most destructive to vegetation both in its larva and perfect condition, feeding on the roots in the one case, and on the leaves and young shoots in the other. The larva lives for three or four years beneath the ground, becoming lethargic in winter, but actively voracious in summer. Their excessive multiplication is usually prevented by birds; but if these be kept away, they increase very rapidly, and become a pest to the cultivator. The perfect insect sometimes makes its appearance in such swarms, as to devastate an entire forest. The *Lucani*, or Stag-Beetles, derive their common name from the peculiar form of the mandibles, which are large, curved, and toothed, like stag-horns. The *L. cervus* is one of the largest British insects, the males being two inches or more in length. This species flies about in the evening in the middle of the summer, especially round the oaks, upon the wood of which the larva feeds, remaining in that state for several years before undergoing its final transformation. Some of the exotic members of this group are very large, and splendidly coloured.

In the Melasoma, one of the herbivorous families, the body is of an ashy-brown or black colour, and for the most part the wings are absent, the elytra being united along the suture. They live for the most part in the ground, beneath stones, or in the sand—often, also, in low and dark parts of buildings, such as cellars, stables, &c. This tribe of insects is very tenacious of life; individuals have been known to remain alive for six months without food, and stuck on a pin. To this family belong the *Blaps mortisaga*, a beetle often found in dark and dirty places about houses; and the *Tenebrio molitor*, of which the larva is known under the name of the meal-worm, living among corn and flour. The perfect insect frequents bakehouses, corn-mills, &c. where it may often be found in the evening.

In the family Trachelides, one of the most remarkable species is the well-known blistering-fly (*Cantharis vesicatoria*), abundant in Spain and France, and distinguished by its fine metallic colours. To a different section belongs the Rhyncophorus, or *Weevil* tribe, so destructive in our stores of grain. One of this family is the celebrated diamond beetle (*Curculio imperialis*), a native of South America, and the most splendid of all beetles. The Trimera are a section of beetles, generally of small size, one of the most familiar being the lady-bird (*Coccinella*), which is of great benefit to plants, by feeding on the aphides which infest them.

II.—Orthoptera.

The order Orthoptera comprehends all insects that have the mouth armed with jaws fitted for mastication, and two pairs of wings; of which the anterior encase the others, the posterior being membranous, and folding longitudinally during repose. In many respects they resemble the Coleoptera; and they are closely connected with that order by the *Forficulidæ*, or Earwig tribe, which partake of the characters of both. But they differ from the Beetles in the softer covering of their bodies; in the partially membranous character of the anterior pair of wings, which seem intermediate between the horny elytra of Beetles and the membranous wings of other insects, and which do not meet along the back when closed; and in the fan-like manner in which the posterior wings are folded up beneath them, which is permitted by the straight direction of their veins. They differ also in their metamorphosis; for whilst that of the Beetles is complete, that of the Orthoptera is only partially so; for the larva and pupa closely resemble the perfect insect in form, walking and feeding in the same manner, and differing little except in the absence of the wings and wing-covers, which are gradually developed in the latter.

This order comprises numerous well-known insects, often of large size and splendid colours; such as grasshoppers, locusts, walking-leaves, as well as cockroaches and earwigs. Some of the largest of known insects belong to it; a few species attaining a length of eight or nine inches, and an equal expansion of wings. Comparatively, few are inhabitants of temperate regions; the order attaining its greatest development, both in number, size, and colour, between the tropics. All the known Orthoptera are terrestrial, both in their perfect and two previous states. Some are purely carnivorous, and others are adapted to a mixed diet—the Cockroaches, for example, being capable of feeding on almost any organised matter, whilst the great majority feed upon plants—hence, from their large size, and the quantity which each individual can devour, they are among the most destructive of all the insect tribes, when they appear in large numbers. This is particularly the case with the locusts in warm countries, the ravages of which not unfrequently cause famine and pestilence both among men and beasts.

The Orthoptera are usually divided into two sections—the Cursoria, whose legs are all alike, and adapted for running, and whose wings and wing-covers rest horizontally on the body; and the Saltatoria, the thighs of whose hind legs are much larger than the rest, in consequence of which they possess great powers of leaping. In some of the latter the wings meet at an angle when folded, like the two sides of a roof; and the males have the power of making a sharp creaking noise.

The Cursoria contain three well-known forms—

the *Earwig*, *Cockroach*, and *Mantis*. The Mantis family are purely carnivorous insects, of which none are natives of this country. The first pair of legs is enormously enlarged, and forms a very powerful organ of attack. They frequent trees and plants; and the forms and colours of their wings and bodies are often so adapted to those of the leaves and twigs which surround them, as to give them remarkable power of eluding observation. Hence these have been called walking-leaves. One species, the *Mantis religiosa*, is regarded by the natives of the countries it inhabits with superstitious reverence, on account of its occasionally assuming the attitude of prayer. This is, however, the position in which it lies in wait for its prey; the front of the thorax being elevated, and the two fore legs held up together, like a pair of arms, prepared to seize any animal that may fall within their reach. They are extremely voracious insects; and, if kept together without food, will fight, the victor devouring its conquered adversary. Allied to the mantis is a very singular genus, the *Phasma*, of which the different species have received the names of walking-stick, spectre insects, &c. Their bodies are extremely prolonged, and rounded; and in their colour they much resemble dried sticks, previously to the development of the wings, which are usually green and leaf-like. The legs are all equal, so that they are distinguished from the Mantidæ on the one hand, and from the Saltatoria on the other; but they are not able to move rapidly either in the larva or perfect state.

The family Saltatoria consists of numerous species allied to the well-known *Crickets*, *Grasshoppers*, and *Locusts*. Besides the peculiarities already mentioned, they are remarkable for the deposition of their eggs in the ground, which is generally accomplished by means of a long horny ovipositor. The mode in which the sound is produced varies in different species: in the locusts, it is caused by the friction of the posterior thighs, like the bow of a violin, against the wing-covers; in others, it is occasioned by the friction of two talc-like spots, on the inner sides of the wing-covers, against each other. The larvæ of the mole-crickets and the common social locust are among the most destructive of the insect races.

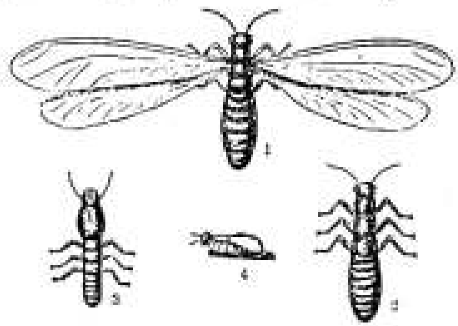
III.—Neuroptera.

The Neuroptera resemble the Coleoptera and Orthoptera in the structure of the mouth, but differ from them in the conformation of the wings. The anterior as well as the posterior pair are here membranous and transparent. In both, the veins form a very beautiful and minute network, subdividing and uniting again, so as to divide the whole surface into a large number of cells, which very much exceed in number those of the wings of any other tribe of insects. The posterior wings are usually as large as the superior, or sometimes even larger; if narrower, they are generally longer.

The body of the insects of this tribe—which contains the well-known *Dragon-flies*, *May-flies*, *Ant-lions*, and *White Ants or Termites*—is generally prolonged, and destitute of any very hard integument. They differ in the character of their metamorphosis as well as in their adult structure; for in some, the metamorphosis is complete, the larva undergoing a marked change of form; in others there is not much difference, except in the absence of wings, between the larva and the perfect insect. By these differences the order may be subdivided into two groups, in the first of which the pupa is active, whilst in the second it is quiescent, except just before the assumption of the perfect state. The first of these groups may be further divided into those which have terrestrial larvæ, such as the *Termitidæ*, and those which are aquatic in their preparatory states, as the *Libellulidæ*, or Dragon-flies, and the *Ephemeræ*, or Day-flies. These pass the first two stages of their lives in water, respiring by means of peculiar organs placed at the sides or extremity of the abdomen. In other respects their larvæ and pupæ nearly resemble the perfect insect. They creep out of the water to undergo the final metamorphosis.

The Ephemeridæ derive their name from the short duration of their lives in the perfect state. They generally arrive at their final change at sunset in the fine days of summer and autumn, along the margin of the streams, &c. in which they have been developed. In this stage of their existence they take no food; after a few hours of apparently happy life, during which they provide for the development of a new generation, they cease to have a place on earth.

The Termitidæ, or White Ants, are terrestrial, active, and carnivorous or omnivorous, in all their stages. In several points of their structure they approach the Orthoptera; whilst in their habit of living in societies they resemble the Hymenoptera. Unlike the social tribes among the former, however, the neuters or sexless individuals in these communities officiate only as soldiers; and those which are here denominated workers, are, in reality, the larvæ, which closely resemble the perfect insect, except in the absence of wings. These



1. and 2. Perfect Termites; 3. Soldier; 4. Worker.

insects commit the most extraordinary ravages, the numbers in each colony being almost incalculable, and their voracity extreme. Their nests are sometimes concealed below the surface of the earth, or in the interior of trees, timbers, &c.; and through these they bore galleries in such a manner, that though the outer surface is left untouched, they fall to pieces on the slightest violence. Sometimes the nests are elevated to several feet above the surface of the ground, and have a pyramidal roof. When arrived at their perfect state, the Termites quit their habitation, and fly abroad during the evening or night in great numbers; they lose their wings before the morning, and many of them, falling to the ground, become the prey of birds, reptiles, &c. The females, however, are sought by the workers, which imprison them in royal chambers (as they have been termed) in the centre of the nest. The abdomen subsequently attains an enormous size, from the quantity of eggs it contains; and these, when deposited, are carefully tended by the workers, and defended by the soldiers.

IV.—Hymenoptera.

In the membranous character of their four wings, the insects of this order resemble the Neuroptera; but they cannot well be mistaken for them. The anterior wings are usually much larger than the posterior; the veins or nervures are much fewer in number than in the Neuroptera, and do not form a close network by their ramifications, as in that order. In some of the minute species the wings are almost, or even entirely, destitute of nerves. Another character furnished by the wings consists in the connection of the anterior and posterior during flight, by means of a series of minute hooks along the front edge of the latter, which catch the hinder margin of the former, so as to produce one continuous expansion. The principal character, however, is derived from the structure of the mouth; for although considered as mandibulate insects, the Hymenoptera are better fitted for imbibing their nourishment by suction than for obtaining it by mastication, their maxillæ being much prolonged and channelled, and even uniting at their base into a tube, so as to form a kind of proboscis. This is well seen in the bee. They are also peculiarly distinguished by a prolongation of the last segment of the body in the females, into an organ which is in one division of the order a *sting*, and in the other an *ovipositor*, or instrument for depositing the eggs, usually possessing the power of boring a hollow for their reception.

The Hymenoptera are further remarkable for the great development of their instinctive faculties, and of their locomotive powers. It is in this order that we find the most remarkable examples of contrivance and skilful adaptation of means to ends; but this adaptation results, it would appear, not from an exercise of *intelligence* on the part of the animals themselves (as in man and the higher Vertebrata), but from their blindly following out a plan laid down for them by the Almighty Designer. This inference may be deduced from the *invariability* of the operations performed by different individuals among the same species, so that a history of the life of one is equally applicable to all. The adjustment of instinctive actions to each other is nowhere more remarkable than in the case of the *social* insects, which are chiefly restricted to this order. The Bees, Wasps, Ants, Saw-Flies, Ichneumons, and Gall-Flies, have attracted the attention of the observer of nature from the earliest period.

The insects of this order undergo a complete metamorphosis, the larvæ being amongst the most imperfect of those of any tribe. In the greater proportion of the order, they are destitute of feet, and resemble little worms. These are dependent upon the instinctive care of the parent for support; which is either provided for by the deposition of the eggs in situations where the future grub will be certain of an ample supply of food, or by the active exertions of the parents, which convey to the young the food they have collected for them. This charge more especially devolves on the *neuters*, or undeveloped females, which constitute the majority of the hive—there being generally only one queen-mother, and comparatively few males. When arrived at their full growth, and after undergoing several previous moultings, the larvæ are transformed into inactive pupæ, in which all the limbs of the future insect are visible, encased in distinct sheaths, and folded on the under surface of the thorax. During this part of their existence they take no food. In their perfect state, these insects for the most part take but little nourishment; and this almost exclusively consists of the nectar of flowers. Many of them, however, such as the Wasps, attack and destroy other insects; but these are often destined, not for their own support, but for the nourishment of the young. In the number of genera and species, this order is inferior only to the Coleoptera. It has been estimated as containing one-fourth of the whole insect population.

The family of Ichneumonidæ may be regarded as peculiarly characteristic of the entomophagous or insect-devouring division. The female deposits her eggs, by means of her sharp-pointed ovipositor, only in the bodies of other insects, chiefly the larvæ of caterpillars, on which the young may feed when hatched. Some of them have a very long ovipositor, which is used to insert the eggs into the bodies of caterpillars that live beneath the bark, or in the crevices of trees; whilst those which have this instrument short, place their eggs in or upon the bodies of caterpillars, or pupæ, to which they can obtain easier access. They do not confine themselves to these situations, however; but employ for the same purpose the eggs or pupæ, still preferring the larvæ when they can find them. The young Ichneumons, when hatched as footless grubs, sometimes in considerable numbers in the body of one larva, devour only the fatty parts, which are not absolutely necessary to life; but when ready to undergo their metamorphosis, they either pierce through the skin, and escape, or else kill their victim, and perform their changes within its body.

The family Formicidæ is composed of the well-known and singularly interesting tribes of ants which are distinguished by their habit of residing under ground in societies, and by the existence of *neuters* among them, by which class the labours of the community are chiefly performed. The males and females, which constitute but a small proportion of each community, are alone furnished with wings; the former are the smallest. The neuters are somewhat smaller than the males, and mostly resemble the females in conformation; but the thorax is much narrower, and contracted in the middle, not having to give attachment to wings.

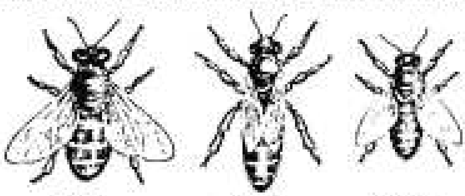
1. Female; 2. Male; 3. Worker.

The nests of ants are differently constructed in the different species, but in all are very curiously and regularly arranged. The males and females leave them as soon as they have acquired their wings, and go forth together into the air. The males soon die, without entering their former abode; of the females, some return, and deposit their eggs in the original nest, whilst others go off to a distance, and become the foundresses of new colonies. They lose their wings at this period, either stripping them off with their own feet, or being deprived of them by the neuters.

The neuters not only construct the nest, but carefully tend the young grubs, supplying them with food, moving them on fine days to the outer surface of the nest to give them heat, and carrying them back again at the approach of night or bad weather, and defending them when attacked by enemies. The winged ants having all perished at the commencement of the cold weather, the neuters only survive the winter. Some of the neuters are larger and rather differently formed from the rest, and appear to be the chief defenders or soldiers of the community. A most remarkable instinct is observed in some species—that of making war upon colonies of smaller ants, carrying captive the larvæ and pupæ of the neuters, and keeping them in slavery when hatched. Ants are well known to be extremely fond of saccharine matters, and they seem greatly to relish the fluid which exudes from the bodies of aphides and coccidæ. Some species, it has been asserted, collect aphides, and keep them, as it were, in pastures, which they connect with their nests by means of galleries excavated along the stems and branches of trees. The foregoing are a few of the chief facts relating to the economy of this tribe, on which many volumes have been written; and it may be safely asserted that there is none whose habits are calculated to afford more of interest and entertainment to those who seek acquaintance with them, either by the recorded observations of others, or by their own.

The family of Vespidæ, or *Wasps*, is distinguished from the other Hymenoptera by their wings being folded, when at rest, throughout their entire length. In general, these insects are social, the communities, however, being small; in such cases, there are neuters which are not destitute of wings. There are also some solitary species among whom no neuters exist. The best known of the Social Wasps, such as the common species of this country, construct their nests with bits of wood, bark, &c. which they separate with their jaws, and reduce to a pulp; and this, when expanded and dried, forms a paper-like substance. With this are built layers of hexagonal cells, one row being joined to the under side of another. The top row is attached, in some species, merely to the under side of a branch, or to the top of a slight hollow, by which it may be in some degree protected; but in others the whole comb is enveloped in a covering, formed by several layers of the same paper-like substance, with one or more apertures. Wasps feed, in their perfect state, upon insects, meat, fruit, &c. and nourish their young with the juices of these substances. A Brazilian species stores up an abundant provision of honey.

The *melliferous*, or honey-bearing *bees*, form two families; in one of which all the species are solitary, and are of only two kinds—males and females; whilst the others mostly live in societies, but are chiefly distinguished from the former by certain peculiarities in the structure of the mouth. Of the solitary Bees—ANDRENIDÆ—which construct nests for themselves, there are many curious varieties, some of which go under the names of Mason, Carpenter, and Upholsterer Bees, from the material with which they work—the first agglutinating bits of sand or gravel; the next excavating wood by means of their powerful jaws; and the last constructing their cells of portions of leaves. The habits of all may be studied in detail with extreme interest. Of the social species, APIDÆ, there are two principal groups—the Humble-Bees, or Wild-Bees, and the Hive-Bees. The common Humble-Bees of this country live in curious underground habitations, in societies usually of fifty or sixty, but sometimes of two hundred or three hundred individuals, all of which, with the exception of one or two fertile females, die during the winter. It is in the Hive-Bees that the arts of construction are exhibited in the most elaborate degree. Their societies consist of but one female, commonly termed the queen; several hundred males, which are known as drones; and about twenty thousand working bees, or neuters. It is by the latter that all the labours of the hive—the construction of the combs, the collection of food, both honey for the adults and pollen for the larvæ, and the nourishment of the grubs—are performed. The accompanying figures exhibit the



Male. Female. Neuter.

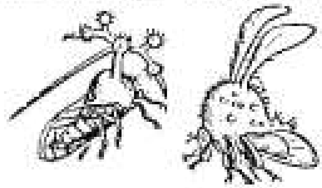
relative sizes and aspects of these three orders. The wax of which the comb is constructed is secreted by the insects themselves, in little scales, which work out from between the segments of the abdomen. These are taken up and kneaded by the jaws, and applied in the proper place. The drones are killed at the end of the summer; but the queen and great part of the workers remain; and when, in the summer, they increase so much as to over-people the hive, colonies are sent forth with young queens, in search of another habitation.

V.—Homoptera.

The insects contained in this order present many curious anomalies of structure and habit, and depart more widely from the general type than is the case in almost any other division of the class; hence it is difficult to assign any general characters which shall include them all. It is in the structure of the mouth that there is the greatest agreement. This is adapted for suction, the tongue being elongated and channelled into a gutter, and being surrounded by delicate lancet-like organs which pierce the tissues of plants. All the insects of this group subsist on vegetable juices; and many of them, from the amount of damage they commit, are very injurious to the cultivator. Some of the females are furnished with an ovipositor, provided with several toothed saws; and with this they make incisions into the leaves or stems of plants, into which they introduce their eggs. The anterior pair of wings is usually similar to the posterior in consistence, both being composed of a firm membrane: that which chiefly distinguishes the Homoptera, however, from the Heteroptera is, that the substance of the anterior pair, whatever be its nature, is the same throughout, and that, when folded, they are roof-like.

The CICADIDÆ are the largest of the order; one species measuring between six and seven inches in the expanse of its wings. Their peculiar characteristic consists in their musical powers. By a peculiar apparatus situated beneath the abdomen, they are enabled to produce a continued sound, nearly monotonous, but of considerable power. In some species, the sound is so loud and shrill, as to be heard at the distance of a mile.

The family CERCOPIDÆ consists of insects of small size, but which are remarkable for the grotesqueness of the forms which many of them assume: some inhabit this country, and are known by the name of cuckoo-spits and frog-hoppers; but the most singular species are confined to the tropics. The curious appendages,



Borydium Globulare. Borydium Cruciatum.

represented in the accompanying figures, of a Brazilian species, result from an extraordinary development of the first segment of the thorax. The insects of this family are often beautifully varied in their colours; they are constantly found amongst plants, and on trees, upon the juices of which they subsist, in all their stages. Of the best-known species of this country, the larva and pupa invest themselves with a frothy secretion, whence the vulgar name is derived. Some of this tribe are employed by certain species of ants for the same purposes as the Aphides, in consequence of their secreting a saccharine fluid.

The family of APHIDÆ, commonly known as *Plant Lice*, is extremely obnoxious, on account of the injuries committed by its members against almost every kind of vegetable. The Aphides live in great numbers upon the surface of the plant, and suck the juices, by means of their proboscis, from the young shoots, leaves, stems, and even roots. They thus greatly weaken its vigour, and often distort young shoots and leaves; some species cause little gall-like excrescences by the irritation they produce. In many of the species, a large proportion of the individuals never acquire wings, in which case the pupa is not to be distinguished from the mature larva or imago states, whilst at certain parts of the year, other individuals of the same species, and of both sexes, acquire wings. The wingless Aphides, which may be seen in the spring and early summer, are all females capable of producing fertile eggs, and from these are reared the winged males and females which are seen later in the season. Their rapidity of production is enormous, nine generations having been obtained within three months. The young are sometimes produced alive, whilst in other cases (according to the season, and other circumstances) eggs are deposited. Many of the *blights* so injurious to the gardener and the agriculturist, consist really of Aphides, although, from the minuteness of the insects themselves, they often escape observation.

The family of COCCIDÆ, sometimes called *Scale Insects*, although ordinarily of very small size, are amongst the most injurious to vegetation of any tribe. Their powers of propagation are excessive, and when they once gain possession of a plant or young tree, its death is almost certain, the minute size of the larvæ rendering it impossible to exterminate them. They furnish, however, some very important products. The bodies of many species are very deeply coloured through their whole substance, and yield dyes of great value, the richness of which seems to depend upon the nature of the plant on which they feed. The species employed by the ancients was a native of the Levant; but that which furnishes the *cochineal* so highly valued at the present time, was originally confined to Mexico, where it feeds on the cacti; it has, however, been introduced, along with its proper food, into Spain and Algiers, and also into the hothouses of this country. About 800,000 lbs. weight of cochineal are annually brought to Europe, each pound of which contains about 70,000 insects. The lac of the East Indies, which is extensively used in the composition of varnishes, sealing-wax, &c. is the product of another species of Coccus.

VI.—Heteroptera.

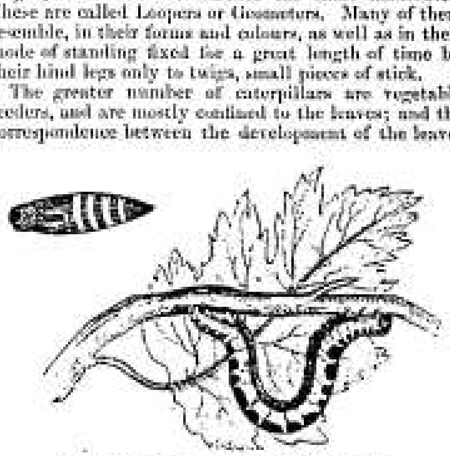
These insects bear a close general resemblance to those of the last order: as in them, the structure of the mouth, which is wholly adapted for suction, indicates that their nourishment consists solely of the juices of plants or animals; but they are at once known from them by the character of the anterior pair of wings, which are coriaceous at the base, and membranous towards their point, and which fold nearly horizontally, partly lapping over each other. By far the greater number of them feed upon the juices of plants; but some of them prey upon other and weaker insects, and a few species, as the common bug, suck the juices of larger animals. The majority of this order are found in tropical climates; and the species which inhabit these regions are mostly ornamented with a great variety of beautiful colours and markings, often vying with the most splendid of the Beetle tribes. Many species, however, are of aquatic habits, and these are all of an obscure black colour. Nearly all the terrestrial species have the power of emitting, when suddenly alarmed or touched, a powerful odour, which is of a pleasing character in some, but in others (as the common bed bug) very offensive. Others seem to eject a poisonous fluid into the wound they make, for the purpose of suction. In some, the wings are altogether undeveloped, or the upper pair is wanting. All the members of the order continue active, and require food, during the various stages of their existence.

VII.—Lepidoptera.

The order Lepidoptera, characterised, as formerly stated, by the downy covering of the wings (which is composed of minute scales, arranged with great regularity upon the membrane itself), contains some of the most beautiful forms of the whole class, as well as some of the largest. The number of species it comprehends is probably as great as that of any other order except the Coleoptera, and may probably number about one-fifth of the whole Insecta. All the members exhibit the well-known forms of *Butterflies* and *Moths;* and there is so much general resemblance among them, that the difficulty of classification is often considerable. The scales from which the order takes its name are generally of an oval form, terminating at one end in a kind of stalk, by which they are attached to the membrane of the wing; and on this they are arranged in rows, overlapping each other like tiles on a roof. They may be easily rubbed off with the finger; and the bare membrane is left, which is then seen to correspond with the wings of other insects. The number of scales covering the wings of the silkworm has been estimated at about 400,000. It is entirely to the scales that the colours of the wings are due; and sometimes these are so brilliant, as to be almost painful to look upon, if a strong sunlight is reflected from the surface. In some species the wings are partially, or even almost entirely, destitute of scales.

The Lepidoptera, in their perfect state, are formed to exist entirely upon fluid nutriment, which they suck up by means of a long trunk, which is usually coiled up spirally under the head. All the other parts of the mouth usually possessed by insects, may be detected in that of the Lepidoptera, but in a different state of development. The antennæ are variable in size, and always composed of a number of joints. The eyes are usually large, and contain numerous facets. The curious phenomena of the metamorphosis are presented to our notice more remarkably, perhaps, in this order than in any other. All the beings commonly known as *Caterpillars*, are the larvæ of Lepidoptera. They are produced from eggs of various forms and curious markings, which have been deposited upon leaves that are to serve as the food of the larvæ when hatched. The three first segments of the larva have each a pair of simple, short, and jointed feet, which are the rudiments of those of the perfect insect. Behind these are a variable number of temporary appendages, called pro-legs, which are thick, short, fleshy limbs, armed at their extremity with a great number of minute hooks, and furnished with powerful muscles. There are usually five pairs of these—four of them succeeding the true legs, and another arising from the last segment of the body. Those possessing pro-legs on nearly every segment, crawl upon all the feet at once, after the manner of the Myriapoda; but those which have only a small number of pro-legs, adopt a different method. They seize fast hold of the objects on which they are stationed with the six true legs at the fore part of the body, and then elevate the intermediate segments into an arch, until they bring the pro-legs behind close to the others; they then disengage the true feet, and retaining hold with the pro-legs, thrust the body to its full length, and then recommence the same manœuvre. These are called Loopers or Geometers. Many of them resemble, in their forms and colours, as well as in their mode of standing fixed for a great length of time by their hind legs only to twigs, small pieces of stick.

The greater number of caterpillars are vegetable feeders, and are mostly confined to the leaves; and the correspondence between the development of the leaves



Caterpillar and Chrysalis of the Magpie Moth.

and flowers of plants on the one hand, with that of the caterpillars and butterflies which are respectively to feed upon them, cannot but strike every one as a beautiful instance of creative foresight. But there are some caterpillars adapted to feed on flowers (such as come forth early in the year); and others attack seeds, roots, and even the woody portion of the stem. Moreover, there are a few which live in this state upon animal matter, such as wool, hides, leather, and fat. Many can digest a considerable variety of alimentary materials; whilst there are others that can only find support on some one kind, as, for example, the leaves of some particular species of plant. Their habits are also extremely various. Some burrow into the substance of leaves; others envelop themselves in the membrane of the leaf itself. Many construct cases or sheaths, either fixed or portable, by agglutinating various substances together; and there are some which live in societies under a tent of silk which they spin in common, and which serves to defend them from the inclemency of the weather. They usually throw off their skin four times before undergoing the transformation into the chrysalis state. For this they prepare by spinning a cocoon, in which they are enclosed during the greater part of that epoch. Some construct this entirely of silk; others attach together portions of leaves, or particles of earth, by silken threads. These threads are formed by a glutinous secretion from glands which seem analogous to the salivary glands of other animals; and this being forced out through a small opening at the end of the lip, hardens as it dries in the air. There are some caterpillars which form no cocoon, but which are contented with suspending themselves, by the attachment of the hinder part of the body, to some solid support, or by a silken thread coiled around them. The *chrysalis*, or nymph, has the whole body enclosed in a tough envelope, under which, however, the form of the parts of the future insect may be discerned. At the moment of the final transformation, it discharges from its intestine a red liquid, which softens one end of the cocoon, and allows the exit of the moth. Generally, one end of this envelope is weaker, or even fitted by the arrangement of the threads for the escape of the insect.

The *Butterfly*, when it throws off its last envelope, and comes forth into the air, of which it is henceforth to be one of the gayest inhabitants, is not altogether perfect, although capable of very soon becoming so. The wings appear at first very slightly developed, and hang loosely by the sides; and it is not until the animal has injected their tubes with air, by taking several full inspirations, that they become expanded so as to serve for flight. From that period, the body is supported by them during by far the greatest proportion of the active state of the insect.

One of the most remarkable of the SPHYNGIDÆ, or Moth family group, is the death's-head moth (*Acherontia atropos*), recognised by the skull-like patch on the back of the thorax. This emits a squeaking kind of sound, sometimes rather loud, but upon the mode in which it is produced entomologists are not agreed. In consequence of the peculiar aspect of its body, the sudden appearance of this insect in large numbers has been popularly regarded as ominous of evil. It is a great enemy to bees, and enters their hives undefended, devouring the honey, and alarming the inhabitants so, that they seem to keep aloof from it.

The genus *Bombyx* is an extremely important and interesting one, as it is by the caterpillar of the *B. mori* that all the silk now employed in Europe is produced. The larva feeds especially upon the mulberry, although it may be grown upon other plants; but as the silk produced by the former is preferable, that tree is grown to a great extent in Italy and the south of France, where the breeding of silkworms is carried on. The quantity of nutriment they require is enormous in proportion to their original size, but probably not greater than that consumed by other caterpillars. The care bestowed upon them, however, draws attention to the fact. The larva is reckoned to weigh, when first hatched, about one-hundredth of a grain; previously to its metamorphosis it increases to ninety-five grains, or 9500 times its original weight. It is reckoned that, for the larvæ proceeding from *an ounce* of eggs, nearly *two thousand pounds* of leaves are requisite. The caterpillars of another species of Bombyx are very remarkable for their curious habits. They live in societies on the leaves of the oak; and spin, when young, a kind of silken tent, divided within into cells. They may be seen to issue from it in the evening in procession. One of them advances at the head, and seems to act as a guide; two then follow; next three; then four; and so on, each rank containing one more than the preceding one: hence they have been called processionary caterpillars. Each spins a separate cocoon; but they are united in regular apposition, laid side by side against each other.

The family TINEIDÆ contains those little moths which are so injurious to woollen stuffs of every kind, as well as to furs, skins, feathers, and other objects of natural history, upon which their voracious larvæ feed. They use the same materials also for the construction of their movable cases or sheaths, which they enlarge with the increasing size of their bodies, both by adding to their extremities, and by slitting them along and inserting a new piece, so as to increase their diameter. In these tubes they undergo their metamorphosis, after closing the orifice with silk.

VIII.—Diptera.

The Two-Winged Insects constitute one of the most extensive orders of the whole class, not only in regard to the number of distinct species, but also from the swarms of individuals of the same species. Many of them also have been constant attendants upon man in all ages. They do not attract attention from their size, however, for there are few that exceed an inch in length; nor is it on account of their beauty, for the majority of them are of dull colours; their forms, too, are rarely elegant, and the transformations of many are unknown. They owe the notice they have attracted chiefly to their habits, and especially to those which affect man and the domestic animals, both in their perfect and early states. However annoying these are, it must not be forgotten that other Diptera are of extreme service, by cleansing the surface of the earth of vegetable and animal impurities; the carcase of any animal would be much more prejudicial in its decomposition, than when principally eaten up by these voracious creatures. The mouth of the perfect insects is formed only for imbibing fluid matter, and in many tribes is furnished with lancets for puncturing the flesh from which they suck the juices; both the channels through which they draw the fluid, and these accessory organs, consisting only of the usual parts of the mouth, altered in form and arrangement.

The CULICIDÆ, or *Gnat* tribe, are distinguished by their beautifully tufted antennæ. Gnats are well known to abound chiefly in damp situations; the reason being, that their larvæ are inhabitants of the water. The mosquitoes which infest many countries, especially in warm latitudes, differ but little from the common gnats. They sometimes appear in such swarms, especially in marshy districts, as to be kept off only by fire.

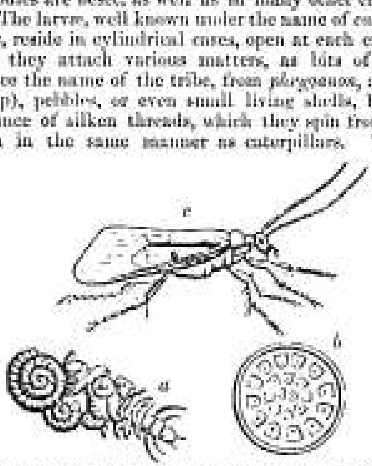
To the Gad-Fly tribe (TABANIDÆ) belong the largest Dipterous Insects, pre-eminently distinguished for the tormenting powers which the different species possess, by piercing the skins, and sucking the blood, of various quadrupeds, and even of man himself.

The form and habits of the MUSCIDÆ, or *Fly* tribe, are generally known: the family is an extremely numerous one, above 1700 species having been recorded as existing in Europe, of which about half are indigenous to this country; and there are probably at least as many more which have not been described. The strong general resemblance which exists among all the species, makes it very difficult (especially when their small size is considered) to discriminate them readily. The larvæ of these insects, commonly known as *maggots*, are soft, verniform, footless grubs, possessing on the head a couple of retractile hooks, by which they can cling to the substances on which they feed. They devour various substances, both animal and vegetable, living, recently dead, or far advanced in putrefaction. The eggs are deposited by the female, as in other instances, in the neighbourhood, or in the very substance of the food which is adapted for the support of the larva, however little to its own liking.

The ŒSTRIDÆ, or *Bot-Flies*, are a family very remarkable in regard to their structure and habits. The perfect insects resemble large meat-flies in form, are very hairy, and generally have these hairs coloured in rings, like humble-bees; but they are seldom seen, the duration of their lives being very short in this condition. Their chief peculiarity consists in the absence of any proper mouth in the imago (in which respect there is an analogy with the Strepsiptera), and in the peculiar habitation of the larva. This is always found in living animals; its situation, however, varying with the species, of which almost every herbivorous mammal has one or more peculiar to it. The egg is deposited by some in situations where the larva may burrow into the flesh, where it occasions inflammatory tumours, the fluids contained in which afford it nourishment. In other cases, the eggs or larvæ, existing upon spots which the animal is in the habit of licking, are conveyed by the tongue into the mouth, whence they pass into the stomach. There they remain until full-grown; and then they quit the body (as do also those that inhabit the flesh), and fall to the ground, beneath the surface of which they undergo their transformations. The larvæ of one species, which inhabit the sheep, are found in the cavities in front of the bones of the skull and higher parts of the nose. Man is subject to the attacks of one or more species, which do not, however, infest this country.

IX.—Trichoptera.

This order is a very small one, and consists but of one tribe, the PHRYGANIDÆ, which have been commonly associated with the Neuroptera. But there seems good reason for ranking them as a separate order, connecting the Neuroptera with the Lepidoptera, for they resemble the latter in the distribution of the nerves of the wings, and in the hairy covering with which both the wings and bodies are beset, as well as in many other characters. The larvæ, well known under the name of *caddice-worms*, reside in cylindrical cases, open at each end, to which they attach various matters, as bits of stick (whence the name of the tribe, from *phryganon*, a twig or chip), pebbles, or even small living shells, by the assistance of silken threads, which they spin from the mouth in the same manner as caterpillars. These



Phryganea: *a*, Larva in its case; *b*, Grating; *c*, Imago.

cases they bear about with them, protruding the three first segments, with their legs, when they creep forwards, and withdrawing these upon the slightest alarm: they never quit the cases of their own accord. Different species appear to prefer different materials for the construction of their cases; but they have the power of employing almost any which fall in their way, when those they prefer are deficient. The food of some of the larvæ is vegetable, but others prey upon smaller aquatic larvæ, such as those of Neuroptera.

When about to assume the pupa state, the larvæ fix their cases to some solid substance beneath the water, and close the two extremities with a kind of grating, that admits of the passage of water through the tube, which is necessary for respiration. When nearly arrived at their perfect form, they make their way out by the pair of hooked jaws with which they are then furnished, and swim about with great activity by means of the two hind legs, crawling also upon the four first. The pupæ of the larger species creep up the stems of plants, &c. and undergo their final change in the air; but the smaller ones merely come to the surface, where they shed their pupa skin in the same manner as gnats, the old envelope serving them as a raft. They live but a short time in the perfect state, taking no nourishment, and engaged only in propagating the race.

X.—Strepsiptera.

This is a small order, containing only a single group of insects; but these are so anomalous in structure, that it is not merely impossible to associate them with any other order, but it is even difficult to assign their proper place in the class. They are all of small size, none being known to exceed a quarter of an inch in length, and they are all parasitic in the larva state upon the bodies of bees and wasps. As they possess less of general interest than of curiosity to the scientific naturalist, they need not here be treated of.

WINGLESS INSECTS.

Besides the foregoing orders, which constitute the true insects, three others must be included in the class, on account of the correspondence in their general structure, although they present only one or neither of the two characters which have been stated to distinguish it—the presence of wings in the perfect state, and the metamorphosis. These three orders are, the APHANIPTERA, or *Flea* tribe, which have the rudiments of wings, and undergo a metamorphosis; the PARASITA, or *Louse* tribe, which is entirely destitute of wings, and undergoes no metamorphosis, but agrees with the true insects in having only six legs; and the THYSANOURA, including the *Spring-tails*, in which there are appendages to the abdomen, representing the legs of the posterior segments, so that these may be regarded as approaching the Myriapoda.

The habits of the common fleas of this country are well known; but there is a West Indian species, which, though of minuter size, is still more obnoxious. This is the *Pulex penetrans*, commonly known as the chigoe, or jigger. It chiefly attacks the naked feet, buries itself deeply in the skin, and then deposits there an immense number of eggs. The larvæ of these, when hatched, produce great irritation, and not unfrequently sores, from which even death has sometimes resulted. Most of the lower animals are infested with one or more species of the louse family, from the attacks of which they are not able to defend themselves; and man is subject to a peculiar disease, which seems very much to favour their production. Their generations succeed each other with great rapidity.

CLASS VI.—ARACHNIDA.

The class Arachnida — including the *Spiders* and their allies—was for a long time confounded with that of Insects, and has been only recently separated. The characters which the members present are perfectly distinct from those either of Insects on the one hand or of Crustacea on the other; nevertheless, they exhibit relations with both those groups.

The Arachnida may be distinguished from Insects by the absence of any division between the head and thorax; the compound mass thus formed is termed the cephalo-thorax. Again, Insects, in their mature state, are always provided with six legs, and no more; the Arachnida have eight of these members. Moreover, the eyes are not compound, but more resemble those of higher animals. From Crustacea they are separated by the softness of their bodies, but still more completely by their exclusively atmospheric respiration. The organs by which this function is performed vary in different tribes. In the *Acari*, or Mites, and their allies, these resemble the tracheæ of insects, and are distributed through the body; whilst in the Spiders, Scorpions, &c. they consist of rounded cavities, or air-sacs, into which the air is admitted by spiracles situated on the abdomen, and which are lined by a membrane plaited into numerous folds, which resemble gills, and lie in apposition like the leaves of a book. On this character is founded the subdivision of the class into *pulmonary* and *tracheary* Arachnida.

The majority of the Arachnida feed upon insects, which they seize alive, or upon which they fix themselves, and from which they suck the juices. Others live as parasites upon the bodies of vertebrated animals. There are some, however, which are only found in flour, cheese, and upon certain vegetables. These last, which mostly belong to the tracheary order, exhibit an affinity to insects not only in their structure, but in their metamorphosis; for they undergo great changes after they come out of the egg, an additional pair of legs being often developed; whilst in the others nothing else than a moult or casting of the skin occurs.

I.—Trachearia.

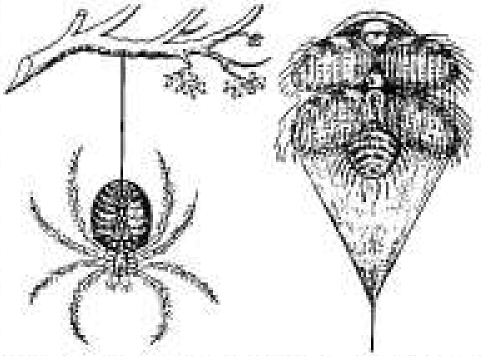
This order contains several remarkable forms, of which the one best known is that of Acaridæ, or *Mite* family, the majority of the species of which, however, are very minute, or almost microscopical. They are very extensively distributed; some being wanderers under stones, leaves, the bark of trees, in the ground, or upon articles of food; whilst others subsist as parasites upon the skin, and in the flesh, of different animals, often greatly weakening them by their excessive multiplication. There are some species which infest insects, especially the carrion beetles. Several of the Mites much resemble spiders in form and habits, as, for instance, the *acarus telarius*, the red spider of hothouses, which forms upon the leaves of various vegetables, especially lime-trees, webs which injure them greatly. The *Ixodes*, of which the various species, known under the name of *Ticks*, are so annoying to some animals, also belong to this group. Although naturally much flattened in form, they acquire by suction a very large size, swelling out like a blown bladder; and they bury their suckers so completely in the flesh, that they cannot be detached without great difficulty. Some interesting aquatic species of this tribe exist.

II.—Pulmonaria.

In this order the respiration is performed by means of air-sacs contained on the under side of the body, and opening externally by stigmata, or little pores; sometimes these apertures are eight in number, four on each side, but sometimes four, or even only two. This diminution appears to indicate a gradual elevation in the character of the apparatus.

The family of Pedipalpi is distinguished from that of Araneidæ principally by the great development of the palpi, which form extended arms, terminated by a pincer or claw. The entire body is clothed with a hard skin. In the *Scorpions*, which constitute the principal part of this family, the abdomen is very much prolonged, forming a sort of tail, which is terminated by a sting furnished with a venomous secretion. The wound of this sting, although very painful, does not seem to be ordinarily dangerous. A small species inhabits this country; but it is between the tropics that the scorpions attain their greatest development. They usually live on the ground, hiding themselves under stones or other bodies, among ruins, where such exist, and dark and cool places generally; even the interior of houses. They run quickly, and curve the tail over the back. They can turn it as an arm of offence or defence.

The Araneidæ, or true *Spiders*, constitute the only other class of pulmonary Arachnida. In these, the palpi are not developed to anything like the same degree as in the scorpion tribe; they rather resemble feet; but the jaws are armed with sharp and hooked fangs, and are perforated near their points, for the emission of a poisonous secretion provided for the destruction of their prey. Nearly all of them are provided with organs, situated at the hinder part of the body, for spinning a very delicate silken thread; but the use to which it is to be applied varies in different species. In some, it forms webs, in which are entangled the insects on which they feed; in others, it is employed to make a delicate lining for their habitation; and in others, it is chiefly used for the fabrication of a sort of cocoon with which the eggs are surrounded. The apparatus provided by nature for elaborating and emitting this silken substance, or *gossamer*, is a beautiful piece of mechanism. Within the animal there are several little bags or vesicles of a gummy matter; and these vesicles are connected with a circular orifice situated at the abdomen. Within this orifice are five little teats, or *spinnerets*, through which the gossamer is drawn, as represented in the accompanying figure. It must not be concluded, however, that there is only one film of gossamer produced by each spinneret; the fact is, these teats are studded with thousands of minute tubes, too small for the naked eye to perceive, and each of these emits a thread of inconceivable fineness. These minute tubes are known as *spinnerules*, and the films which proceed from them unite, like so many strands of a rope, to form the thread of gossamer by which a spider suspends itself. The finest thread



which human mechanism can produce is like a ship's cable compared with the delicate films which flow from the spinnerules of the largest spider. These films are all distinctly separate on coming from the spinneret; but unite, as shown in the preceding illustration, at a short distance, not by any twisting process, but merely by their own glutinous or gummy nature. The spiders are all extremely voracious in their habits, feeding only upon prey which they have themselves killed. When they have got an insect between their claws, either by entrapping it in their web, or by their stealthy mode of pursuit, they plunge their poisoned mandibles into its body, and the bite is usually soon fatal.

The *Mining-Spiders*, found in the South of Europe, construct, in dry shelving situations exposed to the sun, subterranean cylindrical galleries, often two feet deep, and so tortuous, that the traces of them are lost. These they line with a silken tube, forming at its entrance a movable lid, composed of silk and earth, attached to the silken lining by a sort of hinge; and this is adapted, by its size, situation, and weight, to close the opening so precisely, as scarcely to allow its entrance to be distinguished from the neighbouring soil. When the spider enters its retreat, or passes out of it, the door shuts of itself. The *Mygale* spins a sort of cocoon round its eggs, enclosing a hundred or more; they are hatched within it, and the young undergo their first changes before quitting it. The *Clotho* is remarkable for the curious habitation which it constructs for its young. It spins a kind of circular cocoon or tent, which it attaches to the under side of stones, or to crevices in rocks, by seven or eight points, leaving festoons between those, the edges of which are free. At first, this consists of only two folds, but others are gradually added; and beneath them all a lining of peculiarly soft texture is constructed for the reception of the eggs. The young remain in this for some time after they are hatched, and are supplied by the parent with food. The *Argyroneta* forms a winter retreat for itself beneath the water. It spins an oval silken chamber, open at the bottom like a diving-bell, which it attaches by cords to water-plants. It then carries down successive bubbles of air beneath its body, by crawling down their stems; and these bubbles it transfers to its bell until it has filled it. It then takes up its abode in this cell, where it remains for the winter, first closing the mouth of the bell. The *Epeiræ* are among the most remarkable for the strength of their webs; some of the exotic species—noted for the variety of their forms, colours, and habits—spinning nets which are sufficiently strong to catch small birds, and even to annoy man when he happens to come in the way of many together.

CLASS VII.—CRUSTACEA.

The animals composing this group may be regarded as representing in the sea the insects and spiders of the land. They are distinguished by their external shell, formed by a secretion from their own bodies, and by their breathing apparatus, which, unlike that of the other articulata, is adapted for aquatic respiration. The shell is periodically cast and renewed; and the animals have even the power of reproducing limbs which have been lost. The number of legs possessed by the Crustacea is greater than that of perfect insects, being never fewer than four pairs, besides the pair of claws which may be considered as metamorphosed legs. In the lower genera, the number of legs, true and false, becomes so much greater, that they approximate to the myriapoda. As in all other articulate animals, the eyes of the Crustacea are compound.

The class is divided— first into two divisions, one characterised by the possession, and the other by the want, of organs for the prehension or division of the food. Then there are subdivisions, according to the forms of the extremities, the eyes, and other structural peculiarities. Without going into the details of this classification, we shall notice a few of the more remarkable orders, of which the following rank under the first grand division:—

1. Decapoda.	4. Lœmodipoda.	7. Phyllopoda.
2. Stomapoda.	5. Isopoda.	8. Copepoda.
3. Amphipoda.	6. Cladocera.	9. Ostrapoda.

In the order Decapoda, we find the highest general organisation, the largest size, and the most varied habits; it is the one most useful to man, and most interesting to the naturalist. The lobsters, crabs, cray-fish, prawns, shrimps—in fact, nearly all the species that are ever used as food— belong to it. Their growth is slow, but they usually live a long time. Their habits are mostly aquatic; but none of them are killed at once by being withdrawn from the water; and some pass the greater part of their lives in air. They are naturally voracious and carnivorous; the first pair of legs is usually transformed into a pair of powerful claws, by which they seize their food, and convey it to the mouth. This order contains three families—the Brachyoura, or short-tailed Decapods, to which the name of Crabs is commonly given; the Macroura, or long-tailed, such as the Lobster, Cray-fish, &c.; and the Anomoura, in which the abdomen is prolonged, but destitute of a shell, so that they seek protection in the empty shells of Mollusca.

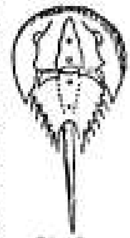
As illustrations of the structure and habits of the Brachyoura, the common *Crabs* will suffice; but a peculiar tribe, that of the *Land-Crabs*, should be specially mentioned. These often live at a considerable distance from the sea, and even burrow under ground. Their gills are kept moist by a kind of spongy structure in the interior of the cavity which encloses them; and from this a sufficient amount of fluid is secreted, to prevent them from being dried up. Some species, though living on land, are confined to damp situations. Others, however, inhabit elevated regions, and migrate towards the sea once a-year to deposit their spawn. The Macroura are distinguished not only by the length of their tail, but by having it expanded at the extremity into a pair of fin-like processes, which afford valuable assistance in swimming. This family is a very extensive one, and contains the largest species of the whole class. The Anomoura are commonly known by the name of Hermit-Crabs, from their remarkable habit of seeking protection in the empty shells of mollusca. The shells they seem to prefer for this purpose are those belonging to the family Trochoidæ. The abdomen or tail is inserted into the upper part of the cavity, of which, after a time, it assumes the perfect form, so that when withdrawn, it presents all the markings of it. The thorax and head occupy the lower part of the spire; and the mouth is closed by one of the claws, which is usually larger than the other, and serves as an operculum when the animal is withdrawn. When they outgrow the habitations they have selected, they quit them, and go in search of others; and they try one shell after another, by slipping the tail into it, until they have found one whose size and form suit them.

The Amphipoda constitute an extensive order, in regard both to the number of species contained in it, and the amount of individuals which are sometimes seen collected together. The greater number of them are marine, but some are found in brooks and reservoirs; all, however, are more or less aquatic in their habits. They are of small size, and swim and leap with agility. The best-known British species is the *Sand-hopper*, which burrows in the sand, and which, unlike the greater part of the order, seldom enters the water.

The Isopoda not only resemble Myriapoda in external form, but in many parts of their internal structure. The greater number live in water; but many species, such as the common Wood-Louse, are inhabitants of the land. Having no special apparatus, however, for keeping the respiratory surface moist, they can only exist in damp places. The *Oniscus*, or Wood-Louse, frequents dark and concealed places—such as cellars, caves, chinks in walls, or hollows under stones. It feeds upon decaying vegetable and animal matter, and only comes forth from its retreat in damp weather. It has the power of rolling itself completely into a ball.

To the order Phyllopoda, which is characterised by the prolonged form of the body, and the flattening of the extremities which adapts them for swimming, belongs a large number of species, whose movements are generally very regular and equable. The *Branchipus*, one of the most characteristic examples, is found, often in great numbers, in small puddles, and most abundantly after heavy rain. The eggs are capable of being dried up without injury, and are hatched soon after being moistened.

The remarkable order Xyphosura, is separated from the foregoing by the absence of organs for conveying food into the mouth. It receives its name from the sword-like prolongation of the carapace, which is used as a weapon by the natives of the regions in which the animals exist. The *Limuli*, or King-Crabs, as they are commonly termed, are peculiar to the East Indies (abounding in the neighbourhood of the Moluccas) and the coast of America. They sometimes attain the length of two feet. Their legs are very short, not extending beyond the margin of the shell. The anterior ones assist in conveying food to the mouth; the posterior are modified for respiration.



Limulus Polyphemus.

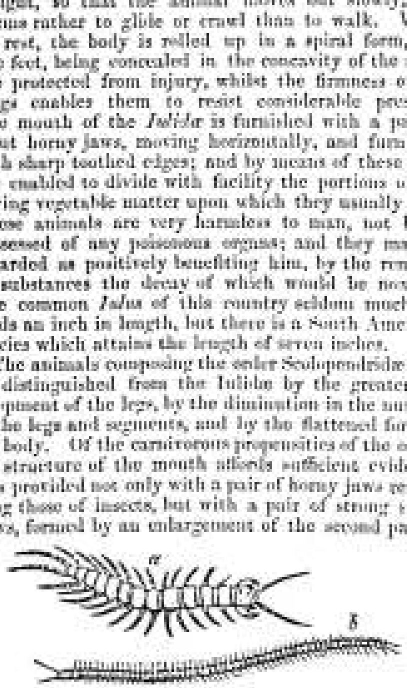
Near the *Limuli* should probably be placed the remarkable group of *Trilobites*, which are at present only known in a fossil state, but which were very abundant in former epochs of the earth's history. (See Geology.)

CLASS VIII.—MYRIAPODA.

The class Myriapoda is the lowest in which we meet with articulated members, or distinct jointed legs, as well as with an articulated body. Most persons are familiar with the common forms of this class—the *Centipedes* (hundred legs) and the *Millepedes* (thousand legs); and a minute description of them is therefore unnecessary. On examining any of these animals, the following points will be observed:—The covering of the body is firm, and of a somewhat horny character, resembling that of many insects. The division into segments is very distinct; a flexible membrane being interposed between each pair of firm rings or plates. The first segment, or head, is furnished with eyes formed upon the same general plan as those of insects; and also with a pair of long-jointed antennæ, which are prebably organs of touch. On the side or under surface of the animal may be seen a row of minute pores, a pair usually existing on each segment, which are the apertures for the admission of air to the respiratory organs. The different parts of the nervous system are repeated in a similar manner, a pair of ganglia being found in every division of the body. The class may be divided into two orders—the IULIDÆ, or *Millepedes*; and the SCOLOPENDRIDÆ, or *Centipedes*.

The Iulidæ, consisting of animals bearing a general resemblance to the *Iulus*, or common Millepede, are the most nearly allied to the Annelida, both in external form and in the arrangement of the several organs. The *Iulus Terrestris*, or Gallyworm, is a species often found concealed under stones, or beneath the bark of decaying timber. Its body is long and cylindrical, and is composed of between forty and fifty hard rings, which, except at the head and tail, differ but little from one another. Each segment gives origin to two pairs of small legs, which arise close to the middle line along the under surface of the body. These are scarcely large or strong enough to support its weight, so that the animal moves but slowly, and seems rather to glide or crawl than to walk. When at rest, the body is rolled up in a spiral form, and the feet, being concealed in the concavity of the spire, are protected from injury, whilst the firmness of the rings enables them to resist considerable pressure. The mouth of the *Iulidæ* is furnished with a pair of stout horny jaws, moving horizontally, and furnished with sharp toothed edges; and by means of these they are enabled to divide with facility the portions of decaying vegetable matter upon which they usually feed. These animals are very harmless to man, not being possessed of any poisonous organs; and they may be regarded as positively benefiting him, by the removal of substances the decay of which would be noxious. The common *Iulus* of this country seldom much exceeds an inch in length, but there is a South American species which attains the length of seven inches.

The animals composing the order Scolopendridæ may be distinguished from the Iulidæ by the greater development of the legs, by the diminution in the number of the legs and segments, and by the flattened form of the body. Of the carnivorous propensities of the order, the structure of the mouth affords sufficient evidence. It is provided not only with a pair of horny jaws resembling those of insects, but with a pair of strong sharp claws, formed by an enlargement of the second pair of



a, Lithobius Forcipatus; *b*, Geophilus Longicornis.

legs, which are perforated at the tip with a minute aperture, through which a venomous fluid is probably instilled into the wounds made by them. Small insects seized in these claws are seen to die very speedily, and in warm countries the bite of the large species of Centipede is a source of great irritation to man, being reputed more injurious than that of the scorpion.

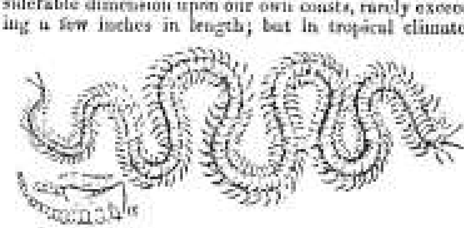
CLASS IX.—ANNELIDA.

The class Annelida is the lowest in which the articulated structure is distinctly manifest. It is composed of animals having a worm-like body, without true jointed legs; and marked by transverse lines that divide it into a succession of rings or segments, which, except the first and last, differ little from each other but in size. Many of them are remarkable for the red colour of their blood; and, on account of this character, they have been regarded as approaching nearer to the vertebrated sub-kingdom than any other class of articulated animals. This is not universally observed, however, for in some species the blood has a greenish tint, and in others it is nearly colourless, as in most of the invertebrata. The body is usually soft and flexible, the rings being possessed of little firmness, and no internal skeleton of any description being present. It is not only flexible, but capable of great alteration in its dimensions, as may be seen in the common earthworm and leech.

The greater part of the class are solely inhabitants of the water, and are provided with external appendages for exposing the blood to its influence, which are analogous in function to the gills of fishes, but which are often distributed over the whole surface, and are also concerned in locomotion. It may be regarded as the *regular* form of these animals to possess such appendages upon every segment; but not unfrequently the body is enclosed in a tube, and then the gill-tufts are collected in the neighbourhood of the head, where they may be protruded from its opening. The earthworm and a few other species are adapted to live on land, and they have a series of air-sacks arranged along the interior of the body on each side, opening externally by orifices, of which a pair may be seen upon each segment. The first segment, which may be termed the head, contains the mouth, sometimes provided with an apparatus of jaws; and also generally furnished with eyes, and with variously-shaped tentacula, which are apparently instruments of touch. The last segment is occasionally destitute of the appendages with which the rest are provided, and these are replaced by a sucker, which is of great assistance in locomotion.

The class is subdivided into orders by the differences in general conformation and habits exhibited by the tribes which compose it; and especially by the character and distribution of the respiratory organs. The first order, DORSIBRANCHIATA, includes those which have the branchial appendages or gill-tufts disposed regularly along the body, sometimes extending its entire length, and sometimes restricted to the segments about the middle. In the next, TUBICOLA, we find worm-like animals inhabiting fixed and permanent residences like the Mollusca. Sometimes they are enclosed in shelly tubes, formed by an exudation from their own surface (as the *Serpula*), and sometimes in casings constructed by the agglutination of foreign substances (*Sabella* and *Terebella*). The disposition of the gill-tufts around the head is the principal character which distinguishes the animals themselves from those of the first order. In the third order, TERRICOLA, the body is destitute of all external appendages, except some minute and almost imperceptible bristles; for the respiratory organs are here developed internally, the animals being formed to crawl upon the ground. And in the last, SUCTORIA, the body is destitute even of these bristles, but is furnished with a sucker at each extremity.

The dorsibranchiate annelids do not attain any considerable dimension upon our own coasts, rarely exceeding a few inches in length; but in tropical climates,

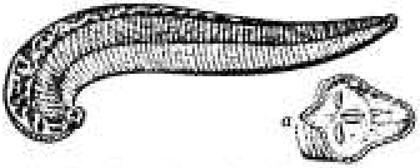


Syllis Monilaris: *a*, lateral appendage magnified.

some species are found of comparatively gigantic proportions, having their bodies composed of 400 or 500 segments, and occasionally measuring four feet from one end to the other. Their general form will be seen in the preceding figure, which represents the *Syllis Monilaris*; and the enlarged view of one of the lateral appendages will show the parts of which it consists. In the centre there is a tuft of delicate bristles, which may be regarded as the chief organ of respiration, the blood being sent into them to be exposed to the air contained in the water: above and below there are separate bristles, much more elongated, of which the lower one has a jointed character; these are instruments of locomotion, and may be regarded as rudimentary legs. The arrangement of these parts differs much, however, in the various families. One of these, the *Aphrodita*, or Sea-Mouse, is well known on our coasts, numbers being often cast up by a storm. The body is flattened, and shorter and broader than that of other Annelida. The back is covered by two longitudinal ranges of broad membranous scales, under which the gills lie concealed. The most common species is about six or eight inches long, and two or three broad. A great part of the body is covered by bristles of brilliant lustre, and of colours which vary with the light; so that the animal is scarcely surpassed in beauty of colouring by any other. The *Arenicola piscatorum*, known to fishermen by the name of *Lob-worm*, is another species common on our coasts, and is eagerly sought as a bait. It burrows, like the earthworm, in the sand; and the place of its excavations may be known by the little heaps which it casts up.

The order Terricola includes very few genera, of which the *Lumbricus*, or common *Earthworm*, is the chief. They live, in general, beneath the surface of the ground, either perforating the dry soil, or burying themselves in mud, where many of them lead a semi-aquatic life. When the earthworm is boring, it insinuates its pointed head between the particles of earth, amongst which it penetrates like a wedge; and in this position, the anterior part of the body is fixed by spines or bristles curved backwards, which prevent it from slipping. The hinder parts are then drawn forwards by a longitudinal contraction of the whole animal—a movement which the spines do not oppose. This swells out the anterior segments, and forcibly dilates the passage into which the head had been already thrust. The spines upon the hinder rings then take a firm hold upon the side of the hole thus formed, and prevent any backward movement; the head is again forced forward; and, by a repetition of the process, the animal makes its way through soils which it would at first have seemed impossible for it to penetrate. The burrowing of earthworms is a process exceedingly useful to the gardener and the agriculturist; and these animals are far more beneficial to man in this way, than injurious by devouring the vegetables set in the soil. They give a kind of under-tillage to the land, performing the same below ground that the spade does above for the garden, and the plough for arable land, and loosening the earth, so as to render it permeable to air and water. It has lately been shown that they will even add to the depth of the soil, and create mould where none existed before. This they do principally by the exercise of their digestive process. They take a large quantity of the soil through which they burrow into their intestinal canal; from this they extract the greater part of the decaying vegetable matter it may contain, and reject the rest in a finely-divided state, forming what are known as worm-casts. By the accumulation of these, a field which was manured with marl, has been covered, in the course of 80 years, with a stratum of new earth averaging a foot in depth.

The order Suctoria contains the common Leech and its allies, which are all of aquatic habits, but not all agreeing in its blood-sucking propensities. Most of the tribe, however, live at the expense of some other animal. The structure of the mouth of the leech is very interesting. It is situated in the middle of the cavity of the anterior sucker; and three little cartilaginous bodies, usually called *teeth*, but more properly *jaws*, are seen to be disposed around it, in such a manner, that the three edges form three radii of a circle. Each of these has two rows of very minute teeth at its edge; so that it resembles a small semicircular saw. It is imbedded at its base in a bed of muscle, by the action of which it is worked in such a manner as to cut into the skin—a sawing movement being given to each piece separately. It is in this manner that the tri-radiate form of the leech-bite is occasioned; each ray being



Leech: *a*, the anterior sucker and teeth enlarged.

produced by a separate little saw. The lacerated character of the wound is very favourable to the flow of blood, which is further promoted by the vacuum created by the sucker. The greater number of the leech tribe are inhabitants of fresh water; some, however, are only found in the sea; and there is one terrestrial species, a native of Ceylon, which appears to be more voracious than any other, and to be one of the greatest pests of that fine island.

CLASS X.—CIRRHOPODA.

The animals composing this class have so many characters in common with the Mollusca, that they have been generally regarded as belonging to that sub-kingdom. The body and its appendages are themselves quite soft; and the skin has the loose spongy muscular character which corresponds with the *mantle* of Molluscs. From its surface is secreted a shell, composed of several pieces, but not differing in general aspect from multivalve shells belonging to that division. Further, the shells are either themselves firmly united at their base to some solid masses, or they are attached by a footstalk; so that the conditions in which the animals exist closely resemble those to which we observe a number of the Mollusca peculiarly adapted. On the other hand, when we examine the animal itself, we find that it is perfectly symmetrical in its form—a character nowhere existing among the Mollusca which are enclosed in shells. Its body is prolonged, and exhibits a tendency to division into segments; and from each of these there arises a pair of appendages on each side, which possess something of a jointed structure. These *cirri*, as they are termed, are long tapering arms, fringed with cilia, or little hair-like filaments; and they have gills at their base. Further, the mouth is furnished with lateral jaws, which no Mollusc possesses; and the nervous system consists of a double cord, with a pair of ganglia in each segment of the body, precisely as in the other Articulata. The most interesting proof, however, that the Cirrhopods belong to this division, is derived from the history of their development. On their liberation from the egg, they present a form much more analogous to that of the lower Crustacea than to that of the adult animal, which they only acquire after a series of metamorphoses. They are furnished with antennæ and eyes, and move freely through the water; but when they become fixed, they lose also these organs of sense. The shell is not formed of simple layers, like that of the Mollusc, but is traversed by a complex series of canals, through which nourishment is conveyed to it.

The Cirrhopoda are divided into two principal groups—the *pedunculated* and the *sessile*. The latter, of which the common *Balanus*, or *Acorn-shell*, is an example, have the base of the shell fixed immediately to rocks; in the former, such as the well-known *Barnacle*, the shell is attached by a peduncle or footstalk, which consists of a tube of leathery consistence, and often of considerable length. In both groups, the animals, not being able to go in search of food, obtain it through currents produced by the action of their cilia. The shell of the common barnacle consists of five pieces, of which two are large valves, somewhat resembling those of a mussel; two smaller pieces are jointed to those near the point; and one unites the valves along the back edge. These cover the whole of the mantle. Barnacles are abundant in all seas, and fix themselves, in preference, to wood; so that a piece of timber which has been for a short time floating in the ocean, is almost sure to be partly covered with them; and ships' bottoms, if not protected by copper, are rendered so foul, as greatly to impede their sailing.

CLASS XI.—ROTIFERA.

The class Rotifera is one composed entirely of animalcules which can only be distinctly seen with the microscope; and it takes its name from the wheel-like organs with which most of them are provided, whence they are commonly known as Wheel-Animalcules. It is only within a very recent period that the complex structure of these beings has been understood, and that they have been separated from the animalcules of simpler organisation. It is on account of the prolonged form of their bodies, the position of the mouth and eyes at one extremity, the occasional marking of transverse lines indicating a division into segments, and, most of all, by the character of the nervous system, when that can be detected, that the Rotifera are ranked in the articulated sub-kingdom. Unquestionably, they bear more general analogy to that than to any other; but they must not be considered as characteristic specimens of it.

The structure of the common wheel-animalcule, *Rotifer vulgaris*—which may be found in many collections of stagnant water, especially such as have been long and freely exposed to the atmosphere—will afford a good illustration of that of the class. The body exhibits a prolonged form when fully extruded; but, as the integument is very elastic, it may be drawn up into a circle, or made to assume a great variety of shapes. At one end, it is furnished with a pair of projections, which are surmounted by circular fringes of cilia. It is by the vibration of these cilia that the currents are produced in the water around, which give an appearance as of the continual revolution of wheels. Between the wheels a sort of head extends forwards, on which a couple of red spots may be observed, which are believed to be eyes. The mouth is situated at the base of this central projection. At the opposite end, the body is prolonged into a kind of tail, furnished with three prongs; and by this the animal fixes itself when working its cilia. These animalcules feed chiefly upon others of smaller size and simpler character. The currents set in motion draw in whatever small bodies are within their scope; and from these are selected what is adapted to afford nutrition. Sometimes the animal folds in its wheels, and moves along a solid surface by the suckers with which its head and tail are furnished, in the same manner as a leech; at others, it remains altogether inert for a considerable period. One of the most remarkable points in its history is its power of being revived by the application of moisture, after having been entirely dried up. This experiment, however, does not always succeed.

CLASS XII.—ENTOZOA.

This class derives its name from the peculiar condition in which the animals composing it exist, most of them being inhabitants, during their whole lives, of the bodies of other animals, generally those of higher organisation, from the juices of which they derive their nourishment. Many of them possess a distinct worm-like form, the body being much prolonged, and exhibiting a division into segments, and the mouth being situated at one extremity. These, therefore, evidently belong to the Articulated series. There are others which, in the absence of all distinct organs, and also in the circularity of their form, seem to approximate more to the Radiata. Some species, formerly assigned to this class, are now known to be lowly-organised forms of Crustacea.

A division of the Entozoa into two sections has been proposed, founded upon the general peculiarities of their structure. In the first and highest, there is a distinct intestinal tube, with an orifice at each end; and traces of a nervous and muscular system, more or less developed, may be detected. This division evidently approximates to the Annelida. It includes, among many other species, the *Filaria*, or Guinea-Worm, which burrows in the flesh of man and other animals in warm climates: if undisturbed, it will often continue its operations for a considerable time without much uneasiness; but, if disturbed, it sometimes occasions the most excruciating pain. When it shows itself externally, it should be extracted slowly, for fear of breaking it, in which case the remainder would retreat, and continue to exist: it grows to the length of several yards. The *Ascaris lumbricoides*, or Round Worm of the intestines, also belongs to this group. It infests not only man, but many of the lower animals, and often occasions severe disease, and even death. It derives its second or specific name from its resemblance to the earthworm. The short active Thread-Worms, sometimes infesting the lower part of the intestine, are another species of the same genus.

In the lower division of the class, there is no distinct alimentary canal; the cavities for the reception of food, as well as those for other purposes, being, as it were, channelled out of the soft, almost homogeneous tissues of the body. Some of these still preserve the worm-like form: such are the so-called eels in vinegar; and the curious little parasites which have been recently discovered to infest the muscles of man. To this group also belongs the *Tænia Solium*, or Tape-Worm, in which we find a remarkable repetition of organs. The body is distinctly divided into joints or segments, which sometimes amount to several hundred, the whole animal occasionally attaining the length of ten feet. These segments are all connected by the nutritive canal, which runs from one end to the other; but the reproductive apparatus is repeated in each division. The head is small, and possesses four mouths, surrounded by a double circle of small hooks. Its existence is essential to the life of the body, the latter dying if it be broken off; but if some of the joints remain attached to the head, it continues to grow and form new ones. In this repetition of parts we see a tendency towards the type of the Polypifera.

One of the simplest of all the Entozoa is the common *Hydatid*, or *Acephalocyst* (headless bag), which seems to consist of nothing but a globular membranous bag, filled with a limpid colourless fluid. It exhibits no motion, or indication of sensation, when stimuli of any kind are applied to it; and it is often difficult to distinguish it from the tissues in which it is found. Its power of reproduction, however, by the formation of *gemmæ*, or buds, between its layers, shows it to be entitled to the rank of an independent being: the young Hydatids are thrown off internally or externally, according to the species. Among the animals associated with this group is the *Distoma*, or fluke, which infests the liver of sheep, and is also found in other domestic quadrupeds, and even in man. It is about an inch in length, and a quarter of an inch in breadth, having the form of a minute sole; and possesses eyes, situated on the most conspicuous part of the head. The power of multiplication in these animals is very great; the ducts of a single liver have been known to contain a thousand, with innumerable germs of others. They usually accompany the disease called *rot* in sheep; but they do not appear to be necessarily connected with it. They most frequently infest sheep that are pasturing on marshy grounds, in the waters of which their germs are probably contained; and it seems to be rather the unhealthiness of the situation than the development of the flukes, which is the real cause of the rot, since flukes infest the healthiest sheep during the autumn and winter months.

MOLLUSCA.

The range of animal forms comprehended under this sub-kingdom is so extensive, that it would be extremely difficult to frame any definition applicable to them all. The highest class approaches Fishes in many points of its organisation; whilst in the lowest we not only lose sight of some of the characteristic peculiarities of the group, but we find a near approximation to the higher Polypifera. In all the Mollusca, the body, as the name imports, is of soft consistence, and is enclosed in a soft elastic skin, lined with muscular fibres, which is termed the *mantle*. This skin, in many instances, is not applied closely to the body, but forms a membranous bag, having apertures (which are sometimes prolonged into tubes) for the entrance and egress of water. Through these the respiratory organs, which are situated within the cavity, are regularly supplied with pure fluid necessary for aërating the blood; and the mouth, when not capable of being projected beyond this cavity, is supplied with food by the same stream.

The Mollusca possess in general a very complicated digestive and circulating apparatus; but the organs of sensation and voluntary motion are comparatively undeveloped. The great bulk of their bodies is made up of the stomach and intestines, the liver and other glands connected with the alimentary canal, the respiratory apparatus, and the ovary for the production of germs (which is usually very large); whilst the muscular system, which in the Articulata forms so large a proportion of the whole structure, is frequently reduced to a few scattered fibres, and in but few instances attains any complexity and power. A considerable number of Molluscs are formed for an existence as completely stationary as that of the Zoophytes, and are dependent for their nourishment on the supplies of food casually brought within their reach by the waves and currents of the ocean; a few have powers of locomotion which enable them to forage actively for themselves; while the greater number wander sluggishly, like the snail, from place to place, devouring with voracity such supplies as they meet with, and being capable of fasting for long intervals when none comes in their way.

It is from the surface of the mantle that the calcareous matter is exuded which forms the shell, in those species which possess such a protection; its particles are held together by a sort of glue, which exists in much larger proportion in some species than in others. In very hard and brittle shells, if the calcareous matter be removed by the action of an acid, the animal matter that remains appears in separate flakes. But in many other shells thus treated, the animal portion retains its form after the removal of the lime; and there are a few in which the (so-called) shell consists only of a substance like horn, without any intermixture of calcareous particles. Such a substance appears to be formed by the young animal before the true shell is secreted; and it is also the first that appears when the animal is repairing the effects of an injury to the old one. It is this that constitutes what is commonly termed the *epidermis* of shells—a covering possessed in their natural state by all that are not enveloped in a fold of the mantle, but which is commonly removed when the shell is preserved, as it obscures the beauty of the exterior. The shell is most solid and massive in those species which lead an inactive life; and is usually light and thin, or altogether deficient, in those whose powers of locomotion are greater. Its thickness often varies greatly amongst different individuals of the same species, according to the roughness or tranquillity of the waters they inhabit.

Taking the general conformation of the animals as a guide, naturalists divide the Mollusca, first, into those having a *head*—that is, a prominent part of the body on which the mouth is situated, with organs of sense in its neighbourhood—and those which are *acephalous*, or headless. Among the former we perceive three very distinct types of structure:—

The Cephalopoda, or *Cuttle-Fish* tribe, have feet or tentacula arranged in a circular manner around the head. In this group we find the nearest approximation to the Vertebrata.

The Pteropoda constitute a small but interesting class, characterised by the possession of a pair of wing-like expansions of the mantle, and by the great symmetry of their bodies. These expansions serve as fins, by which they swim with considerable velocity.

The Gasteropoda form the most extensive group of the whole. The two former are confined entirely to the sea; in this we find species adapted to live in fresh water, and even on land. The Gasteropods have but one muscular expansion or foot, and this proceeds from the under surface of the body, as may be well seen in the common snail.

In each of these orders we observe a considerable variation in regard to the relative size and even the existence of a shell; for whilst there are some species entirely destitute of this protection (such being called naked Molluscs), there are others which possess it in a slight degree, having it generally concealed in a fold of the mantle, and others in which it completely envelops the body, when they withdraw themselves under its protection. In the different species of Snail and Slug, all agreeing closely in general structure, every variety of this kind may be witnessed.

In the headless Molluscs, on the other hand, we find two very distinct groups; in the first of which the shell is constantly present, whilst in the second it is as invariably absent. The general structure of the latter is much inferior to that of the shell-bearing class, and approaches more nearly in several of its characters to the Polypifera:—

The highest class of Acephalous Molluscs is named Conchifera, from the constant presence of a shell, which is nearly always formed of two pieces, or *bivalve*.

The lowest is denominated Tunicata, the shell being replaced, as it were, by a leathery or cartilaginous envelope or tunic, which encloses the whole body.

CLASS XIII.—CEPHALOPODA.

The class Cephalopoda, which is so named from the arrangement of the feet or locomotive organs around the head, must be regarded as the highest among the Mollusca in respect to the complexity of its organisation, and it is the one which approaches most nearly to Vertebrated animals. In the general form of their bodies, and in their adaptation to rapid motion through the water, many species bear a considerable resemblance to fishes, and are, indeed, commonly reputed as such. The name of the class expresses the character which distinguishes it from all others. On the head, which is furnished with eyes resembling those of higher animals, and also with organs of hearing, and perhaps also of smell, are disposed in a circular manner the curious appendages which have received the name of *feet* or *arms*, and to which either term may be justly given, as they are organs of prehension as well as of locomotion. These are usually eight or ten in number; but in the true *Nautilus* they amount to nearly a hundred. The mouth, which is situated in the centre of the circle of arms, is provided with a pair of firm horny mandibles or jaws, of which one is sharply pointed, and overlaps the other when closed, so that the whole very much resembles the bill of a parrot. This beak encloses a large fleshy tongue, roughened with horny prickles; and the œsophagus leads to a muscular stomach, which closely resembles the gizzard of birds. All the Cephalopoda are aquatic, and consequently breathe by gills. These are disposed symmetrically on the two sides, and are covered by the mantle. This envelope includes the whole body, but there is an opening in it which gives passage to the head. Through this opening the water enters to the gills, and it is expelled through a tubular prolongation of the mantle termed the *funnel*, which also serves as the excretory canal.

Most of the Cephalopods possess something analogous to the shells of other Molluscs, although it often exists in a form and position which might almost prevent its being recognised as such. The only species at present known in which the body of the animal is enclosed within it, as in the shells of Gasteropods, are the *Nautilus* and the *Argonauta* (Paper Nautilus). In the former of these the shell is spiral, and is divided by transverse partitions into chambers, in the last or outermost of which the animal lives; and when it wishes to enlarge its shell, it prolongs the mouth of it, which widens as it is prolonged, and throws a new partition across the bottom. The shell of the Argonaut has no such chambers, and the animal, when hiding within it, occupies the whole of its cavity. In the common *Sepia* (Cuttle-Fish), on the other hand, the shell is reduced to the form of an oval plate—commonly known as the *cuttle-fish bone*—which is enclosed within a fold of the mantle, and lies upon the back of the animal. In some of the more slender and flexible species even this is nearly wanting; all that remains of a shell in the *Loligo* (Squid) being a horny plate, somewhat resembling a feather in shape, whence it is termed the *pen*.

The arms of all the Cephalopods are covered with very curiously-constructed suckers, by which they are enabled to take firm hold of anything to which they are applied. These act by excluding the air, and thus producing a vacuum, exactly upon the principle of the boys' leathern sucker. In this manner they are enabled to master animals which it would have been supposed entirely out of the power of their soft unprotected bodies to combat successfully. They are generally agile as well as voracious, and prey upon almost all other classes of marine animals. Their especial articles of food, however, are Fishes and Crustacea; and they are probably the only animals which are able to restrain the inordinate multiplication of the larger members of the latter class. The firm armour and powerful claws of the crab or lobster are no protection against these soft-limbed cuttle-fish, which wind their arms round these bodies, and, fixing every part by means of their suckers, tear apart the divisions of the shell by means of their hard parrot-like bills. So firmly do these suckers adhere, that while the muscular fibres remain contracted, it is easier to tear asunder the substance of the limb than to release them from their attachment.

The species which are unprotected by an external shell are furnished with a curious means of escaping from their enemies. This is the secretion of a dark fluid, which, when emitted by the animal, tinges the water around to such a degree, that it can escape in the cloud it has made. The fluid is usually stored up in a bag communicating with the funnel, through which it is ejected under the influence of alarm. This ink-bag, as it is termed, is collected from the species inhabiting the Indian seas; the ink forms a valuable pigment, known to the artist as *sepia*, the name of the animal which furnishes it.

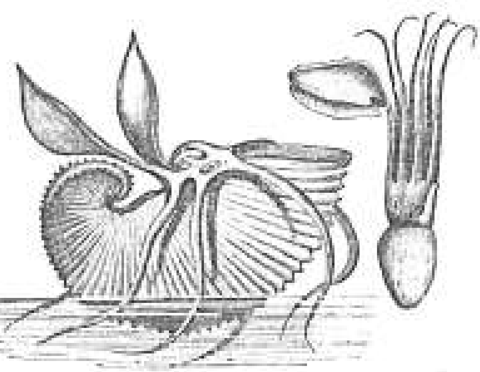
The Cephalopods may be subdivided into two great orders. In the higher division, which approaches the nearest to vertebrate animals, the *branchiæ* or gills are two in number, and the order is termed DIBRANCHIATA; whilst in the one most closely allied to the Gasteropods, the branchiæ are four in number, and the order is therefore termed TETRABRANCHIATA:—

I.—Dibranchiata.

The Dibranchiate order includes all the best-known forms of the class. It is divided into two tribes, in one of which there are but eight arms, whilst in the other there are ten, of which, however, two are different from the rest. The first of these, termed OCTOPODA, may be considered as the highest in point of general organisation; the second, termed DECAPODA, presents many points of approach to the Tetrabranchiata, both in the increased number of arms, and in the presence of an inner circle of short tentacula, as well as in several internal characters. The *Sepia*, or common Cuttle-Fish, is a characteristic example of the DECAPOD family. Some species of it abound in almost all seas. It has two long slender arms, which are furnished with suckers only at their extremities; and by these the animal is said to fix itself, as by anchors, when exposed to a rough sea or strong current. They are probably employed also in seizing prey, which is brought by them within the range of the others. To this family we are also probably to refer the *Spirula*, a little-chambered shell, the animal of which is very imperfectly known; and a large number of fossil chambered shells, known as *Ammonites, Orthoceratites, Belemnites*, &c.; the last of which was probably analogous to the Sepia, including the shell, like the bone of the cuttle-fish, within the body. [See GEOLOGY.]

The OCTOPODS, which form the highest family of the order, have but eight arms, without tentacula; and they are destitute of lateral fins, so that they depend entirely upon the arms for their movement through the water. Accordingly, it is found that these are very large and powerful, and that the body is proportionally short. The arms are generally united at their bases into a kind of circular fin, by the motion of which the animal can swim backwards with great energy. The common *Octopus*, or *Poulp*, of European shores, has the arms six times the length of the body, and each furnished with 120 pairs of suckers. It can leave the water, and creep over the beach, taking hold of the ground before it by the extension of its arms, and then dragging the body towards the point at which the suckers are attached.

A very interesting species of the Octopod group is the *Argonauta Argo*, commonly called the *Paper Nautilus*, from the whiteness and delicacy of its shell. As the animal has little in common with the true Nau-



Shell of Argonaut, with animal in the reputed position.

tilus, it would be much better if the latter designation were entirely abandoned, and the term *Argonaut* substituted for it. The shell is not chambered, but possesses one spiral cavity, into which the animal can withdraw itself entirely; this, however, has no muscular attachment to it, whence it has been supposed by many naturalists that it was only a parasitic inhabitant which had taken up its abode within it, and that the shell, from its resemblance to that of Carinaria, was formed by a gasteropod mollusc allied to that genus. It has been proved, however, by the interesting experiments of Madame Power, that the shell increases regularly with the growth of the animal, which possesses the power of repairing it when injured; so that no doubt can exist that the Argonaut is the original constructor of it.

Of the eight arms of the Argonaut, six taper gradually towards the extremities; but two are expanded into wide membranous flaps. From very early times, this animal has been reputed to swim on the surface of gives passage to the head. Through this opening the water enters to the gills, and it is expelled through a tubular prolongation of the mantle termed the *funnel*, which also serves as the excretory canal.

Most of the Cephalopods possess something analogous to the shells of other Molluscs, although it often exists in a form and position which might almost prevent its being recognised as such. The only species at present known in which the body of the animal is enclosed within it, as in the shells of Gasteropods, are the *Nautilus* and the *Argonauta* (Paper Nautilus). In the former of these the shell is spiral, and is divided by transverse partitions into chambers, in the last or outermost of which the animal lives; and when it wishes to enlarge its shell, it prolongs the mouth of it, which widens as it is prolonged, and throws a new partition across the bottom. The shell of the Argonaut has no such chambers, and the animal, when hiding within it, occupies the whole of its cavity. In the common *Sepia* (Cuttle-Fish), on the other hand, the shell is reduced to the form of an oval plate—commonly known as the *cuttle-fish bone*—which is enclosed within a fold of the mantle, and lies upon the back of the animal. In some of the more slender and flexible species even this is nearly wanting; all that remains of a shell in the *Loligo* (Squid) being a horny plate, somewhat resembling a feather in shape, whence it is termed the *pen*.

The arms of all the Cephalopods are covered with very curiously-constructed suckers, by which they are enabled to take firm hold of anything to which they are applied. These act by excluding the air, and thus producing a vacuum, exactly upon the principle of the boys' leathern sucker. In this manner they are enabled to master animals which it would have been supposed entirely out of the power of their soft unprotected bodies to combat successfully. They are generally agile as well as voracious, and prey upon almost all other classes of marine animals. Their especial articles of food, however, are Fishes and Crustacea; and they are probably the only animals which are able to restrain the inordinate multiplication of the larger members of the latter class. The firm armour and powerful claws of the crab or lobster are no protection against these soft-limbed cuttle-fish, which wind their arms round these bodies, and, fixing every part by means of their suckers, tear apart the divisions of the shell by means of their hard parrot-like bills. So firmly do these suckers adhere, that while the muscular fibres remain contracted, it is easier to tear asunder the substance of the limb than to release them from their attachment.

The species which are unprotected by an external shell are furnished with a curious means of escaping from their enemies. This is the secretion of a dark fluid, which, when emitted by the animal, tinges the water around to such a degree, that it can escape in the cloud it has made. The fluid is usually stored up in a bag communicating with the funnel, through which it is ejected under the influence of alarm. This ink-bag, as it is termed, is collected from the species inhabiting the Indian seas; the ink forms a valuable pigment, known to the artist as *sepia*, the name of the animal which furnishes it.

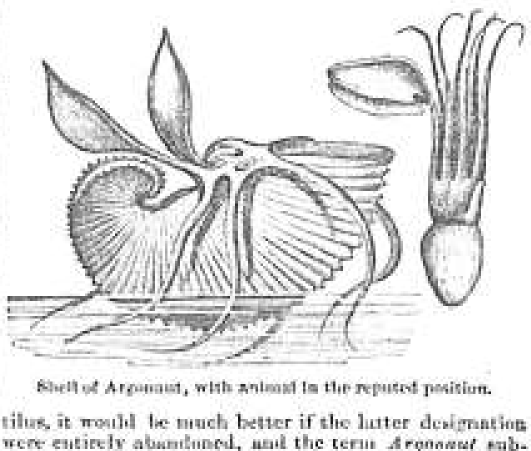
The Cephalopods may be subdivided into two great orders. In the higher division, which approaches the nearest to vertebrate animals, the *branchiæ* or gills are two in number, and the order is termed DIBRANCHIATA; whilst in the one most closely allied to the Gasteropods, the branchiæ are four in number, and the order is therefore termed TETRABRANCHIATA:—

I.—Dibranchiata.

The Dibranchiate order includes all the best-known forms of the class. It is divided into two tribes, in one of which there are but eight arms, whilst in the other there are ten, of which, however, two are different from the rest. The first of these, termed OCTOPODA, may be considered as the highest in point of general organisation; the second, termed DECAPODA, presents many points of approach to the Tetrabranchiata, both in the increased number of arms, and in the presence of an inner circle of short tentacula, as well as in several internal characters. The *Sepia*, or common Cuttle-Fish, is a characteristic example of the DECAPOD family. Some species of it abound in almost all seas. It has two long slender arms, which are furnished with suckers only at their extremities; and by these the animal is said to fix itself, as by anchors, when exposed to a rough sea or strong current. They are probably employed also in seizing prey, which is brought by them within the range of the others. To this family we are also probably to refer the *Spirula*, a little-chambered shell, the animal of which is very imperfectly known; and a large number of fossil chambered shells, known as *Ammonites*, *Orthoceratites*, *Belemnites*, &c.; the last of which was probably analogous to the Sepia, including the shell, like the bone of the cuttle-fish, within the body. [See GEOLOGY.]

The OCTOPODS, which form the highest family of the order, have but eight arms, without tentacula; and they are destitute of lateral fins, so that they depend entirely upon the arms for their movement through the water. Accordingly, it is found that these are very large and powerful, and that the body is proportionally short. The arms are generally united at their bases into a kind of circular fin, by the motion of which the animal can swim backwards with great energy. The common *Octopus*, or *Poulp*, of European shores, has the arms six times the length of the body, and each furnished with 120 pairs of suckers. It can leave the water, and creep over the beach, taking hold of the ground before it by the extension of its arms, and then dragging the body towards the point at which the suckers are attached.

A very interesting species of the Octopod group is the *Argonauta Argo*, commonly called the *Paper Nautilus*, from the whiteness and delicacy of its shell. As the animal has little in common with the true Nau-

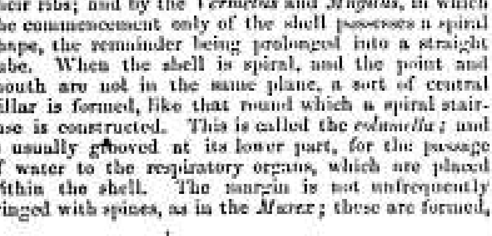


Shell of Argonaut, with animal in the reputed position.

tilus, it would be much better if the latter designation were entirely abandoned, and the term *Argonaut* substituted for it. The shell is not chambered, but possesses one spiral cavity, into which the animal can withdraw itself entirely; this, however, has no muscular attachment to it, whence it has been supposed by many naturalists that it was only a parasitic inhabitant which had taken up its abode within it, and that the shell, from its resemblance to that of Carinaria, was formed by a gasteropod mollusc allied to that genus. It has been proved, however, by the interesting experiments of Madame Power, that the shell increases regularly with the growth of the animal, which possesses the power of repairing it when injured; so that no doubt can exist that the Argonaut is the original constructor of it.

Of the eight arms of the Argonaut, six taper gradually towards the extremities; but two are expanded into wide membranous flaps. From very early times, this animal has been reputed to swim on the surface of it exists, is the same as in the Conchifera. It is in general composed of one piece, and called a *univalve;* in some instances, however, it is a *multivalve;* and in many species there is a small *operculum*, or lid, to the mouth of the shell, which may in some degree be regarded in the light of a second valve. The body is attached to the interior of the shell by muscles, which can withdraw it or project it at the will of the animal; and the operculum can be drawn down upon the mouth with considerable force. It is the habit of some species (as the *Limpet* and *Haliotis*) to attach themselves, by the expanded surface of the foot, to rocks, &c.; these are able to draw the shell closely down upon the rock, with great muscular power, just as the Conchifera draw together their valves; a short interval existing, however, when the animal is not alarmed, for the admission of water or air to the cavity of the shell. A very slight irritation will cause the animal to draw the shell close down on the rock, from which it is then very difficult to detach it. The shell in this class is enlarged at intervals in accordance with the increasing size of the animal. In some, the addition of an entire new interior layer, projecting beyond the old one, is made at every such period, as in the Conchifera; but in others, the new matter is secreted only at the edge of the previous shell, and is joined on, as it were, to it; in these, the line of addition is usually marked by a prominent rib on the exterior, but the interior is beautifully smooth.

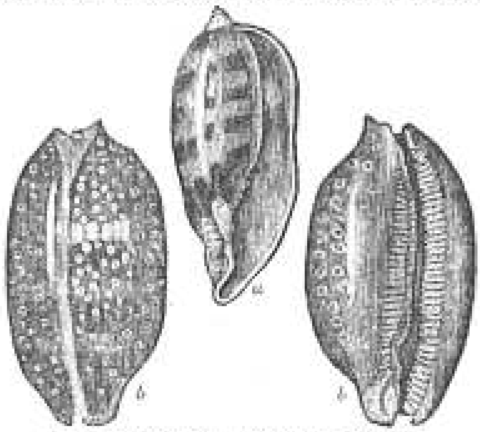
The forms of the Gasteropod shell vary extremely; but those which appear most widely separated may be shown to be connected by intermediate links. The open cone of the Limpet may be regarded as one of the simplest forms; in an allied genus, the *Pileopsis*, we find the point prolonged, and somewhat rolled upon itself; and by various links of this kind, we are brought to the regular spiral of the snail. From this we may return to the long straight form, by the *Scalaria*, in which the coils of the spire touch each other only by their ribs; and by the *Vermetus* and *Magilus*, in which the commencement only of the shell possesses a spiral shape, the remainder being prolonged into a straight tube. When the shell is spiral, and the point and mouth are not in the same plane, a sort of central pillar is formed, like that round which a spiral staircase is constructed. This is called the *columella;* and is usually grooved at its lower part, for the passage of water to the respiratory organs, which are placed within the shell. The margin is not unfrequently fringed with spines, as in the *Murex;* these are formed,



Murex Tenuispina.

like similar appendages in the Conchifera, by prolongations of the mantle; and the dissimilar number of them in different specimens has caused the arrangement of many species, which, now that the habits of the animal are better known, prove to be but different forms of the same. For it has been ascertained that the animal has not only the power of forming new spines, but of removing old ones, especially such as would interfere with the continued growth of the shell. The edge of the mantle is applied against their bases, and a kind of absorption of shelly matter seems to take place—a notch being formed, which causes them to be easily broken off. Various analogous changes are produced by a similar process in other shells, the portions first formed being wholly or partially removed. Sometimes the walls of the older portion are thinned, for the purpose of lightening the shell; and in other cases the top of the cone is altogether removed, a groove having been formed around its interior, which renders it so weak, as to be easily broken off. In the latter cases, the animal previously withdraws itself from the part to be separated, and throws a new partition across, by which the top of the shell remains closed after the division. A shell thus deprived of its apex is said to be *decollated.*

It is not only by such removals that the form of univalve shells undergoes a great change. Sometimes additions are made to them which completely alter their figure, so that two individuals of different ages would be scarcely supposed, at first sight, to belong to the same tribe. In all these cases, however, the form of the young shell may be traced in that of the adult. In the young shell of the *Cypræa (cowry)*, for example, the edge is sharp, and the mouth, or opening, of considerable breadth. This state continues as long as the shell is increasing in size; but when it has arrived at adult age, the outer lip is thickened, and brought so near the other, as to leave but a narrow chink between



Cypræa Exanthema: *a*, young shell; *b*, *b*, adult.

them. At the same time, a prolongation of the mantle on each side deposits a new layer of shelly matter on the outside of the previous one; and as the two prolongations meet along the back (the line of their junction being usually evident on the shell), this additional coat, which is very hard and *porcellanous* in its texture, encloses the whole previous shell.

The *operculum* is principally confined to the aquatic Gasteropods. It is sometimes of the same texture as the shell itself, and sometimes horny. It does not always close the entire mouth of the shell, but it is sometimes made to fit it, at all stages of growth, with the most beautiful accuracy. Some of the land species also possess an operculum; but in general they are destitute of it, and they form during hybernation a temporary closure to the mouth of the shell, by a viscid secretion, which hardens into a thin plate, and includes within it a bubble of air. Behind this, a second, and even a third similar partition is occasionally found, as in the common snail.

The subdivision of this extensive class into orders, is effected by arranging the different tribes according to the character and position of the respiratory organs. Cuvier presents the following orders:—Pulmonea, Nudibranchiata, Inferobranchiata, Tectibranchiata, Heteropoda, Pectinibranchiata, Tubulibranchiata, Scutibranchiata, Cyclobranchiata.

Of the order Pulmonea, the greater part live on land, but some are aquatic. They all feed chiefly upon vegetables, and many of them exclusively so; but some are extremely voracious, and will devour almost any organised matter that falls in their way. They are diffused through all climates, particular species being restricted to each. Those without a shell, commonly known as Slugs, constitute the family Limacinæ. In the common *Slugs*, as in most of the terrestrial species of this order, we observe a prominent head, with four tentacula, and at the end of the longer pair the eyes are situated. These tentacula can be drawn inwards, by a process resembling the inversion of the finger of a glove. On the back there is a kind of shield, or disk, formed by the mantle, which sometimes encloses a small shell. This shield covers the pulmonary sac, the opening of which is on its right side, and the head can be withdrawn beneath it. The snails and their allies, constituting the family HELICINÆ, are closely allied to the slugs; differing in little else than the possession of a shell, into which the body may be withdrawn. The common garden snail of this country, and the *Helix pomatia*, or edible snail of France and Italy, are well-known examples of the family. More striking ones are to be found, however, in tropical climates; where some species of the genus *Bulimus* attain to great size, the eggs being as large as a pigeon's. In some species, the direction of the coils of the shell is opposite to what it is in the generality of spiral shells: such are said to be *reversed*.

The order TECTIBRANCHIATA shows an approximation towards that disposition of the gills which characterises the great bulk of the class; the animals composing it are marine, and live chiefly on the shore, or on floating sea-weeds. A very characteristic example of the order is the *Aplysia*, commonly termed Sea-Hare, which is abundant on many parts of the British coasts. Its vernacular name is probably derived from the peculiar form of the superior pair of tentacula, which are flattened and hollowed like the ears of a hare. The head has a very distinct neck. The branchiæ consist of leaflets arranged in a complex manner, and situated on the back, beneath a fold of the mantle, which also encloses a flat horny shell. The digestive apparatus is very complicated, consisting of a membranous crop, like that of birds, a gizzard, having cartilaginous walls, and a third stomach, beset with sharp hooks in its interior. These animals feed on sea-weed. They are very sluggish in their movements; but have a peculiar means of defence, consisting of a deep purple liquid, which they can discharge from the edge of the mantle when alarmed, and by which the surrounding water is discoloured, so that they cannot be discerned.

The order PECTINIBRANCHIATA is not only by far the most numerous in the whole class, but contains the animals which may be regarded as its most characteristic members. They have all two tentacula and two eyes, sometimes raised on stalks, as in the snail. The mouth is prolonged into a sort of proboscis, and the tongue is furnished with little hooks, or recurved spines, which enable it to wear down the hardest bodies by slow and oft-repeated action. The cavity in which the gills are fixed occupies the last whorl of the shell; and in some of the order there is a tubular prolongation of the mantle, termed the *siphon*, for the purpose of conveying water into this cavity, so that the animal can breathe without leaving its shelter. By the presence or absence of this organ, and by the form of the shell, which here appears to bear a sufficiently constant relation with that of the animals, this large group may be arranged under the following families:—1. TROCHOIDÆ, in which there is no siphon, and which have the mouth closed by an operculum: of this the common periwinkle is a characteristic example, though very small in proportion to tropical species. 2. CAPULIDÆ, which have a wide open shell, very much like that of the limpets, without operculum or notch at the margin for the passage of a siphon. 3. BUCCINOIDÆ, which have a spiral shell, and a canal at the end of the columella for the passage of the siphon: this is sometimes extremely prolonged, as in the Murex; and the genera exhibiting this character are all carnivorous in their habits. To this family belong the animals forming the greatest number of marine univalve shells preserved in the cabinets of collectors.

The order SCUTIBRANCHIATA is a small one, containing but two principal genera, which do not differ widely from the limpets, except in the disposition of the gills. The shells are very open, without an operculum, and the greater number are not in any degree spiral. In the *Haliotis*, the shell is slightly twisted; and from a faint resemblance it is thought to bear to the ear of a quadruped, it has been called the Sea-Ear. This animal, in its living state, is one of the most beautiful of Gasteropods, on account of the variety and richness of its colours. Its shell, when the surface is polished, possesses a pearly lustre, with resplendent metallic hues. It is consequently much sought for as an ornament.

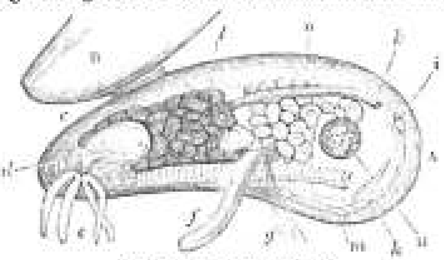
The general form of the *Limpets*, which principally compose the order CYCLOBRANCHIATA, is well known; and the peculiarity in the position of their gills has already been mentioned. Closely allied to the limpets in general structure, but differing remarkably in the formation of the shell, are the *Chitons* (*chiton*, a tunic), of which some small species inhabit our shores, but which attain to much greater size between the tropics. Their shell, which is of a leathery or horny structure, is composed of a number of plates arranged behind one another with great regularity, and connected by a very complex series of ligaments and muscles, which reminds the naturalist of those which unite and move the different segments in articulated animals.

CLASS XVI.—CONCHIFERA.

The Molluscs belonging to this class are, in common with the Tunicata, destitute of a head; that is, the mouth is not situated upon a prominent part of the body, nor assisted in its choice of food by organs of special sensation in its neighbourhood, but the entrance to the stomach is buried between the folds of the mantle. The part of the structure of these animals which is best known is the *shell*. This is composed of particles of lime, exuded from the surface of the mantle, in combination with a glutinous secretion, by which they are united together. If one of the valves of a bivalve shell be examined, it will be seen to consist of a number of layers, of which the outer one is the smallest, each inner one projecting beyond the one that covers it. This is more evident in such shells as that of the oyster, in which the layers adhere loosely together, than in others in which they are more compact. The shelly matter is thrown out at intervals from the surface of the mantle; and as the animal enlarges at each interval, the new layer extends beyond the old one. In this manner a constant relation is preserved between the size of the animal and that of its shell; and the addition of the newly-formed portions, not to the edge only, but to the interior of the whole previous shell, strengthens the latter in proportion to its increase.

The valves are connected together in various ways. In the first place, they are jointed by a *hinge*, which is in some instances so firm and complicated, that it holds them together when all the soft parts have been removed. This hinge is sometimes formed by the locking of a continuous ridge on one valve into a groove in the other, and sometimes by a number of little projections, or *teeth*, which fit into corresponding hollows in the opposite valve. In the neighbourhood of the hinge (sometimes outside, sometimes inside, or both) is fixed the *ligament*, which is composed of an elastic animal substance; this answers the purpose of binding the valves together, and at the same time of keeping them a little apart, which may be regarded as their natural position. When the animal wishes to draw the valves closely together, it does so by means of the *adductor* muscle, which is fixed to the interior of both valves at some distance from the hinge, and of which the insertion can be easily traced by a somewhat rough depression of the interior surface of each valve.

In order to describe the general structure of the Conchifera, it will be advantageous to select some particular illustration; and the common *mussel* is well adapted to this purpose. On opening such a shell, it is seen that the two valves are lined by a membrane, divided into two halves along a considerable part of the edge of the valves, but united near the large end. In some Conchifera, as will be presently seen, the two halves of the mantle are separated along their whole extent; whilst in others, as in the Tunicata, they are completely closed, with the exception of the two orifices for the ingress and egress of water, which are sometimes drawn out into long tubes. In the mussel, the water enters through a slit in the closed part of the mantle, and passes out by another in its neighbourhood; but the water thus introduced is principally for the supply of the gills, as the mouth, or entrance to the stomach, is placed at the small end of the shell, where the mantle is quite open, and can take in food from the surrounding water, which comes into free contact with it. The gills in all Conchifera consist of four ribbon-like fringes, fixed to the mantle along the edge of the shell most distant from the hinge.



Interior of common Mussel.

A, right valve; B, left valve; c, hinge; d, stomach; e, tentacula or feelers; f, foot; g, byssus; h, branchial orifice; i, vent; k, termination of the intestine; l, liver; m, gills; n, adductor muscle; o, ovarium.

Near the small end of the shell is seen the stomach, with the short tube leading to it, the orifice of which is furnished with four tentacula or feelers. To the right of this is seen the long and complicated intestinal tube, with the liver lying in separate masses amongst its folds. And nearer the larger end, the cavity of the shell is chiefly occupied by the ovarium, in which the eggs are formed. Close to this is the adductor muscle, by which the valves can be drawn together with considerable force. The intestinal tube is seen to terminate near the opening at the posterior (or right-hand) extremity of the shell, which discharges its contents, and serves for the exit of the respiratory current.

The foregoing description will apply, with slight variations, to the structure of almost all Conchifera; but we have now to notice two organs, which are absent in some, and in others more largely developed than in the present instance. From the lower part of the shell, passing out between the separate edges of the mantle, is seen the *foot*, a fleshy muscular organ, somewhat resembling the tongue of higher animals, and not containing any hard support, or being protected by any envelope. This foot, which is the only special locomotive organ possessed by the Molluscs of this class, serves a great variety of purposes, sometimes enabling the animal to leap with considerable agility along a hard surface, sometimes being used to bore into the sand or mud, and at others serving only to affix the animal to some firm support. From the base of this foot there proceeds, in the mussel, a band of hair-like filaments, forming what is called the *byssus*, from a Greek word of the same name, signifying fine flax. These sometimes exist in great abundance, and serve, by being fixed by their extremities to the shore or bottom of the sea, to anchor the shell, and yet to allow the animal freedom of motion within certain limits. In many cases the byssus is altogether absent.

Of the Conchifera, some, as the oyster, are attached to one spot during all but the earliest period of their lives; others adhere by the byssus, or by the foot, by which they obtain a certain range; and others are free during the whole of their lives, swimming and leaping with considerable agility. Some appear to be directed in their movements by powers of sight; and in these are perceived small red spots at the edges of the mantle, which are believed to be eyes. The Conchifera do not appear to have much choice of food, nor are they provided with any other means of obtaining it than the ciliary action, which introduces constant currents of water into the mouth. In general, they do not attain a great size, but they are, on the whole, larger than any Molluscs except the Cephalopods. A few species attain considerable dimensions—a *Pinna* having been known four feet long, and a *Tridacna* (Giant Clamp-shell) having been found to weigh 600 lbs. They are distributed over the whole globe, principally frequenting the shores or shallows. Each region has certain species peculiar, or most abundant in it, and there are few which are not limited to one hemisphere. The temperate zone appears as favourable to the development and multiplication of some species as the torrid zone to others; but the largest kinds are found only in warm latitudes.

In the subdivision of this class into orders, the degree in which the two lobes of the mantle adhere along the margin of the shell, is the character chiefly rested on; the presence or absence of the foot, and of the byssus also, are important characters; and along with these, the structure of the hinge should be attended to. On these grounds, the five following orders are established by Cuvier:—1. Ostraceæ, the *Oyster* tribe, in which the two halves of the mantle are separated the whole way round, and the foot absent, or very small: they are usually fixed by the shell to solid bodies. 2. Mytilaceæ, the *Mussel* tribe, in which the mantle remains open in front (at the end where the mouth is situated), and closed behind, an aperture being left for the egress of the fluid. They have a foot strong enough to crawl by, and commonly affix themselves by a byssus. 3. Chamaceæ, or *Clamp-shells;* in these the mantle is closed, with the exception of three apertures, two of which are for the ingress and egress of water, and the third for the passage of the foot, which is here usually more powerful. 4. Cardiaceæ, or *Cockle* tribe, in which the mantle is not only closed, but extended at the respiratory apertures into tubes of greater or less length. The foot is very strong. 5. The Inclusa, in which the mantle has only one opening for the passage of the foot; at the posterior end it is prolonged into tubes of great length, that can be extended far beyond the shell, as in the common *Solens*, or Razor-shells.

The Ostraceæ exhibit the nearest approach to the Tunicata, both in the absence of the foot, the entirely fixed condition of the body, and in the low grade of their general organisation. The shell itself is usually fixed by adhesion to other masses; in a few, the animal is attached by a byssus. Their continued abundance in the British seas, notwithstanding the large quantities constantly being consumed, is less surprising when we reflect upon their astonishing fertility, as many as 1,200,000 eggs having been detected in a single individual. The *Pectens*, or *clams*, as they are commonly called, have a hinge like that of the oysters, but differ in having the surface of the valves raised up into ribs, and in having two angular projections, commonly termed *ears*, by the sides of the hinge. Many of them are very elegantly coloured, and they are the most active of the whole order, being entirely unattached, and swimming with greater quickness than would have been expected from their imperfect means of locomotion. The *Anomiæ* are nearly allied to the oysters, but have a remarkable peculiarity in the structure of the shell. The

Anomia Ephippium.

greater part of the adductor muscle passes through a fissure in one of the valves, to be attached to a third plate, sometimes shelly, and sometimes horny, by which the animal adheres to foreign bodies; the remainder joins one valve to the other. Thus we have a *multivalve* shell formed by an animal which, both in structure and habits, corresponds closely with the bivalve oyster.

The foregoing tribes of Ostraceæ, and many more which might be enumerated, are distinguished by the presence of only one adductor muscle; in the remainder of the order, as in most other Bivalves, there exists a second. Among these may be mentioned the *Etheria*, which is a sort of fresh-water oyster; and the *Avicula*, that furnish the greater number of the pearls so highly prized as ornaments, and commonly called *Pearl Oysters*, from their general resemblance to the same tribe. The pearl is produced from the same substance as that which lines the shell, and which is commonly known as mother-of-pearl. It seems usually to result from some irritation of the mantle, which causes it to excrete an unusual quantity of pearly matter at one spot; and grains of sand, or other small particles, which, by getting between the membrane and the shell, seem to have caused such an irritation, are often found in the centres of pearls. Sometimes, again, pearls are found at points where the shell has been pierced by a boring mollusc; and it has been proposed to cause the formation of pearls by perforating the shell; but the specimens so produced have seldom that regularity of form which is as important to their value as is their size or lustre.

The order Mytilaceæ is well represented by the common *Mussel*, which has been already described. The various species of this group are extensively diffused; and from their abundance in particular localities, and their palatability, they serve as important articles of food. The *Anodon* is a fresh-water mussel, closely allied in general conformation to those inhabiting the sea, but differing remarkably in the absence of teeth in the hinge, whence the name of the genus is derived. The *Unio* is another fresh-water genus, having a more complicated hinge. It is remarkable for the pearly aspect of the lining of the valves, and for producing small pearls, sometimes in considerable abundance. These are not so pure in their colour, however, as those of the Avicula, and are but little esteemed. Some species of Unio are common in the lakes and rivers of Britain, but the greater number—and these the most remarkable for their size and colour—are peculiar to North America.

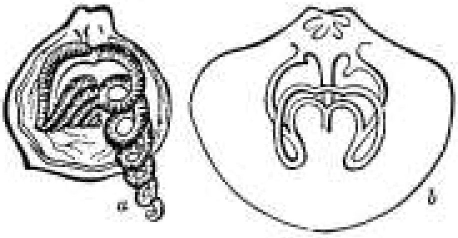
The order Chamaceæ includes but a comparatively small number of species, most of which are peculiar to tropical climates. The most remarkable is the *Tridacna gigas*, or Giant Clamp-shell, of the Indian Ocean, which sometimes attains the weight of many hundred pounds. Smaller specimens are often brought to this country; the valves being used to receive water from small fountains, &c.; and on the continent they are employed as reservoirs of holy water in the churches. The foot has a structure so tough, that, to separate the shell attached by it, it is necessary to chop it with a hatchet, like a cable. The animal being edible, is sought by the natives of the islands near which it lives, especially the Moluccas. It is usually seen in water a few feet deep, with its valves slightly separated; a pole is pushed down between them, which alarms the animal, and causes it to draw the valves together. The pole is thus firmly grasped, and by this the shell may be lifted from its bed.

In the animals of the order Cardiaceæ, or *Cockle* tribe, we usually find greater activity than in any others of the class. Here the foot comes to be a very important organ, possessed of great muscular power, and capable of being applied to a variety of uses. Many of the *Cardiaceæ* bury themselves in sand or mud; and it is in such that we find the respiratory orifices prolonged into tubes. In the common cockle, however, these tubes can scarcely be said to exist, the orifices not being prolonged beyond the shell. Its foot is very large, and can be bent nearly double in the middle; by doing this, and then suddenly straightening it, the animal is enabled to take considerable leaps. The hinge is very beautifully constructed; and the two valves lock closely together. The *Trigonia*, so called from the three-cornered shape of its shell, a very interesting genus, abundant in former ages of the globe, but now restricted to the shores of New Holland, seems allied to the cockle in the structure of its hinge and shell, in the size of its foot, and in its general organisation, although its mantle is divided into two lobes along the whole margin of the valves, as in the oyster.

In the order Inclusa we usually find the valves, when joined together, presenting more or less of a cylindrical form, as in the common Razor-shell of our shores. A hollow is left at each end, and from one the foot is projected, through a passage in the mantle, whilst the other gives exit to the respiratory tubes, which are often prolonged to a great length. The animals live almost uniformly buried in sand or mud, in rocks or wood. The *Solen*, or Razor-shell, is a very characteristic example of the order, which contains, however, some forms that depart very widely from it. The foot, which can be projected from the lower end, is firm and pointed, and serves as an admirable boring instrument, by the use of which the animal can burrow in the sand with great rapidity, sinking very deep when alarmed. The *Pholas* is a very interesting genus, the animal of which nearly resembles that of the Solen, although the shell is formed of several pieces—namely, two principal portions, and a variable number of accessory pieces. Some species of this genus bore in mud, others in rocks, and a few in wood—all of them hiding or lurking; hence their name, from *pholeos*, a lurking-place. Their action seems purely mechanical. They fix themselves firmly by the powerful foot, and then make the shell revolve; the sharp edges of this commence the perforation, which is afterwards enlarged by the rasp-like action of the rough exterior; and though the shell must thus be constantly worn down, yet it is replaced by a new formation from the mantle.

We now pass on to some very remarkable forms of this order, in which the bivalve character of the shell gradually disappears, being replaced by a new structure, of which no examples have been yet seen. The *Teredo*, or Wood-worm, as it is commonly termed, is an animal of the same general organisation as the Pholas; but its valves are smaller in proportion to the body, and its tubes still more prolonged—at least when the animal may be regarded as full-grown. By means of the mechanical action of its valves, it perforates timber, in the same manner as the Pholas penetrates stone. As it advances, the respiratory tubes are prolonged, so that their orifice remains at the entrance of the burrow, which is very small in proportion to the cavity formed by the animal as it increases in size. This orifice is furnished with a pair of valve-like shelly plates, termed *palmulæ*; by the action of which a current of water is driven towards the body of the animal, to serve for its respiration, and at the same time to supply it with food. The gallery is lined by a calcareous exudation from the surface of the tubular prolongation of the mantle, which forms a kind of secondary shell. The Teredo is an animal extremely destructive to timber, especially in warm climates, from which it seems to have been originally introduced into the seaports of Europe. In other genera the valves are lost in the shelly tube, so that the ordinary structure of the class is no longer apparent.

Besides the orders now described as composing the class Conchifera, there is a very curious group which should also be included in it, although established as a separate class by many naturalists. This is the group Brachiopoda, containing only three genera at present known—namely, *Terebratula*, *Lingula*, and *Orbicula*—but formerly of much greater comparative importance. These animals have all bivalve shells, differing in no essential particular from those of the Conchifera in general. The two former genera are attached, however, by a footstalk proceeding from an opening in one of the valves near the hinge, to solid substances. There are not only several muscles provided for the closure of the shell, but another set to open it—an organisation which no other Bivalves possess. The most peculiar part of their structure, and that from which they derive their name, consists in the presence of two very long arms, or tentacula, between the origin of which the mouth is situated. These can be projected to a considerable distance from the shell, or drawn in and coiled up spirally within it. They do not appear, however, to seize upon prey; but rather, by means of the cilia with which they are fringed, to create currents which may bring food to the mouth. In the Terebra-



Terebratula:
a, valve with the spiral arms; *b*, valve with arms removed.

tula, these arms are fixed at their bases to a very curious framework within the shell, the use of which is uncertain; but it is believed to aid, by its elasticity, in separating the valves from each other. This framework is most complex in the species in which the arms are shortest. The species of Brachiopoda at present known live at great depths in the ocean; and many of their peculiarities seem to have reference to that particular condition. They are distributed through all latitudes.

CLASS XVII.—TUNICATA.

The lowest and simplest of the molluscous classes is that to which the name of Tunicata has been given, in order to mark the peculiar structure of the animals composing it. They bear a general resemblance to those which form bivalve shells, but are of inferior organisation. They are peculiarly distinguished from them, however, by the entire absence of any shelly envelope; and by the possession, instead of it, of a *tunic* or external coat, of greater firmness than the rest of the structure, which surrounds the whole body, and affords it protection, besides being the medium of its attachment to the substances upon which these animals usually rest. This external tunic is extremely variable in colour, consistence, and form. Sometimes it is dark, and of leathery toughness; sometimes even cartilaginous; and in many species it exudes a glutinous matter, by which particles of sand, gravel, comminuted shells, &c. are attached together, so as to form an additional envelope, possessed of great firmness. Sometimes, on the other hand, the whole body is extremely soft and delicate in its structure, and the tunic a thin transparent membrane.

The greater number of the animals of this class are attached, during the principal part of their existence, either to each other, or to solid bodies. In a few species, a number of individuals are united by a stem which contains vessels establishing a connection amongst them all; so that they closely resemble the compound Polypifera. More commonly, however, they live in societies, each individual being distinct from the rest, but a number adhering together to form one mass, which is often enclosed in a common envelope. In other instances, each animal is completely separate from the rest, although a number are found in the same locality. Where this is the case, the animals are severally fixed to rocks or other solid masses, either by the adhesion of the tunic, or by a sort of footstalk prolonged from it. The whole activity of the life of these molluscs may be said to consist in the transmission of a current of water through a cavity within the mantle, by which the purposes of respiration and the supply of food are at once accomplished. The class is divided into two orders—the Ascidiæ and Salpæ—with reference to the arrangement of the two orifices through which this current passes.

RADIATA.

The general fact, that, in every complete natural group, there are some members which exhibit most plainly its characteristic peculiarities, while there are others in which these cannot be distinctly traced, or are altogether obscured, is nowhere more evident than in this sub-kingdom. For whilst in some we find the *radiated* arrangement of parts almost invariably preserved, and, if left at all, only slightly departed from, we can only trace it indistinctly in others, and in others, again, it cannot be at all perceived. Thus, when we examine a Star-Fish, a Medusa, or a Sea-Anemone, we observe that they all have a circular form, that the mouth is in the centre of one of the surfaces, and that the several parts arranged round these are but repetitions of one another; and an internal examination would show the contained organs to have the same character. If from these we pass to certain other species of the same groups, we should find the external form slightly modified, being prolonged or shortened in one particular direction, and the disposition of the interior organs no longer radiated. Again, in the Sponges, all trace of a circular arrangement of parts disappears. Yet these, and other groups in which the radiated type is equally absent, must be associated with the classes more characteristic of it, on account of their general conformity of structure, and in some instances their very close alliance.

The great diversity, not only in form, but also in degree of organisation, that exists amongst the Radiated classes, prevents much being stated of their general characters that shall be applicable to all of them. Thus, although the skeleton is external in some species, as the Sea-Urchin and Star-Fish, it is internal in others, as the Corals and some of the Jelly-Fish. Although most of them have a distinct mouth and stomach for the reception of aliment, others imbibe it, like plants, only by absorption through their exterior. Although some exhibit a high degree of sensibility, others are so apathetic, as scarcely to manifest any feeling of injury when severely wounded.

The class Polypifera, containing the *coral-forming animals*, may perhaps be regarded as the most characteristic of the group. These animals usually associate themselves together into compound masses, of which every part is capable of existing independently of the rest, and each polype exhibits in itself the radiated structure, which cannot be detected in the entire mass; but all have a certain degree of connection with each other, which may be compared to that existing among the different buds of a tree. Even the species which do not form solid structures, such as the Sea-Anemone, remain almost constantly attached to the same spot.

The Acalephæ, commonly termed *Sea-Nettles*, or *Jelly-Fish*, have no such tendency to aggregation, and never attach themselves to solid bodies, but wander at large through the ocean. By these characters, and by their extreme softness, the animals of this class are readily distinguished.

The Echinodermata also live solitarily, and have the power of free movement, except in a few species which approach the Polypifera; but they are readily distinguished from the Acalephæ by the density of their texture, and especially by the roughness of the integument, which is usually beset with prickles or spines, as in the Star-Fish and Sea-Urchin.

In the two following classes, no distinctly radiated structure can be seen:—

The POLYGASTRICA, which are generally known as *Animalcules*, are beings of extreme minuteness and general simplicity of structure. In the absence of distinct organs for the various purposes of the economy, they correspond with the lower Radiata, but they differ in the extreme activity of their movements. A separate division of the Animal Kingdom might almost be formed for them alone, so difficult is it to assign them any place in the ordinary scale. Some of them exhibit a tendency to associate into compound structures, like the Polypifera.

The PORIFERA, or *Sponge* tribe, are of all animals those which approach nearest to plants, in the absence of the characters peculiar to the kingdom in which they are placed, and in the want of definiteness of form. Certain movements exhibited by them, however, and their close affinity with some of the Polypifera, render it convenient that they should be classed among animals.

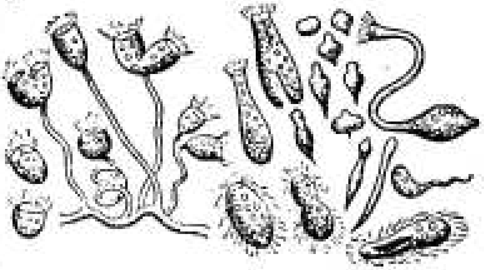
CLASS XVIII.—POLYGASTRICA.

This class includes the greater part of those minute beings termed *Animalcules*, which have been, from the time of the discovery of the microscope, such fertile sources of wonder and delight both to those who have themselves observed them, and to those who have heard from others of their marvels. Previously to that epoch, it was not suspected that beings existed of such minuteness as to be invisible to the eye, much less was any idea entertained of the extreme smallness of many species; and still more improbable and absurd would the statement have been deemed, that such beings are not of rare occurrence, but abound in every drop of stagnant water, and even exist in the whole mass of the ocean. Yet such has been shown to be the fact.

Animalcules may be obtained without difficulty for microscopic examination during the warmer part of the year, by skimming the surface of ponds, especially those in which the water exhibits a red or green tinge, or in which it is covered with duckweed, or with the slimy film which may often be noticed. Many curious species frequent these situations; but the commoner ones may be obtained with even less difficulty, by placing soft vegetable matter, of almost any description, in vessels with water, and exposing the mixture to the sun and air for a few days. As soon as decomposition begins actively to take place, animalcules may be detected in the fluid, and in a short time they often crowd it most densely. These are generally at first of a simple kind; but new species soon prevail, and those first seen disappear. Different kinds of vegetable matter seem to favour the development of the different species; and there are some species that can be produced in no other way than from an infusion of some particular substance.

In the class Polygastrica are included all the most minute species of true animalcules, and some among the larger ones; but as a whole, the beings composing it are smaller than the Rotifera, and far smaller than those of any other class. The largest among them are but with difficulty seen by the naked eye; and of the dimensions of the smallest the mind can scarcely form an adequate conception, although they may be numerically stated. The class takes its name from the belief entertained by the celebrated Prussian naturalist Ehrenberg (who has devoted almost his whole life to the study of microscopic forms of existence), that the animals composing it are especially characterised by the possession of many distinct stomachs or digestive sacs.

The bodies of these animalcules are of soft consistence, and very transparent, so that they resemble flakes of very thin jelly. Their forms are extremely variable; and in some species, the same individual at different times alters its shape so completely, that it could scarcely be recognised. Indeed many mistakes have occurred from this cause. The softness of the tissues of the Polygastrica is also seen when, in swimming, they encounter an obstacle; there seems scarcely any limit to the change of form to which many will submit, in order to pass the obstruction. They are not all so flexible, however; for in some species the body is enclosed in a siliceous sheath of very great delicacy, which gives support and protection to the still more delicate structures it contains. It is the accumulation of such sheaths that has given rise to the collections of Fossil Infusoria (as they have been termed), which will be hereafter noticed. Sometimes the whole body is contained within the sheath; whilst in other instances a sort of trunk or foot may be projected from its opening.



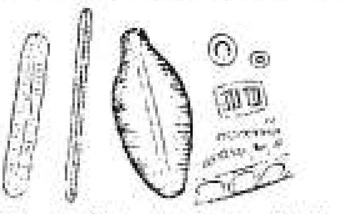
Various Forms of Animalcules.

The bodies of the Polygastrica are usually fringed with cilia, by the vibrations of which they are assisted in their own movements, and also in the acquirement of their food. Sometimes these cilia are disposed along the whole extent of the edges of the body; in other instances they surround the mouth only, and from that part they are seldom absent.

For some time after the discovery of the Infusoria, it was supposed that they must obtain their nutriment by absorption through the substance of their bodies, for no mouth, stomach, or alimentary tube could then be discerned. But by placing them in water, through which very small particles of colouring matter (such as indigo or carmine) were diffused, it was perceived that these particles are introduced into the interior of the body, and are collected in cavities hollowed from the general mass. And subsequently, the improved powers of the microscope have enabled an entrance to the interior of the body or mouth to be discovered in almost every instance, and a second orifice in a considerable number of species. The mouth is commonly furnished with a border of cilia, and sometimes with a set of projecting bristle-like teeth, which are used in laying hold of smaller animalcules, on which the possessor of this apparatus feeds. The introduction of food into the cavity of the body in those species which are destitute of this appendage, may be best watched by diffusing colouring particles through the water in which they are swimming. They are seen to be drawn into the mouth by the vortex or whirlpool occasioned by the action of the cilia; and soon after entering it, they are observed to be united together into little round balls, as if they had been compressed in a small spherical cavity. These balls are sent, one after the other, into the general cavity of the body, where they seem to lie in the midst of a soft gelatinous pulp, and in which they perform a slow revolution—the foremost ones escaping at intervals from the second orifice, whilst new ones are being pushed in from the mouth behind. This is all that can as yet be stated with certainty in regard to the digestive apparatus; since the opinion of Ehrenberg, that the whole body is occupied by a series of small, distinct globular cavities or stomachs, connected by an intestinal tube, is not adopted by other naturalists. Nothing will therefore be said of his classification of these animalcules, which is principally based upon characters furnished (according to his idea) by the arrangement of the stomachs.

The largest species of the Polygastrica probably never exceed 1-20th of an inch in length; the smallest at present known are about 1-2000th of a *line* in diameter; but there is no reason to suppose that this is by any means the limit of minuteness. They usually multiply by spontaneous division, the body of the parent splitting into two or more parts, each of which soon becomes a perfect being, capable of going through the same process. From observations which have been made upon the species in which these changes are most rapidly effected, it has been calculated that, under the most favourable circumstances as to food, temperature, &c. a hundred and forty million millions may be produced in four days!—a degree of fertility which assists in explaining the almost universal diffusion of these creatures, and their sudden appearance in such countless swarms.

Our ideas of the vast amount of animal life existing in this class have lately received a considerable extension, by the discovery that their remains, minute as they are, not unfrequently accumulate into masses of great extent. It is only of those species in which the bodies are covered with an envelope containing earthy matter that the remains can be thus preserved; and the substance formed by their aggregation seems to be an impalpable powder, such is the minuteness of each particle. Such substances have long been known under various names. One is the Tripoli, or Rotten-



Fossil Remains of Animalcules, forming Tripoli.

stone, used in the arts for polishing metals: another is the *berg-* or *mountain-meal*, used in Sweden, on account of its supposed nutritious qualities, mixed in bread with flour and the inner bark of trees in times of scarcity. Both these, as well as many other substances, consist entirely of the siliceous shields or envelopes of animalcules, closely allied to, if not identical with, species at present existing; and the quantity of animal matter which is dried up in the latter, and which may be determined by the effect of heat (this dissipating the animal portion, and leaving the siliceous particles unchanged), is sufficient to account for its nutritious properties.

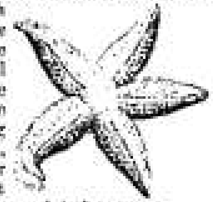
CLASS XIX.—ECHINODERMATA.

The class of Echinodermata, comprehending those well-known animals, the *Asterias* (Star-Fish) and *Echinus* (Sea-Urchin), takes its name from the prickly skin with which most of the tribes it includes are provided. But this is not a universal character; for some of the species, which border upon other groups, have a skin destitute of any appearance of spines. There is little difficulty, however, in distinguishing the animals of this class from all others, for in nearly the whole of them the radiated structure is very evident; and they are the only animals among the Radiata which have the power of moving from place to place, and have at the same time an integument firm enough to resist external pressure.

Although the character and degree of organisation in the different subdivisions of this class may be regarded as about the same, the form of the organs, and the mode in which they are arranged, are very different, so that it will be better to describe each group separately. The class may be distributed into three orders: the STELLERIDA, including the Star-Fishes and their allies; the ECHINIDA, including the Echinus and its allies; and the HOLOTHURIDA, a group less commonly known, and differing much from the others.

I.—Stellerida.

The common *Asterias*, or Star-Fish, which may be taken as a type of the order Stellerida, is covered with a tough leathery skin, beset with prickles. The animal has the form of a star, with five or more rays springing from a central disk. In the middle of one side of the disk is situated the mouth, and this side, according to the usual habits of the animal, must be considered the lower one, or that by which attachment and locomotion are performed. The mouth opens into a globular stomach, which sends out prolongations into the several rays; but there is no intestine in this animal, nor any second orifice to the digestive cavity, so that the indigestible portions of its food, which consists of young shellfish and the like, are rejected by the mouth.



Asterias: upper surface.

The order Stellerida includes a large number of forms, having a general resemblance to the *Star-Fish*, but differing much in the relative proportion of the body and rays. Thus, in some species the arms seem to make up the entire animal, no central disk being present, save that formed by their union. In others, the arms appear simply appendages to the central disk, to which the stomach and other important organs are confined. In several instances the arms send off lateral appendages; and these occasionally again subdivide, so that a branch-like structure is produced, such as we find in the *Comatula*.

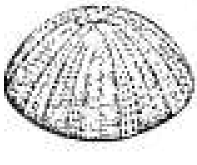
A very remarkable tribe, included among the Stellerida—once a group very important in its numbers, and in the extent of its diffusion through the sea, but now presenting only two or three comparatively small species—is that known under the name of *Crinoidea*, or Lily-like animals. These are formed much upon the plan of the Comatula, but they are attached by a jointed stalk to solid substances, usually to the bottom of the sea. They thus remind us of the Polypifera, which they seem to connect with the Echinodermata. This group contains two principal subdivisions—the *Encrinites* and the *Pentacrinites*. The former are distinguished by the roundness of their stems, the joints of which being flat and perforated in the centre, are known under the local names of wheel-stones, St Cuthbert's beads, &c. The latter have pentagonal stems. [See GEOLOGY.]

II.—Echinida.

In the Echinida we find the body usually of a somewhat globular shape, and enveloped in a firm shell, composed of a very regular series of plates jointed together. In the Echinus, the shell of which is commonly known as the Sea-Egg, we observe two orifices situated at the poles, as it were, of the globe. The larger of these orifices is the mouth: at the smaller one the intestinal tube terminates. The mouth, as in the star-fish, is generally directed downwards. It is furnished with a very curious apparatus of teeth, which are worked by powerful muscles, attached to projections of the shell, that may be seen on the inner margin of the mouth; and their points can even be protruded beyond the mouth, so as to lay hold of prey brought to them by the long tubular feet. By the action of the teeth, the food is ground down before it passes into the intestinal tube, which is here of considerable length, and takes a couple of turns round the shell before its termination. Round the second orifice of the shell are disposed the ovaria, which are very largely distended with eggs at some seasons, and are eaten under the name of the *roe of the sea-egg*.

It is the exterior organisation of these animals, however, that presents us with the greatest sources of interest. On looking at the Echinida in their living state, we see that most of them are covered with spines of considerable size, instead of with such small prickles as the Asterias bear. Moreover, these spines are seen to be movable at their bases, and their power of motion is due to their peculiar connection with the shell. Each spine is spread at its root into a cup-like form, and the hollow of this cup fits upon a little knob or tubercle projecting from the surface of the shell, so that a complete ball-and-socket joint is formed. The spines are connected to each other, and held on the shell by the skin which covers the latter, and which is attached around their roots; and it is by the contractions of this skin that they are moved.

On looking at the exterior of the shell of an *Echinus*, it is seen that the tubercles are arranged with great regularity, and that the larger ones are confined to particular rows of plates, which are hence called *tubercular* plates. Between these are smaller plates, commonly bearing smaller tubercles, and perforated with a number of minute holes, for the passage of the tubular feet; these are called *ambulacral* plates. The tubular feet, like the spines, are much longer than in the star-fish. They are always capable of being projected beyond the spines; and, taking an attachment by the suckers at their extremities, they can cause the shell to roll, as it were, upon the points of these. In some species, the spines are five or six inches long, whilst the diameter of the body is much less. The tubular feet often escape notice, on account of their transparency; and the animal appears to be walking upon its spines, when it is merely resting upon them as fulcra, and drawing itself forwards by these curious organs. It is to be remembered that the body will weigh much less in water than in air, and thus may be supported upon spines of great delicacy.



Shell of Echinus: a, a, tubercular plates; b, ambulacral plates.

These animals are generally found on sandy shores, and especially in little nooks secluded from the direct influence of the waves. Some of them excavate hollows in the sand by means of their spines, and one species even works its way into solid rock. Their food is of a mixed quality. Fragments of shells, Crustacea, and other marine animal products, are found in their stomachs, as well as portions of sea-weed. They obtain their prey whilst lurking in their hollows, by allowing their tubular feet to play loosely in the water around; and when any small animal touches the sucker at the end of one of them, it is soon secured by the assistance of others, and drawn within the range of the teeth.

III.—Holothurida.

In this order we find the characters of the class remarkably blended with those of the Articulata. The body is not enveloped in a hard shell, but in an elastic skin, destitute of spines or prickles. It retains, in some species, the globular form, but in many it is very much prolonged, so as to be almost cylindrical, and thus to resemble that of the Worms; and it is occasionally even marked by transverse bands, indicating a division into segments. Still, however, a distinctly-radiated conformation may be seen around the mouth; and some of these animals look as if a star-fish were set as a head on the body of a large worm. In the general conformation of the internal organs they correspond with the Echinida; but they are in some respects more complex, and the respiratory organs are constructed upon the plan of those of the Articulata. They thus form a very interesting link of connection between the Radiated and Articulated sub-kingdoms.

The skin of most of the Holothurida is so very elastic, that they can change their size and form in a remarkable degree. They are capable, too, of swimming with considerable rapidity, and some of them crawl like slugs upon solid surfaces. Small species are occasionally found in British seas; but on some tropical shores they are very abundant, and grow to the length of eighteen or twenty inches. They are sometimes eaten by the poor on the Neapolitan coast; but in the Malay Archipelago they are regularly sought, and conveyed to the Chinese market, where, under the name of *trepang*, they bring a high price.

CLASS XX.—ACALEPHÆ.

The name of the class next to be described, the Acalephæ, is derived from the stinging power possessed by nearly all the animals composing it. The word is the Greek term for *nettles*; and by the designations *sea-nettles*, *stung-fishes*, &c. these animals are popularly known; as well as by another, also expressive of a character by which the group is distinguished—*jelly-fish*. It is rather difficult to give any description of the structure of the class that shall include all the members of it, so much do they vary among each other. They all differ from the Polypifera in being unattached to solid bodies, and in having the power of freely moving through the sea; and they differ from the Echinodermata in not being covered with a dense integument. Their extreme softness is one of their most remarkable characters. Some of them attain considerable size, yet with an almost entire absence of a solid framework; indeed it is only in a few species that any such exists. They consist of a sort of network of animal filaments, the interspaces between which are filled up with water; and so large a proportion does this bear, that it drains away when the animal is kept out of its element for a short time, leaving but a thin film of membrane behind it.

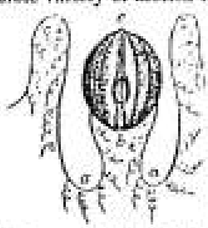
One of the commonest forms of this class is the *Medusa*, which is often seen floating in vast numbers on calm sunny days at a little distance from the shore. The animal consists of a large umbrella-shaped disk, from the under surface of which hang down four broad and long tentacula. Both disk and tentacula exhibit a very beautiful assemblage of colours, like those of the rainbow, when the rays of the sun are reflected from their surface. On the under side of the disk is seen the mouth, situated in the centre, and surrounded by the origins of the tentacula. This is the entrance to a stomach, which lies in the middle of the disk, and is surrounded by four ovarial chambers, having separate

Medusa: a, under surface, showing the mouth in the centre, surrounded by the tentacula, and the ovarial chambers exterior to the origins of these; b, side view, showing the tentacula hanging down in their natural position.

external orifices. The membrane of the disk extends much beyond the stomach and ovarial chambers (which may be described as occupying the part corresponding to that included between the metallic stretchers of the umbrella), and this broad free margin is endowed with muscular powers, and performs a series of undulations, by which the animal is propelled through the water. The extreme softness of the tissues of these *Medusæ* is an obvious reason why they should not expose themselves to the rough surface of the ocean, where they would be beaten to pieces by the waves—or to the proximity of the shore, from which they would soon receive fatal injury. Although so soft, however, they have the power of mastering prey of much firmer structure; and hard Crustacea, as well as other marine animals of high organisation, supply them with food.

An interesting species, allied in general form to the Medusa, but differing from it in a remarkable particular, is the *Rhizostoma* (root-mouth). No mouth is seen in the centre of the inferior side of the disk, but the stomach sends canals into the substance of the tentacula, which terminate in a number of minute pores at the extremity of those organs. By these small pores, as by the roots of plants, nourishment is absorbed into the system, for the ends of the tentacula fix themselves like suckers upon the surface of the animal they have grasped, and imbibe its juices. These and other Acalephæ which move through the water by the undulations of their membranous disk, are included in the order PULMONIGRADA. All the Acalephæ of this order exhibit a very regular disposition of their parts around a centre, so as to be truly *radiated* animals. Some of them attain a diameter of two or three feet.

Another interesting species of this class is the *Beröe pileus*, a small animal not unfrequently found on the coast of Scotland. When at rest in the water, it looks like a bright globe of jelly, about half an inch in diameter. An opening is seen at each pole of the globe, one of which is the mouth, and the other the termination of the alimentary canal, which runs right across the body. Its surface is marked by eight bands, running, as it were, from pole to pole; these bands seem to be of firmer texture than the rest of the body, and on them are placed the rows of cilia, which can act either together or separately, so as to give every possible variety of motion to the body; hence this animal, and others resembling it, are said to belong to the order *Ciliograda*. The Beröe usually swims, by means of them, mouth forwards, and thus a current of water is driven into the stomach without any further effort on the part of the animal. But it is provided with other means of obtaining its food, in two long tentacula, which arise from the posterior part of the body, and are furnished with a number of lateral filaments; these can all be withdrawn and folded into two cavities, excavated, as it were, in the substance of the body, and are easily unrolled when required for use.



Beröe: *a, a*, tentacula; *b*, mouth; *c*, termination of intestinal canal.

The Acalephæ inhabit all climates, but the largest forms are to be seen in tropical seas.

CLASS XXI.—POLYPIFERA.

The animal character of the beings composing the class Polypifera was formerly doubted, as that of the Sponges is at present. The structures which they form, known as Corals, Corallines, &c. have often so much of the plant-like aspect, and sometimes also of an apparently woody structure, that, even in recent times, naturalists have been deceived into a belief in their vegetable nature.

Another popular error in regard to this group, is the attributing the formation of coral to *insects*, and the supposition that it is their habitation, constructed under the same circumstances as the comb of Bees, or the pyramids of the Termites. The real fact is, that the masses of *coral*, *madrepore*, &c. as well as the *sea-fans* and other similar structures, with many smaller and more delicate ones—of which some are ranked among the *sea-weeds*, and others commonly known as *corallines*—are the *skeletons* of the animals by which they are produced, and are to be regarded as parts of the living structure, so long as the flesh which clothes or lines them retains its vitality.

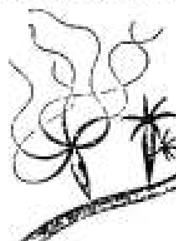
If, for example, the stem of the common *red coral* be examined when clothed with its living flesh, its surface is seen to be scattered over with polypes, the structure of each of which bears some resemblance to that of the sea-anemone; but these, so far from being independent of one another, like so many sea-anemones attached to the same rock, are connected by a system of vessels which traverse the flesh, and bring them all into communication. Nevertheless, any one of these would live if detached from the rest, and would gradually produce others, until a new structure was formed, similar to that of which it was originally a part. Moreover, if a piece of the gelatinous flesh be stripped from the stem, *this* will be competent to form both new polypes and a new skeleton.

Such compound beings, then, of which the polypes only form a part (like the leaves or flowers of plants), are not improperly termed Polypifera, or Polype-bearing Animals. But there are many kinds of Polypes which have no tendency to this kind of aggregation, and which are never found but in a solitary state. Such are the *Sea-Anemones*, and the *Hydra*, or fresh-water polype. And various degrees of intimacy of connection between the polypes of compound structures may be traced in different species.

The class may be divided into four orders, characterised by four distinct types of structure: in each of these we shall find polypes existing almost or altogether independently of one another; and species closely allied to these, in which they are intimately associated. As the distinguishing characters of the orders cannot be understood without a knowledge of the structure of the polypes belonging to each, it will be better to proceed at once to the description of them, the amount of popular information on the subject being small. We shall begin with the one generally accounted the simplest.

1.—Hydroida.

The *Hydra*, or fresh-water polype, the type or leading example of this order, is a minute animal, often found in great abundance, clustering round aquatic plants in stagnant pools. It seems to consist only of a kind of bag, constituting the stomach, round the mouth of which is disposed a circle of long arms, or *tentacula*, whilst the opposite end is prolonged into a foot, terminated by a kind of sucker, by which the animal attaches itself. Although little able to move from place to place, the hydra secures an abundant supply of food by its arms, which serve as so many fishing-lines. When any aquatic worm or insect touches one of these, it is entrapped by it, and other arms are speedily brought to its assistance; so that by the simultaneous contraction of the whole, the prey is conveyed to the mouth, even if strong enough to make powerful resistance. Not unfrequently it can be seen to move about violently within the stomach for some little time; but the powerful digestive secretion speedily begins to act upon it, and its soft parts are dissolved, the hard ones being usually ejected by the mouth. When this solution has been performed, the fluid which results from it is seen to be distributed by a kind of circulation through the walls of the stomach and the arms.



Hydra.

Nothing in the history of the hydra is so remarkable as its power of being multiplied by division, and of repairing the effects of other rough treatment. In regard to this, there really seems no limit. Not only can the body reproduce the arms, the mouth re-form the tail, and the tail the mouth; but from a minute fragment, the perfect hydra is reproduced, so that an individual cut up into forty or fifty pieces, will be converted into as many separate polypes. Two bodies, also, may be grafted together by the side, the tail, or in any other way; and monsters with two heads, two tails, &c. may be easily produced. The power of any one part to perform the functions of the rest, is remarkably shown by the fact, that the polype may be turned inside out; so that what was before the lining of the stomach becomes the external integument, and *vice versâ*, without its comfort being perceptibly impaired.

The hydra is not known to subdivide spontaneously, however, but it propagates itself by a process resembling the budding of plants. A little knob first projects from the side of its body, this enlarges, and from the top of it are seen to spring a number of small processes, which are the arms. In the centre of these an opening appears, constituting the mouth of the young polype, which gradually assumes the form of its parent, and begins to catch prey for itself. Still, however, the cavity of its stomach communicates with that from which it was at first prolonged; but the passage is gradually narrowed, and at last obliterated. When quite independent, the young polype detaches itself from the parent, and has no further relation with it. Several of these buds may spring from the same polype at once, provided it be well supplied with food, and the temperature be warm; and a second generation may even show themselves upon the first, whilst still continuous with the parent structure.

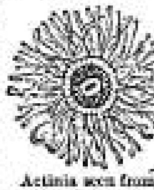
The entire substance of the hydra is soft, and no part seems possessed of greater firmness than the rest. In some other species, however, we find a tendency to the consolidation of the exterior into a kind of horny tube or sheath; and when a number of polypes are associated together, a compound structure is thus produced. In these compound structures, of which the Sertularia is an example, the cells are connected by stems and branches, in the same manner as the buds of a plant; and through the base of each cell there is a canal lined by an extension of the lining membrane of the polype, and uniting with the channels which pass through the whole structure. Thus all the polypes are brought into connection with each other, and with the general mass or polypary.

Portion of Sertularia: *a, a*, polype-cells with polypes; *b, b*, ovarial vesicles.

These polyparies, formed by the association of hydraform polypes, are among the most graceful and elegant of all the structures with which this class presents us. They are of minute size, when compared with the massive productions of other tribes; and the uniform absence of stony deposit gives them a degree of flexibility which adds much to their gracefulness. There are few shores on which some species may not be picked up. They are commonly mistaken for sea-weeds.

II.—Helianthoida.

A common form of polype—apparently so different from the hydra, that the relationship between them would not have been suspected by an uninformed observer—is the *Actinia*, or sea-anemone. There are probably no shores over the whole globe, except the very coldest, on which some species of this interesting creature are not to be found. The mouth is in the centre of the upper surface, and is surrounded by tentacula; and these are numerous, and arranged in several rows. The under side forms a large sucker, or disk; by this a very firm hold is taken of the rock or other surface to which the animal adheres. The stomach does not occupy the whole cavity of the body, but only the central portion; and the space between its wall and the outer integument is divided, by vertical membranous partitions passing directly from one to the other, into a number of radiating chambers, in which the germs of young *Actiniæ* are produced, and sometimes nearly matured. The tentacula of the sea-anemone can be contracted in the same manner as those of the hydra; and they are furnished with a sort of sucker at their extremities, by which they can draw towards the mouth any substance which comes in contact with them. These animals are extremely voracious. Shell-fish and small Crustacea appear to be their usual diet.



Actinia seen from above.

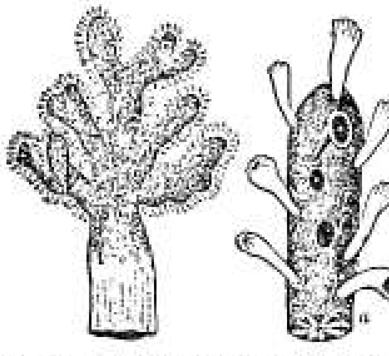
There are some of this order which form a stony deposit in the substance of their base, and in the membranous partitions between the radiating chambers. Of these, one small species inhabits the British seas; it belongs to the genus *Caryophyllia*. A very beautiful coralline formation of this description is that produced by the *Fungia*, an animal allied to the sea-anemone, and inhabiting only tropical seas. It consists of a thick round plate, sometimes several inches in diameter, from one surface of which arise thin vertical plates, radiating very regularly from the centre to the circumference. From the presence of these thin plates, or *lamellæ*, the whole of this group of corals and madrepores have been designated as *lamelliform*. The individual polypes belonging to such structures are connected by a gelatinous flesh enveloping the whole, which seems to answer to the membranous pith lining the stems of the compound Hydroïda. It is by this flesh, rather than by the polypes themselves, that much of the stony mass is deposited, as may be seen by examining many species in which the intervals between the cells are considerable. The variety of aspect which these masses present is very great; but there is little difference, so far as is known, in the structure and habits of the individual polypes, which form part of the beings in their living state.

None but *stony* corals are formed by Polypifera of this order; but there are many of that description which do not belong to it, of which we shall hereafter speak. However, it is to this order that the greater part of those species belong which are concerned in erecting the massive structures known at present under the names of coral reefs and islands, as well as those which appear to have existed in still greater amount in former epochs of the earth's history, and to have given origin to the greater part of the limestone rocks which constitute so large a proportion of the crust known to us. This order may be denominated that of *Actiniform* polypes, from the general resemblance of the animals composing it to the sea-anemone; or *Helianthoida*, from their similarity in aspect, when expanded, to the sun-flower.

III.—Asteroida.

The next order of Polypifera is one which brings us nearly to the form of the sponge. In the compound groups we have been last considering, the polypes form an important part of the general structure; and in some instances each may be regarded as existing almost for itself alone, even where many are united by the connecting fleshy matter. But in the group to be next treated, the polypes seem quite subordinate, and the general mass appears to have (as in the sponge) much more of the character of a single individual. In these structures we observe, too, that the hard basis or skeleton is seldom so distinct from the living tissue as in the lamelliform corals, the two often passing into each other by almost insensible gradations. The density of the skeleton varies considerably in the different species. Sometimes it is of a spongy character, as in the *Alcyonium*; at others of a stiff, horny texture, as in the *Gorgonia*, or Sea-Fan; and occasionally of a stony hardness, as in the Red Coral.

The *Alcyonia* are found abundantly on many parts of the British shores, and are known to fishermen by the names of *dead-man's-hand*, *sea-fingers*, *sea-paps*, &c. from their flabby texture, and the peculiar forms they present. Their structure is spongy, but they have



Alcyonium: *a*, portion enlarged, showing the Polypes.

usually a more distinct envelope than the true sponges, and this has sometimes a leathery character. Their interior is traversed by a series of canals, which ramify and inosculate with each other.

The polypes themselves have some resemblance to the sea-anemone, but they are usually much smaller, and of more delicate structure. There are, however, some important differences, upon which the character of the order is founded. The tentacula, instead of being numerous, and arranged in several rows, are only eight in number, and form one circle; they are broad, and almost leaf-like, instead of being round and slender; the mouth is situated in the midst of them, and leads to the stomach, which occupies the centre of the body; around the stomach are the *ovarial chambers*, separated by radiating partitions, but only eight in number; the stomach opens into the canal, upon the end of which the polype is placed, and all the fluid which enters the mass appears to be taken in through these mouths; the ovarial chambers also communicate with the canal beneath; indeed they may be said to be a continuation of it, for the partitions between them are prolonged downwards into the canal, forming plaits or folds of its lining membrane, in which the ova or germs are developed; so that these are produced from the general mass rather than from the polype—and the whole structure may be regarded as a higher kind of sponge.

The polypes are capable of being drawn entirely within the protuberances on the surface of the Alcyonia, and even these projections become flattened when the animals are in a state of great contraction. In this condition they are often left by the tide, and if then placed in a glass of clear water, their gradual expansion may be watched. The protuberances from the surface first show themselves, and the polypes, one by one, appear at their summits, and slowly expand their tentacula, until the whole surface appears covered with delicate blossoms. The entire mass then not unfrequently swells to twice or thrice its original size. If any one of the polypes be irritated, it shrinks into its hiding-place, but those near it are not affected. If the irritation of the part be prolonged, however, those in the neighbourhood gradually show themselves influenced by it, and draw themselves in; and in this manner the whole mass may be ultimately affected. The same results, however, may be produced by irritating a portion of the spongy substance intermediate between the polypes. From this it is evident that sensibility to impressions is not confined to the polypes alone, but that the whole mass must be regarded as possessed of animal properties.

There is one species in this order which differs from all the rest in the consolidation of the exterior rather than of the interior tissue; so that a stony *tube* is formed instead of a central stem. This is the *Tubipora musica*, of which the skeleton is known as Organ-pipe Coral. The polypes are not here connected by any system of vessels or uniting flesh; each lives for itself alone, but a number (probably all produced from the same stock, and by offsets from each other) unite for mutual support in one structure. Each polype has a cylindrical form, and its exterior membrane is progressively consolidated into a stony tube, which is thus gradually increasing in length by new deposits at its upper end. At certain intervals, the soft membrane (which is always projecting beyond the mouth of the tube) is flattened down into a sort of collar, which is consolidated likewise; and the collars of the neighbouring tubes, coming in contact with one another, form a sort of floor or shelf, which greatly strengthens the mass. After this collar is formed, the tube is continued as before for another period, when a similar floor is again produced by the simultaneous action of the polypes composing this beautiful structure.

To this order the term of *Alcyonian Polypifera* (from the name of one of its principal groups), may be conveniently applied; it is also known by the designation of Asteroida, from the star-shaped form presented by the tentacula when expanded. Its most luxuriant kinds are natives of tropical seas; thus the *Alcyonium poculum*, or Neptune's cup, which abounds in the neighbourhood of Singapore, is one of the most bulky species at present existing; but the smaller tribes abound in our own seas. No massive stony polyparies are formed by the animals of this order.

IV.—Ascidioida.

The last order of Polypifera far surpasses all the rest in the complexity of its organisation. They seem more independent of one another than they are in the associated groups of the others; but they are not known to exist in an absolutely isolated condition. They all agree in two essential points—the possession of a second external orifice to the digestive cavity, and the presence of cilia on their arms. By these they are distinguished from the other Polypifera. The latter of these characters has been embodied in the term *cilio-brachiata* (ciliated-armed), which is very appropriate. They have also been called *Bryozoa*, from their fancied resemblance to mosses; and *Ascidioida*, from their affinity to the *ascidiæ*, a group in the lowest or tunicated class of molluscs.

The members of this order seem to attain their full development under a less constantly elevated temperature than that required by the Helianthoida. Stony corals are formed by them in many seas of the temperate zone, and the more delicate species abound on our own coasts. This fact is interesting, when we compare the fossil with the recent coral formations.

When we consider the vast extent of the coral formations, which are at the present time effecting so remarkable a change on the surface of the globe, we cannot but be struck with the enormous amount of animal existence that must be concerned in producing them. Much error has prevailed on this subject, however; and in some points exaggerations have been produced through superficial observation. But here, as in almost every department of nature, the truth, as disclosed by a more careful examination, is far more wonderful than the showy covering in which the common love of the marvellous may have enveloped it.

It is generally stated that the coral masses, forming reefs or islands, are built up from the depths of the ocean. This is not strictly true; for it is well ascertained that none of the species which form the massive stony structures of which these are composed, can exist at a greater depth than from 100 to 120 feet. It is evident, then, that supposing the relative level of the land and sea to have been always the same as at present, these coral structures must be based on the summits of submarine mountains or ridges of hills, which rise from the bottom of the ocean, like corresponding hills and ridges upon the dry land; since deep water is almost always to be found in their neighbourhood. This is probably true to a certain extent. There is reason to believe that solid rock exists at no great depth beneath the surface of some of the islands; and there are many in which it forms part of them, a cone of rock rising out of the water, incrusted with a terrace of coral. Moreover, it may be stated as a general fact, that there is no part of those seas in which the temperature, depth of water, and other circumstances, are favourable to the operations of the coral-polypes, in which they are not constantly at work; and thus channels are being constantly rendered narrower and shallower, and harbours are being blocked up which were formerly accessible. But this takes place with less rapidity than is generally imagined.

The coral islands of the Pacific and Indian Oceans constitute a large proportion of the groups with which that vast area is scattered. In some instances they are considerably elevated above its level; but in general their surface is but little raised above it. As the polypes do not build above low-water mark, it does not become at once apparent how even this elevation is attained. It is to be remembered, however, that in the tropical ocean there is an almost constant succession of waves driven by the trade-wind from east to west. These, dashing against the windward side of the islands, break off blocks from the masses of coral, which they cast upon the summit. An accumulation of these blocks, consolidated by smaller fragments, and by the sand resulting from their constant friction, gradually produces a firm rocky superstratum. The surface of this, decomposed by the atmosphere, forms a calcareous soil, which is well adapted to the growth of many kinds of plants; and their seeds being drifted by the sea, or brought through the air by birds, take root in it, so as speedily to cover the island with a luxuriant vegetation. The growth and decay of successive crops gradually covers with a thick layer of mould the previous chalky soil; and this affords support to the most beautiful kinds of tropical plants, which the humidity of the insular atmosphere enables to flourish to a degree rarely seen on continents.

Several of the coral islands take the form of *rings*, containing large basins of water communicating with the sea, which are termed lagoons. These were probably erected on the craters of submarine volcanoes; of the existence of many of which beneath the Pacific Ocean there can be no doubt. They first rise to the surface in the form of circular reefs; the windward side is gradually raised above the sea-level by the process already described; but an opening usually remains at the leeward side, through which the water that washes into the central basin may flow out. As the whole ring is gradually elevated, however, the source of this overflow diminishes, and gradually ceases; the leeward channel is filled up by the growth of coral, and the lagoon is cut off from the sea. This basin, also, is at last filled up by the accumulation of fragments of coral, and by the growth of the more delicate species in its interior; and at last one nearly uniform surface is produced.

There is reason to believe, however, that in many instances the coral extends to a much greater depth beneath the surface than that in which the animals are known to live; and the question then arises, In what manner was it formed? A careful examination of the islands of the Pacific Ocean shows us that many of them, which rise considerably above the surface, are entirely composed of coral. Now, as the coral polypes never build above the level of the sea, it is evident that some subterranean movement, probably of a volcanic nature, must have lifted these islands from the bed of the ocean. In some instances, the height at which coral may be found is very great—not less than eight or nine thousand feet. It is not improbable, then, that as the bottom of some parts of the ocean is rising, that of others should be falling. If a coral island had been originally formed in the usual way, and had then gradually sunk in the water, the polypes would have continued to build it up to the surface; and thus almost any thickness of coral-formation may be produced, by a corresponding slow subsidence.

One of the most extraordinary coral growths known, is the barrier-reef which stretches along the shores of New Holland, at a distance of usually more than a hundred miles from the coast. This is above a thousand miles long; and for several hundred miles has no break wide enough to give passage to a ship. It is scarcely conceivable that a submarine ridge of hill should exist, a thousand miles in length, and approaching everywhere within one hundred feet of the same elevation; for such a ridge is nowhere seen on the dry land. But it is easy to account for this remarkable structure, if we suppose that the ridge was formerly more or less elevated above the surface; and that its different parts gradually became incrusted and capped with coral as they were submerged, after which the growth would continue upon the same parts, until the whole, being thus depressed and covered, became the continuous mass which is now witnessed. That such depressions *are* taking place in some islands of the Pacific, is a fact substantiated not only by the traditions of the natives, but by observations made since they have been visited by Europeans.

There are many instances in which the coral structures of comparatively recent origin have undergone a metamorphosis, which causes them to lose in some degree their original aspect. Large masses, when long exposed to the air, become changed into a solid, often somewhat crystalline rock, in which the traces of organic structure are very indistinct, and with which the *mountain* or *secondary limestone* closely corresponds. This is observed in the Bermudas. Moreover, the coral sand often becomes agglutinated, by the percolation of water through it, into a very hard stone: it is in such a mass that the human skeleton, found on the shore at Guadaloupe, and now placed in the British Museum, is imbedded. This stone, when minutely examined, is seen to consist of a number of rounded grains, cemented, as it were, together; and it closely resembles the rock known to the geologist as *oolite*. Further, where shallow water exists around coral islands, the bottom is found to be covered with a layer of white mud, which is formed by the decay of the animal matter that held together the particles of carbonate of lime in the stony corals, and these are consequently set at liberty in a finely-divided state, and fall to the bottom in a form which, if dry, would constitute *chalk*. Thus we may trace very distinctly the mode in which some of the principal kinds of limestone strata may have taken their origin in coral formations.

Now the mountain limestone, as it is termed—a rock very abundant in Britain, extending over large areas beneath the coal-fields, and sometimes exhibiting an unbroken thickness of nearly 200 feet—is in some parts evidently composed of accumulations of shells, stems of encrinites, &c. But in many others the remains of corals are very distinct; and these are so blended with the rocky mass, as to make it appear probable that the latter also was once in the state of coral, but was gradually changed by the process just described. Further, the collections of other animal remains (shells, fishes, and the like) are just such as we should expect to find on the margin of a coral reef existing at that epoch; and a similar process of fossilisation is taking place on the coral shores of the present epoch—the imbedded series of animals only being different. The great thickness of the beds of this rock may be accounted for, in the same manner as the depth of the coralline masses of modern formation.

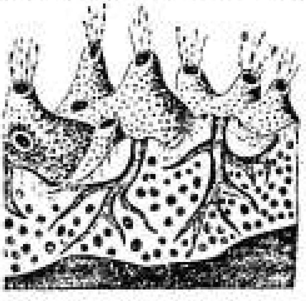
There are observed, in rocks of more recent formation, appearances which still more clearly indicate that they, too, were originally formed by coral polypes. These are often found only within narrow limits, as if they had been reefs or islands of small size. Thus we find a stone called coral-rag in Oxfordshire; and very distinct coral beds in the crag of the eastern coast of England. It is interesting to remark, that the remains of coral which are found in the older limestones, all correspond with those at present abounding near the equator, and exhibit the *lamelliform* character; whilst they are gradually replaced in the newer strata by species more allied to those at present existing in temperate climates. This is one of the many facts which tend to prove that this part of the earth had at some former period a much higher temperature than at present.

We see, then, that vast as are the works of the existing species of this class, they are probably far surpassed by the accumulations of former ages, which constitute, in some form or other, a large proportion of the solid rocks of the terrestrial crust. And thus we see the exemplification of a principle which has frequently come under our notice—that in the economy of Nature nothing is insignificant; and that the most gigantic effects may be produced by the continuous multiplication even of the humblest among the living inhabitants of the globe.

CLASS XXII.—PORIFERA.

Of all the beings usually known under the designation ZOOPHYTES, the *Sponges* and their allies, constituting the class Porifera, appear to have the best claim to the title, since they present so complete an admixture of the characters of plants and animals, that it is difficult to say to which division of the organised world they properly belong. Like plants, they are fixed to one spot during the whole of their lives, subsequently, at least, to their first development; they seem to possess no sensibility, for they can be torn or wounded in anyway, without showing by their movements any indication of being affected by the injury; and they do not appear to have that power of executing voluntary motions which must be regarded as the distinguishing characteristic of animals. On the other hand, they present a structure which is not analogous to anything found in plants, but is similar to that of beings undoubtedly belonging to the Animal Kingdom; with these beings they are connected by intermediate forms, presenting a regular gradation of increasing complexity of structure and variety of function; and there are certain movements, both in the adult and in the undeveloped sponge, which are more analogous to those seen in higher animals, than to any observed in plants. On the whole, however, the evidence for the animal character of the sponges seems to preponderate; and they will be accordingly considered here. Still, there is no doubt that, if they are included in the Animal Kingdom at all, the lowest place in the scale should be assigned to them.

The common sponge is a sufficiently characteristic form of the class, to serve as the foundation of a general account of the structure which prevails in it. On looking at its exterior, we observe that it is covered by a number of closely-set and minute orifices; and that larger openings are disposed at intervals among these. The former are termed *pores*, the latter *vents*. On cutting into the substance of the sponge, it is seen to consist of a sort of network of filaments, interlacing together in such a manner, as to leave large channels and spaces of various forms, which communicate with each other. The large channels terminate in the vents; and on tracing any one of them into the substance of the sponge, it is seen to divide and send off ramifying branches, which at last lose themselves in the spongy network that lies around them; and this communicates with the pores on the external surface. The interlacing fibres, of which the walls of the large canals, and the spongy tissue between them, are alike composed, entirely consist of a sort of horny *animal* matter, as may be perceived by burning a small portion. In other species we find *spicula*, or needle-like crystals, of silex or of carbonate of lime, disposed amongst these, giving to the structure much greater firmness, but depriving it, more or less completely, of that elasticity which is so useful in the common sponge.



Section of Living Sponge.

The substance known as *sponge* is, however, but the skeleton of the animal; the whole substance being beaten and soaked in dilute muriatic acid with a view to bleach it, and to dissolve any adherent portions of lime, before bringing it to market. When alive, the fibrous network is clothed, within and without, by a thin gelatinous substance, very like the white of an egg. This lines all the passages, and covers the exterior; but it drains away when the sponge is removed from the water. In this the peculiar vital endowments of the being appear to reside. These are manifested not only by its slow, but regular growth, but by a curious circulation of fluid constantly taking place within the mass. When a sponge is examined in its living state, beneath the water, a constant current is seen to issue from the vents; being made evident by the disturbance of the water, and by the movement of particles floating in it. It may also be ascertained that a constant flow of water takes place inwards through the pores; for small solid particles upon their edges are occasionally seen to be sucked in. No intermission can be detected during the life of the sponge in these currents, which evidently have for their object to convey the nutritive matter contained in the water into the interior of the mass, and also to carry off the particles which are to be excreted, since thin films detached from the living tissue are seen to pass out from the vents along with the fluid ejected from them.

The relative position of the *pores* and *vents* differs much in the different kinds of sponge. Sometimes all the former are on one side, and the latter on the other. Not unfrequently, the vents are placed on the summit of little conical prominences, which look like craters of a volcano; and the streams issuing from them, when seen under a microscope, may be likened to a miniature eruption. Occasionally the sponge assumes the form of a hollow cylinder, which hangs at one extremity from a rock; the pores are all upon the exterior surface, whilst the vents open into the interior cavity, and their united stream rushes out with considerable energy from the lower end of the cylinder.

Sponges may be multiplied, like plants, by artificial division, each portion becoming a new individual; but it does not appear that this is their natural mode of increase. They propagate by detaching little round gelatinous bodies, termed *gemmules*, from their living tissue; which in time develop the original form of the parent. These are produced in the network between the large canals, into which they find their way; when mature, they pass out of the vents in the current which sweeps through them, and by which they are conveyed to a distance. In these gemmules a peculiar motion, like that of animalcules, may be seen for some time: they swim hither and thither; at last they fix themselves, and begin to deposit the horny or earthy particles which are to form their skeleton; and the system of canals gradually shows itself in their substance. When once they have fixed themselves, they seem to lose all power of further movement, and remain during the rest of their lives attached to the same spot.

Some kinds of sponges are found on almost all shores; and some frequent deep water, whence they can only be obtained by dredging. It is in this manner that the sponge of commerce is procured from the Mediterranean, the Grecian Archipelago, and the other localities it frequents. Sponges are not confined to the sea, however, for there is a species which inhabits fresh water.

With the notice of this group we appropriately close the subject of SYSTEMATIC ZOOLOGY.

NATURAL PHILOSOPHY.

Natural Philosophy is a term of wide import, and has reference to all those branches of physical science which treat of existing bodies, their constitution, their motions, their mutual connections, and their influence on each other. By existing bodies we mean those made known to us by our senses; for a body standing in no connection with our senses, has, so far as we are concerned, no existence. The province of the natural philosopher is therefore to trace the connection subsisting between the varied phenomena brought under his knowledge by means of the senses, and so to arrange them, that they may elucidate each other, and manifest their mutual dependence. When we have established the connection of one phenomenon with another, we are said to have *explained* it; and a natural *law* is obtained as soon as the unchangeable link of connection between the natural phenomena is understood, even should we remain ignorant of the final cause. In this enlarged sense, the science may be considered as embracing all that can be known of the heavenly bodies, of the air, and of the earth and its varied materials and productions. It is usual, however, to divide it into two great branches—*Natural History*, treating of the nature of individual objects, and arranging them into systems, according to their different characters; and *Natural Philosophy*, which endeavours to lay open the laws of the material universe. The former embraces zoology, botany, geology, &c. which are commonly distinguished as *natural* sciences; and the latter mechanics, optics, chemistry, and other departments known as the *physical* sciences. It is also not unusual to employ the term *physics*, in contradistinction to that of *chemistry*, because the former refers more especially to laws not depending upon any change in the constitution of bodies, whereas the latter treats of phenomena almost wholly depending upon such changes. In the present sheet, we shall confine our explanations to the laws and properties of matter and motion, reserving mechanics, hydrostatics, pneumatics, optics, acoustics, electricity, and other branches of natural philosophy as above defined, for subsequent treatment.

I. MATTER AND ITS PROPERTIES.

Matter—or that of which all bodies are composed whose existence is made known to us by means of the senses, or by the test of philosophic experiment—is possessed of various properties, some of which are essential to its existence, while others are only accidental or contingent. The essential properties of matter—are Impenetrability, Extension, Figure, Divisibility, Inertia, and Attraction.

Impenetrability is that quality of bodies in virtue of which each occupies a certain portion of space, and excludes other bodies from existing in the same place at the same instant. In the usual sense, we call any hard body, such as a stone, impenetrable, because it firmly resists our efforts to pierce it. But, as it is understood philosophically (although we can condense, pierce, and remove the greater number of them), all bodies are alike impenetrable, because they equally possess the property of excluding other substances from the spaces which they occupy. This, in fact, is saying no more than that two things cannot be in the same place at once, which is a self-evident truth, whether we apply it to a single particle of matter or a large mass.

Every body, or portion or particle of matter, possesses a certain *extension* or magnitude. It is impossible to form a conception of matter, however minute may be the particle, without connecting with it the idea of its having a certain bulk, and filling a certain extent of space. In common phraseology, we express this property of bodies by the word *size*, or *volume*.

The next property demanding our attention is the *figure* of bodies. Figure, or form, is the result of extension, for we cannot have the idea of a body possessing length, breadth, and depth, without its having some kind of figure, however irregular. The volume of a body has no relation to its figure. Bodies which have the same figure, may possess very different volumes; and bodies may have the same volume, but possess very different figures. Thus two masses of matter may have the same volume, although the one be round, and the other be square.

Matter is divisible into parts, and these parts may again be subdivided into other parts. By this is meant *divisibility*, or separability. To the practical subdivision of matter it seems impossible to assign a limit; and many of the instances of it which may be found in philosophical investigations almost exceed credibility. The thinnest part of a soap-bubble, which is a thin shell of water and the matter of soap, does not exceed in thickness the 2,500,000th part of an inch. The useful arts also furnish many striking examples; but it is in the organised world that the most astonishing proofs of the extreme divisibility of globules, or particles of matter, are to be found. Animalcules—that is, animals which are so small, as to be invisible to the naked eye, and which, by means of microscopes, are seen floating in water—are in some cases so minute, that it would require a million of them to form the bulk of a grain of sand. As these animalcules possess, in every case, a perfect organisation, to enable them to perform all the functions of life, the smallness of their different parts, and the extreme minuteness of the particles of matter which compose them, are too exquisite to be made the subject of calculation: the imagination is lost in the contemplation of their wonderful economy! The effluvium or odour which excites the sensation of *smell*, consists of an incalculable number of particles of matter floating in the atmosphere, and so minute, as to be altogether invisible to the eye. The effluvium given forth by a single grain of musk has been known to perfume an apartment for twenty years, and yet, at the expiry of that period, there was no sensible diminution of the little mass from which the odour-yielding particles had proceeded.

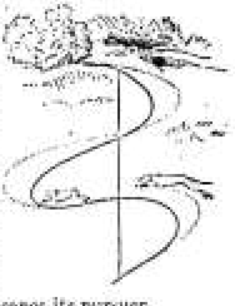
But although divisibility extends far beyond the limits perceptible to sense, it must not be assumed, remarks Professor Müller, that it is wholly unlimited; for to adopt such an assumption, were, in other words, to admit that the size of the ultimate undivisible particle is null, while it is evident that, if the ultimate particle have no extension, it cannot enter into the composition of an extended body. It is upon these considerations that the natural philosopher bases the hypothesis that all bodies are composed of minute particles, which cannot be further disintegrated, but are undivisible, and therefore termed atoms. This fundamental view of the constitution of bodies is now universally embraced by the natural philosopher and the chemist as the atomic theory. In speaking of small particles, without actually wishing to designate them as ultimate portions or atoms, it is usual to employ the term *molecules*, which is synonymous with particles of a mass.

Molecules of matter are never destroyed or lost, although they may disappear from our immediate observation. Under certain circumstances, they may again be collected into a body without change of form. Mercury, water, and many other substances may be converted into vapour, or distilled in close vessels;

without any of their particles being lost. In such cases there is no decomposition of the substances, but only a change of form by the heat; hence the mercury and water assume their original state again on cooling. When bodies suffer decomposition or decay, their elementary particles, in like manner, are neither destroyed nor lost, but only enter into new arrangements or combinations with other bodies. When a piece of wood is heated in a close vessel, such as a retort, we obtain water, an acid, several kinds of gas, and there remains a black, porous substance, called charcoal. The wood is thus decomposed or destroyed, and its particles take a new arrangement, and assume new forms; but that nothing is lost, is proved by the fact, that if the water, acid, gases, and charcoal be collected and weighed, they will be found exactly as heavy as the wood was before distillation. In like manner the decay of animal or vegetable bodies in the open air, or in the ground, is only a process by which the particles of which they were composed change their places, and assume new forms. The decomposition of animals and vegetables beneath the surface of the earth fertilise the soil, which nourishes the growth of plants and other vegetables; and these, in their turn, form the nutriment of animals. Thus is there a perpetual change from death to life, and from life to death, and as constant a succession in the forms and places which the particles of matter assume. Nothing is lost; not an atom of matter is struck out of existence.

Inertia means passiveness, or inactivity. Thus matter is perfectly passive in submitting to any condition in which it is placed, whether of rest or motion. When at rest, it shows an inability or reluctancy to move; and when in motion, it shows an equal inability or reluctancy to come to a state of rest. It is obvious that a rock on the surface of the earth never changes its position in respect to other things on the earth. It has of itself no power to move, and would therefore for ever lie still, unless moved by some external force. Now it is just as true that inert matter has no power to bring itself to rest when once put in motion, as that it cannot put itself in motion when at rest; for having no life, it is perfectly passive both to motion and rest, and therefore either state depends entirely upon external circumstances. Many instances might be given of the tendency which matter has to remain in the condition in which it happens to have been already placed. The following are among the most instructive:—When the sails of a ship are loosened to the breeze, slowly and heavily at first the vessel gets into motion, but gradually its speed increases, as the force by which it is impelled overcomes the inertia of its mass. A great force is necessary at first to set a vehicle in motion; but when once this is effected, it goes onward with comparative ease, so that, in fact, a strong effort is necessary before it can be stopped. If a person be standing in it when it is suddenly set a-going, his feet are pulled forward, whilst his body, obeying the law of inertia, remains where it was, and he accordingly falls backwards. On the other hand, if the vehicle be suddenly stopped, and the individual be standing in the same position as formerly, the tendency which his body has to move forward—for it acquired the same motion as the carriage by which it was borne along—will cause him to fall in the opposite direction.

The following are familiar examples of the inertia of matter:—Upon the tip of the finger let a card be balanced, and a piece of money—say a shilling—laid upon it. Let the card then be smartly struck, and it will fly from beneath the coin, leaving it supported upon the finger. This arises from the inertia of the metal being greater than the friction of the card which passes from beneath it. Coursing, or hare-hunting, affords another striking illustration of inertia. In that field sport, the hare seems to possess an instinctive consciousness of the existence of this law of matter. When pursued by the greyhound, it does not run in a straight line to the cover, but in a zig-zag one. It *doubles*—that is, suddenly changes the direction of its course, and turns back at an acute angle with the direction in which it had been running. The greyhound, being unprepared to make the turn, and therefore unable to resist the tendency to persevere in the rapid motion which it has acquired, is impelled a considerable distance forward before it can check its speed and return to the pursuit. But in the meantime, the hare has been enabled to shoot far ahead in the other direction; and although a hare is much less fleet than a greyhound, by this scientific manœuvring it often escapes its pursuer.

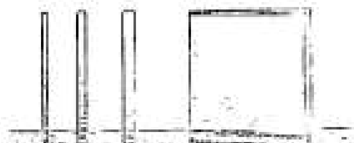


We have now arrived at a most important property—*attraction*—which it is desirable should be carefully studied. It is a fundamental law of nature, ascertained by Sir Isaac Newton, that every atom or particle of matter has a tendency to approach, or to be attracted towards, another atom or particle. This forms one of the leading principles in modern natural philosophy. Experience and observation demonstrate that this power of mutual attraction pervades all material things, and though unseen, except in its results, is ever present with us—is the cause of particles of matter adhering to each other, and forming solid masses—of these masses assuming in many instances a round or globular form—of the falling of bodies to, and their stability on, the earth—and is one of the causes of the whole of the planetary bodies moving in their paths in the heavens. Attraction is of different kinds, although some of these may be merely modifications of others, and has received different names, according to the circumstances under which it acts. The force which keeps the particles of matter together, to form bodies or masses, is called *attraction of cohesion*. That which inclines different masses towards each other, is called *gravitation*, *or attraction of gravitation*. That which causes liquids to rise in tubes, or in very confined situations, is called *capillary attraction*. That which forces the particles of different kinds of matter to unite, is called *chemical attraction*. That which causes the magnetic needle to point constantly towards the poles of the earth, is *magnetic attraction*. And that which is excited by friction in certain substances, is known by the name of *electrical attraction*.

Attraction of cohesion acts only at insensible distances, as when the particles of bodies apparently touch each other. This kind of attraction may be described as the quality in nature which causes matter to cohere or stick together. It is much stronger in some bodies than in others. It is stronger in the metals than in most other substances, and in some of the metals it is stronger than in others. In general, it is most powerful among the particles of solid bodies, weaker among those of fluids, and least of all, or almost entirely wanting, among elastic fluids, such as air and the gases. Thus a small iron wire will hold a suspended weight of many pounds, without having its particles separated; the particles of water are divided by a very small force, while those of air are still more easily moved among each other. These different properties depend on the force of cohesion with which the several particles of these bodies are united.

When the particles of a body can be suspended in the air in a fluid state, they will, if not under the attractive influence of some other body, arrange themselves, by virtue of the same law, around a centre, and take a spherical or round form. Thus a small quantity of dew suspended on the point of a thorn or leaf, becomes a globule, because in that case the attraction of the particles towards their own centre is greater than the attraction of any neighbouring body. Tears running down the cheeks, drops of rain, and hail, are all examples of this tendency in insulated fluid bodies to assume the globular form. When two perfect globules of mercury are brought into contact, they instantly unite together, and form one spherical drop. The manufacture of shot is also a striking illustration. The lead is melted, and poured into a sieve at the height of about two hundred feet from the ground. Each stream of lead, immediately after leaving the sieve, separates into little globules, which, before they reach the ground, are cooled, and become solid: thus is formed the shot used by sportsmen. To account for the globular form in all these cases, we have only to consider that the particles of matter are mutually attracted towards a common centre, and in liquids, being free to move, they arrange themselves accordingly. In consequence of this law of nature, it is considered probable that the planetary bodies, including our earth, were originally in a fluid or gaseous state—that in that state they unavoidably assumed a spherical form, and were then consolidated into their present consistency.

The force by which small tubes, or porous substances, raise liquids above their levels, is called capillary attraction, from *capilla*, the Latin word for a hair. In a wet tea-cup, or other vessel containing liquid, you may perceive the liquid at the sides rising above the level of that of the other parts of the surface; this is caused by attraction. If two glass plates be brought very near each other, so as to stand parallel with their flat sides in almost mutual contact, and then their lower end be dipped into a vessel of water, the fluid will rise up between the plates, and the height to which it rises will be greater the nearer the plates are to each other.



The water rises very little on the outsides of the plates, for this attraction is insensible at even moderately small distances. If a glass tube, with an exceedingly small or capillary bore, be dipped in water, the fluid will rise in the interior of the tube; and the smaller the bore, the higher does the water ascend. A great variety of porous substances are capable of this kind of attraction. If a piece of sponge, or a lump of sugar, be placed so that its lowest corner touches the water, the fluid will rise up and wet the whole mass. In the same manner the wick of a lamp will carry up the oil to supply the flame, though the flame is several inches above the level of the oil. If the end of a towel happens to be left in a basin of water, it will empty the basin of its contents; and, on the same principle, when a dry wedge of wood is driven into the crevice of a rock, and afterwards moistened with water, as when the rains fall upon it, it will absorb the water, swell, and sometimes split the rock. The lower parts of the walls, and also the earthen floors of cottages, are in the same manner apt to become damp, by the attraction of the moisture upwards from the ground—hence the necessity for clearing away all wet earthy matter from the foundations of houses.

Besides these varieties of attraction, there are, as already said, chemical, magnetic, and electric attraction; but as these will be respectively alluded to under the heads CHEMISTRY and ELECTRICITY in the present series of treatises, they do not require particular notice here. We now proceed to consider the kind of attraction which seems to unite all ordinary masses and particles of matter—namely, the *attraction of gravitation*:—

As the attraction of cohesion unites the particles of matter into masses or bodies, so the attraction of gravitation tends to force these masses towards each other to form others of still greater dimensions. The force of attraction increases in proportion as bodies approach each other, and by the same law it must diminish in proportion as they recede from each other. Attraction, in technical language, is inversely as the squares of the distances between the two bodies; that is, in proportion as the square of the distance increases, in the same proportion attraction decreases, and so the contrary. Thus, if at the distance of 2 feet, the attraction be equal to 4 pounds, at the distance of 4 feet it will be only 1 pound; for the square of 2 is 4, and the square of 4 is 16, which is 4 times the square of 2. On the contrary, if the attraction at the distance of 6 feet be 3 pounds, at the distance of 2 feet it will be 9 times as much, or 27 pounds, because 36, the square of 6, is equal to 9 times 4, the square of 2.

The gradual diminution of attraction as the distance increases, is exemplified in the following table. In the upper line, the distance is expressed by progressive numbers; in the lower corresponding squares the diminution of attraction is indicated by the common arithmetical fractions:—

Distance	1	2	3	4	5	6	7	8	and so on.
Attraction	1	$\frac{1}{4}$	$\frac{1}{9}$	$\frac{1}{16}$	$\frac{1}{25}$	$\frac{1}{36}$	$\frac{1}{49}$	$\frac{1}{64}$	and so on.

It is here seen that at the distance of 8, the attractive force is diminished to a 64th part of what it was at 1.

The attractive force of matter is also in proportion to the numbers of the atoms of matter which a body contains: the attraction, therefore, does not proceed from the mere surface of a body, but from all the particles which individually compose it. Some bodies of the same bulk contain a much greater quantity of matter than others: thus a piece of lead contains about twelve times as much matter as a piece of cork of the same dimensions; and therefore a piece of lead of any given size, and a piece of cork twelve times as large, will attract each other equally. The attractive power of any mass acts from the centre. At all equal distances from the centre the attractive power is equal; for instance, in a body perfectly spherical, the attraction to the centre would be the same at all parts of the surface. The distance of the centre of a sphere from its surface is called the *semi-diameter* of that sphere—that is, the half of its thickness. At a point as far from the surface of a sphere as its semi-diameter, its attractive power is diminished to a fourth. At three distances, the attraction is a ninth; at four distances, a sixteenth; and so on. When we wish, therefore, to ascertain the relative amount of the attraction which any mass of matter exercises over another, the rule is, to inquire how many semi-diameters of the one the other is distant from it, and then to multiply that number by itself. The result shows how many times the attraction at this distance is less than at the surface of the former. The moon, for instance, is distant 240,000 miles from the earth, or as much as sixty semi-diameters of the earth; 60 multiplied by 60 gives 3600; consequently, the attraction exercised by the earth upon the moon is a 3600th part of what it would exercise upon the same mass at its own surface. If the earth were a perfectly spherical body, its attraction would be equal everywhere at the level of the sea. As the surface at the pole is about thirteen miles nearer the centre than the surface at the equator, the attraction is stronger at the former than at the latter place: it gets proportionally weaker as we advance towards the equator, on account of the increase of distance from the centre. Hence a mass of iron which is considered a pound weight in Britain, would be less than a pound on the coast of Guinea, and more than a pound in Greenland, for weight is only a result of attraction. If we ascend a mountain, the effect is the same as if we proceed towards the equator—we are always getting farther from the centre of attraction, and consequently weights become lighter. On the top of a hill four miles high, a ball of four thousand pounds weight would be found to be two pounds lighter.

Pressure downwards, or weight, is in philosophical language termed GRAVITY; and under that head it is hereafter treated, in connection with the phenomena of falling bodies.

The attraction of bodies is mutual, and in proportion to the quantity of matter they contain. Therefore, every body, however small, exerts some degree of attraction upon the mass of the earth. Any body which comes immediately under our observation, is so small in comparison to the earth, that its attractive force is altogether unappreciable; but if it were of great density, and of dimensions approaching to those of the earth, then we should see the earth rise to meet the body, or fall towards it. The heavenly bodies, when they approach each other, are drawn out of the line of their paths or orbits by mutual attraction. It is found by experiment, that a plumb-line suspended in the neighbourhood of a mountain, is sensibly attracted towards the mountain from the true vertical line. The mutual attraction of matter is exemplified by the diminution of the weight of bodies as we penetrate into the earth. At the depth of a mile, a body weighing a pound would be found to be lighter than at the surface. This is in consequence of the attraction of the matter of the shell of the earth, which is exterior to the point, being nothing, in consequence of the attractions of its particles on this point counteracting each other; hence the only efficient attraction on it arises merely from the smaller sphere below the point; and therefore the nearer the point is to the centre, the less is this internal sphere, and the less, therefore, is its attraction on the point. Were we to proceed to the centre of the earth, we should there find that weight altogether ceased, because the attractive power would be equal on all sides. Were there a cavity at the earth's centre, the body would hang suspended in space.

The attraction of the earth's mass performs an important function, in binding the atmosphere, which is an elastic fluid, around the surface of our planet, and in causing the air to perforate every open crevice and pore in the superficial substances of the globe. The attractive force, in this respect, produces what is called *atmospheric pressure*—the air being pulled or pressed down by a force equivalent to about 15 lbs. on the square inch, at the level of the sea, and diminishing in proportion to the distance above that level.

THE REPULSIVE QUALITY IN MATTER—HEAT.

While attraction tends to unite and compress the particles of matter, there is another and equally universal principle, known in familiar language by the appellation of *heat*, the tendency of which is to keep the particles of matter at a certain degree of expansion. Heat is often, in scientific works, named *caloric*, from the Latin word for heat. Heat pervades all things, but some in greater degrees than others: even ice has been found to contain a certain portion of it. In fact there is no such thing in nature as positive cold.

The absolute nature of this universal principle is unknown. We only know it by its effects, and the sensations it produces. Some have conjectured that it is a fluid; others think it is a quality or affection of matter, resulting from electrical action. From its producing no sensible difference in the weight of any substance, it has been called an *imponderable body*. Light, magnetism, and electricity are also termed *imponderables*. When the heat of any particular substance, as ice, stone, or wood, is not sensible to us, it is called *latent* (that is, concealed) heat. We may very readily detect its presence in a piece of wood or metal by rubbing or friction. If a metallic button, for instance, be rubbed on a table, it will soon become too hot to be held by the fingers.

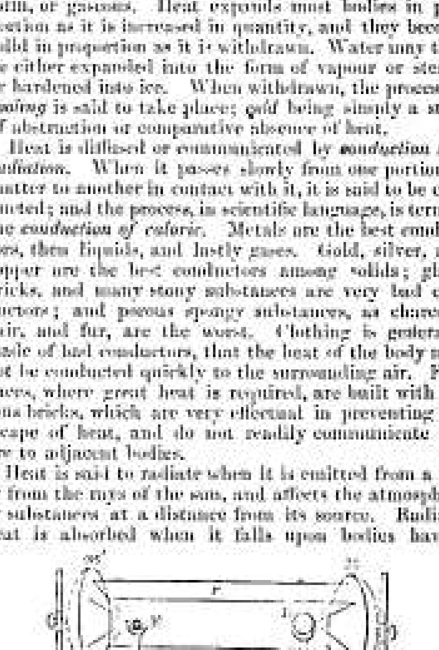
Heat, in its extreme form, becomes fire. Thus, if an ungreased wheel be rapidly turned for a long time on its axle, so much heat will be excited, that both wheel and axle will burst into a flame. The effects of powerful friction are known to savage nations, among whom it is common to produce fire by rubbing two sticks together. Two pieces of flint struck together, or a flint struck hard upon a piece of steel, evolve sparks of fire. By such means many important purposes are served; for instance, the discharge of firearms. Fire can also be evolved from the common atmosphere, by compressing a quantity of it suddenly in a tube, at the bottom of which a piece of tinder has been placed. The evolution of heat by these means, and other circumstances, lead to the conclusion that heat is an element mixed up with the atoms of matter, which it serves to keep at a lesser or greater distance from each other. Thus, as we squeeze the pores of a sponge together, and disengage the liquid which they held in cohesion, so, when compressing or rubbing a portion of matter, do we disengage the heat which it retained amongst its component molecules. In all cases of the development of heat by pressure, hammering, and friction, the cause is the squeezing together of particles which had been kept asunder by the latent fluid, and which fluid must, as a matter of necessity, come forth and make itself sensibly felt or seen.

Heat, then, is a principle of *repulsion* in nature, and in this capacity its uses are as obvious as those of terrestrial gravitation, to which it apparently acts as a counterpoise. The force of attraction is so powerful, that unless for a counteracting principle of repulsion, all bodies would hasten into close contact; there would be no air, no water, no vegetable or animal life; all would be a uniform dead solid mass, and the earth itself might perhaps be reduced to a small portion of its present bulk.

By pervading all things, heat modifies attraction, and, according to circumstances, regulates the density or solidity of bodies. Hence we possess in nature a beautiful variety of substances, some solid and hard, like stone and wood; others soft, or of the jelly form; a third class liquid, like water; and a fourth kind aëriform, or gaseous. Heat expands most bodies in proportion as it is increased in quantity, and they become solid in proportion as it is withdrawn. Water may thus be either expanded into the form of vapour or steam, or hardened into ice. When withdrawn, the process of *cooling* is said to take place; *cold* being simply a state of abstraction or comparative absence of heat.

Heat is diffused or communicated by *conduction* and *radiation*. When it passes slowly from one portion of matter to another in contact with it, it is said to be conducted; and the process, in scientific language, is termed the *conduction of caloric*. Metals are the best conductors, then liquids, and lastly gases. Gold, silver, and copper are the best conductors among solids; glass, bricks, and many stony substances are very bad conductors; and porous spongy substances, as charcoal, hair, and fur, are the worst. Clothing is generally made of bad conductors, that the heat of the body may not be conducted quickly to the surrounding air. Furnaces, where great heat is required, are built with porous bricks, which are very effectual in preventing the escape of heat, and do not readily communicate the fire to adjacent bodies.

Heat is said to radiate when it is emitted from a fire or from the rays of the sun, and affects the atmosphere or substances at a distance from its source. Radiant heat is absorbed when it falls upon bodies having



painted or rough surfaces, such as are presented by bricks and other porous solids, by many kinds of stony matter, and numerous animal and vegetable substances, and makes them warmer as it is taken up. But brilliant and polished metallic surfaces absorb little heat; they reflect or turn it back again. Thus if a red-hot iron ball (B) be placed in the focus of a concave metallic mirror (M), its radiant heat will pass from it to the mirror, and be reflected in parallel rays (*r r*). If these rays be intercepted by a second mirror (*m'*) placed at the distance of a few feet, they can be collected into a focus (F), and made to act upon a thermometer, ignite tinder, phosphorus, &c. In this manner it is possible to set fire to substances at a considerable distance from the source of heat.

As already mentioned, heat can be brought into action in most substances by percussion and rubbing. It is also produced by the burning of certain inflammable substances, as coal and wood; and in this manner its chief purposes in domestic economy are effected. But the most remarkable source of heat is the sun; though whether this luminary is a burning mass, throwing off warmth like a common fire or red-hot ball, or produces the effect by some peculiar and unknown operation, is as yet uncertain. Heat, besides being produced by the sun's rays, and by the friction and combustion of inanimate substances, is evolved by chemical action, a familiar example of which is observable in fermentation. It is by means of a natural chemical action in connection with the circulation of the blood, that heat is resident and sustained in most living animals. A stoppage of the circulation of the blood, as every one knows, leads to an absence of animal heat, or a very considerable degree of coldness. On the contrary, quick circulation of the blood, and active muscular motion, are productive of heat.

Heat is unequally distributed over the globe. At and near the equator, where the rays of the sun are sent in the greatest degree of directness, the greatest heat prevails. In the parts of the earth adjacent to the north and south poles, he transmits his rays so slantingly, as to have little power; and there, accordingly, the air is seldom of a genial mildness. The higher we ascend in the air, the colder it becomes; the summits of very high mountains are always covered with snow. In penetrating into the body of the earth, after gaining a certain depth, the heat becomes greater in proportion as we descend. The interior of the globe is thus by many believed to be at a very elevated temperature, if not in a state of ignition. On the surface, great expanses of sea tend to equalise and temper the degrees of heat and cold in their neighbourhood, and extensive continents have the contrary effect.

The degrees of heat and cold in the atmosphere are called its temperature; and for ascertaining this correctly, with reference to a standard, a very ingenious instrument has been invented. This is called the *thermometer* (a word signifying heat-measurer). It is a glass tube with a bulb at the bottom, into which mercury or quicksilver is put, with a scale of figures along the tube to mark the rising of the quicksilver. This instrument differs from the barometer, inasmuch as the quicksilver is sealed up close from the air. The atmospheric heat, however, affects the metallic fluid in the bulb, and, according to its warmth, causes it to expand and rise in the tube. (For further explanation, see METEOROLOGY.) Our common thermometer has a graduation from No. 1, near the bulb, to 212, the degree of heat of boiling water. In the scale of figures, 32 is marked as the freezing-point — that is to say, when the mercury is at the height of 32, *water freezes*; and the more it is below that point, the more intense is the frost: 55 is reckoned moderate heat, and 76 summer heat, in Great Britain: 98 is the heat of the blood in the average of living men.

The rising of mercury in the tube of the thermometer offers a familiar example of the repulsive power of heat in expanding or dilating bodies. Common experience affords many such examples. A bar of iron is longer and thicker when hot than when it is cold. The iron rim of a wheel slips easily into its place when hot, and gripes or binds fast when it becomes cool. When heated from 32 to 212, air expands 3-8ths of its volume, alcohol 1-9th, water 1-22d, and hammered iron 1-273d. In these, and all similar instances, the expansion arises from the heat lodged among the atoms of matter pressing outwards on all sides, according as it is excited.

When the temperature of the atmosphere falls below the freezing-point (32), which it does principally from the weakness of the sun's rays in winter, the phenomenon of frost, or freezing, ensues. Freezing is a process of congelation, or properly crystallisation, produced by the withdrawal of heat, and by which water assumes the form of ice. When the temperature of the atmosphere rises above the freezing-point, the ice melts, and is resolved into its original element. When the temperature of the atmosphere is below the freezing-point, the particles of water which are upheld in the clouds are frozen in their descent, and reach the earth in the form of flakes of snow. If this freezing take place after the particles have become united into rain-drops, we have hail instead of snow. When the descending flakes of snow come into a temperature above the freezing-point as they approach the earth, they are apt to melt, and in such a case fall in the shape of sleet, which is half-melted snow or hail.

Heat has a constant tendency to preserve an equilibrium in all situations; hence its diffusion through nature, and many of the ordinary phenomena in relation to temperature. When we touch a cold substance with our hand, a portion of the heat of the hand rushes into the substance, and leaves the hand so much deficient of its former heat. On the same principle, when we touch a substance which is warmer than the hand, some of the heat rushes into the hand, and renders it hot. When we pour a quantity of hot water into that which is cold, an equalisation of the two temperatures immediately ensues. When the air at any particular place becomes heated or rarefied, it ascends by virtue of its greater lightness, leaving a vacancy, which the neighbouring air rushes in to supply. This is one of the chief causes of winds. The same principle is observable in the case of heated apartments. If the door of a heated room be thrown open, a current of cold air immediately rushes in to supply the deficiency in the rarefied atmosphere.

Evaporation is always accompanied by the withdrawal of heat, or production of cold, when no heat is directly applied; the heat necessary for the production of the vapour is then derived from surrounding objects, as in the case of dew forming on plants.

In the great operations of nature, the withdrawal of heat to produce intense cold, and the application of heat to produce great warmth, ordinarily take place gradually. Thus, although water freezes at a temperature of 32, it is some time before frost is completely effectual in changing the aspect and condition of liquid bodies; and when the temperature rises a few degrees above 32, after a frost, the ice and snow which have been formed do not vanish immediately; indeed ice will remain unthawed for several days after the temperature has risen some degrees above the freezing-point. By this slow process, either in the absorption or evolution of heat, animal and vegetable structures are not liable to the injury which would ensue from instantaneous changes in the condition of their component or elementary fluids.

Water is increased in volume by freezing, which circumstance explains the ordinary phenomena of the bursting of water-pipes, and other similar occurrences, during frost. When a vessel of moderate strength is filled with water, its expansion, when it is converted into ice, by exposure to a freezing temperature, causes the vessel to burst. If the vessel is not brittle, but possessed of considerable tenacity, as a leaden water-pipe, the rupture will seldom be observed during the continuance of the frost while the water remains in a solid state, but it readily appears when thaw takes place, as the water is then forced out with a velocity corresponding to the vertical height of the column of water in the pipe. The fissures of rocks, too, are widened by the freezing of the water which may happen to lodge in them before frost; and this process, therefore, is a powerful agent in the disintegration of rocks. Portions of steep banks, also, from a similar cause, tumble down after thaw; for the moisture in them expands when frozen, and thus rends them to pieces, which, however, during the frost, are bound together as by cement, and fall down whenever thaw dissolves the moisture.

Heat has a powerful effect in causing certain bodies to shrink and diminish in volume. This happens with those substances which do not liquefy, such as wood and clay. The contraction arises from the heat carrying off the watery particles from the bodies, and thus allowing the constituent atoms to come more closely together. As wood becomes drier, its fibres are sometimes split asunder, so as to emit loud cracking noises, which, in the case of household furniture, are ascribed by the ignorant to supernatural causes.

Heat is further treated of under the articles METEOROLOGY, PNEUMATICS, and CHEMISTRY.

ACCIDENTAL PROPERTIES OF MATTER.

While the beautiful and extensive variety of form in bodies—solid, liquid, gaseous, and the different modifications of them—are to be traced to the operation of chiefly two great leading principles in nature—attraction and repulsion; the peculiar forms or characters which bodies assume from the influence of these and other causes, are usually classed under the term *accidental properties of matter*. The following are these properties:—Density, Porosity or Rarity, Compressibility, Elasticity, Dilatation, Hardness, Brittleness, Malleability, Ductility, and Tenacity.

Density signifies closeness of texture, or compactness. Bodies are more dense when in the solid state, less dense when in the condition of liquids, and least dense of all when gaseous or aëriform. In this manner the degree of density is in agreement with the closeness of the atoms to each other. The density of bodies may generally be altered by artificial means, as is afterwards mentioned. The metals, in particular, may have the quality of density increased by hammering, by which their constituent particles are brought nearer to each other. The denser in substance that a body is, it is the more heavy or weighty. In speaking of the density of different solid and liquid bodies, the term *specific gravity* is used to denote the comparison which is made. Thus the specific gravity of a lump of lead is greater than an equal bulk of cork; or the specific gravity of water is greater than that of an equal quantity of spirituous fluid. For the sake of convenience, pure distilled water, at a temperature of 62°, has been established as a standard by which to compare the specific gravity or relative weights of bodies. Water, as the standard, is thus said to be 1. When, therefore, any body, bulk for bulk, is double the specific gravity of water, it is called 2, and so on to 3 and 4 times, up to 22 times, which is the specific gravity of platinum, the heaviest known substance. Common air is sometimes taken as a standard with which to compare gases, being a more simple mode of comparing the relative weights of aërial substances. But all the solids and liquids are estimated with reference to water as the standard. The following table exhibits the specific weights of a few of the more familiar substances:—

Platinum, coined,	22·100	Porcelain, china,	2·384
... wire,	19·267	Sulphur, natural,	2·033
Gold, coined,	19·325	Ivory,	1·917
Mercury,	13·568	Boxwood,	1·330
Lead,	11·352	Oak, old,	1·170
Silver,	10·474	Amber,	1·078
Copper, hammered,	8·878	Mahogany,	1·063
... fused,	7·788	Milk,	1·030
Steel,	7·816	Sea-water,	1·026
Iron, wrought,	7·788	Water, distilled,	1·
... cast,	7·207	Claret,	·994
Tin,	7·291	Alcohol, absolute,	·792
Antimony,	6·712	Linseed oil,	·953
Diamond,	3·520	Ash-wood, dry,	·845
Flint Glass,	3·329	Beech,	·852
Marble,	2·837	Cork,	·240

Any body of greater specific gravity than water, will sink on being thrown into water; but it will float on the surface if its specific gravity be less than that of water. A body, such as a piece of wood, after floating a certain length of time on water, will imbibe such a quantity of liquid, that its specific gravity will be gradually increased, and in the course of time it may sink to the bottom.

Porosity is the quality opposite to density, and means that the substance to which it is applied is porous; that is, full of small pores or empty spaces between the particles, and that the body is comparatively light. The instances of porosity are numerous in every department of the material world, but those which are connected with animal and vegetable bodies are the most remarkable. Bone is a tissue of pores or cells, and, when seen through a microscope, may be said to resemble a honeycomb. Wood is also a tissue of cells or tubes. If the end of a cylinder of straight wood be immersed in water, whilst the other is forcibly blown into, the air will be found to pass through the pores of the wood, and rise in bubbles through the water. When a gas is comparatively light, it is said to be *rare*, or to possess *rarity*.

By *compressibility* is meant that quality in virtue of which a body allows its volume to be diminished, without the quantity or mass of matter being diminished. It arises of course from the constituent particles being brought nearer to each other, and is effected in various ways. All bodies are less or more capable of being diminished in bulk, which is a conclusive proof of their porosity. Liquids are less easily compressed than solid bodies; nevertheless they, to a small extent, yield, and go into smaller bulk by great pressure. The water at the bottom of the sea, by being pressed down by the superincumbent water, is more dense or compact than it would be at the surface. Atmospheric air and gases are much more easily compressed than liquids, or even than many solids. Air may be compressed into a hundredth part of its ordinary volume. When at this state of compression, it has a great tendency to expand and burst the vessel in which it is confined.

Some bodies have the power of resuming their former volume or shape when the force which diminished it is withdrawn. This quality is termed *elasticity*. Steel is one of the most elastic of metallic bodies, but its elasticity is not nearly so great as that of India-rubber, which, though twisted, drawn out, or compressed in different ways, always resumes its original form. The aëriform fluids—atmospheric air and the gases—are all exceedingly elastic; and so are liquids, such as water, but to a smaller extent.

Dilatability is that quality of bodies by which they are enabled to be expanded or enlarged in their dimensions, without any addition being made to their substance. *Hardness* is the quality which is the opposite of softness, and does not depend so much on the density of the substance, as the force with which the particles of a body cohere, or keep their places. For instance, glass is less dense than most of the metals, but it is so hard, that it is capable of scratching them. Some of the metals can be made either hard or soft: steel, when heated to a white heat, and then suddenly cooled, as by immersion in water, becomes harder than glass; and when cooled slowly, it becomes soft and flexible. *Brittleness* is that quality by which bodies are capable of being easily broken into irregular fragments, and it belongs chiefly to hard bodies. Iron, steel, brass, and copper, when heated, and suddenly cooled, become brittle. *Malleability* is the quality by which bodies admit of being extended by hammering. Some of the malleable metals are gold, silver, copper, zinc at the temperature of boiling water, lead, iron, and some others. Several of the metals possess the opposite quality of brittleness. Gold is the most malleable of all metals, and it may be hammered so thin, as to be translucent, or permeable to light. By *ductility* is understood that property by which metals may be drawn to wire. The most malleable metals are not the most ductile. Tin and lead may be rolled into thin leaves, but cannot be drawn into wire. The most ductile metal is platina, which can be drawn into wire as fine as the threads of a cobweb. *Tenacity* is the quality by which bodies are not easily torn asunder. Steel is the most tenacious of all substances: a wire of this metal, one hundredth of an inch in diameter, will support a weight of 134 lbs.; while one of the same size of platina will sustain only 16, and one of lead only 2 lbs.

II. MOTION AND FORCES.

Motion is the change of place; that is, of the part of space which the body occupies.

Matter, according to the definitions given of its properties, is perfectly passive, or inert. It has been described as possessing the property of inertia, and in this respect it is said to possess an unwillingness or reluctance to move; but these phrases are only figurative, and are used for the purpose of conveying a forcible idea of the passiveness of its character. It is also, in consequence of this property of inertia, or passiveness to submit to any condition to which it is subjected, that a body, when once in motion, will continue to move continually with the same velocity, and in the same direction, till it be disturbed by some external cause.

Any instance of rest which comes under our observation, is only rest in a *relative*, not an *absolute* sense; that is, it is rest as relates to the earth, but not rest as relates to the universe; for though the stone which falls to the ground lies at rest on the earth, the earth is always in motion, and therefore the stone is no more at rest than the insect which sits upon a moving wheel is at rest. Hence, in speaking of bodies coming apparently to a state of rest, we must always recollect that it is only relative, not positive or absolute rest. It is supposed that there is no such thing as absolute rest in creation. All the planets are in motion round the sun; and the sun itself has a motion on its own axis: it is also believed by many astronomers that the sun has an onward or progressive motion in space, besides its rotatory movement; and thus, perhaps, revolves round some distant centre, with all its planets in its train.

Common experience would lead to the conviction that rest is more natural for matter than motion; but this conviction is founded on a limited consideration of circumstances. The reason why we see ordinary moving bodies coming to a state of rest — such as a wheel stopping after having been whirled on its axle, a ball stopping after rolling on the ground, or an object falling to the earth after being thrown upwards—is, that they are sooner or later arrested in their progress by the earth's attraction or their own gravity, by the friction or rubbing against some other body, or by the opposition presented to them by the atmosphere. Except for these three prevailing causes of impediment and stoppage, all bodies, once set in motion, would go on moving for ever. Taking this expanded view of things, and dismissing the erroneous impressions arising from what is obvious only to our limited experience, we find that there is nothing more remarkable in perpetual motion than in perpetual rest.

It is only, however, in the great works of creation, or the heavenly bodies, that perpetual motion is observable. The planetary bodies are under the ever-acting impulses of centrifugal and centripetal forces, and are not impeded by friction, or by the atmosphere, for they move in space, or in a comparative vacuum. Many ingenious attempts have been made to produce perpetual motion on mechanical principles in terrestrial objects, but they have all necessarily failed, as no human effort can destroy gravity in bodies, or altogether prevent friction in movement.

In regard to bodies on the earth, of which a state of rest is the ordinary condition, motion is produced by certain agencies, or impelling causes, either belonging to the phenomena of nature, or to art. The property of capillary attraction causes a motion in liquids under certain circumstances; the winds blow, and cause motion; rivers, in flowing down their channels, and the action of the tides, likewise produce motion; thus there exist many natural causes of motion, which are taken advantage of by man in the economy of arts and manufactures. Motion in the animal economy is produced by a principle of life; but of the nature of this principle mankind are ignorant, and nothing here requires to be said regarding it. The causes of motion about to engage our attention are those which consist of *forces*, whether natural or artificial; and which forces have the property of impelling inanimate objects from a state of rest to a state of motion, of stopping them when in motion, or of altering the character of that motion. These forces are also called *powers*.

Motion, according to the mode in which the force acts, is susceptible of innumerable variations. As the moving body is affected, so may it move rapidly or slowly, proceed in a straight line, turn in a circle or curve; it may move with uniform or irregular speed, or be retarded or accelerated. The body may also move upon, or in respect of, another body which is also moving. Some of these peculiarities in motion will immediately engage our attention; meanwhile, it has to be explained, that, for the sake of convenience in language, and accuracy in the application of terms, certain words are used to define the nature of motion in bodies, and the forces affecting them.

Motion is said to be *common* to two or more bodies when they move in contact, or together; or when, though not in contact, they are carried along in a similar manner, and with the same velocity; that is, when they have a motion in common, or participate in the same motion. Motion is said to be *absolute*, when a body actually moves from one point of space to another, or when it proceeds towards, or when it passes, another which is at rest. Therefore setting aside the idea of the earth's revolution and rotation, we should say that a vessel moving on the sea has an absolute motion, while the land is fixed or stationary. Motion is said to be *relative*, when the motion of one moving body is considered in reference to that of another moving body. Thus if two bodies move in the same direction, their relative motion is the difference of their motions; if they move in opposite directions, it is the sum of their separate motions.

When a force, applied to any material object, is resisted or counteracted, so that no motion ensues, it is called a *pressure*; and forces so counteracted are said to *balance* each other, or to be in *equilibrium*.

The degree of speed in the motion of bodies is called *velocity*. Velocity is measured by the space or distance passed over, with an invariable motion, and in a given time, as one second. Thus if a body, in one second, with an invariable motion, pass over twenty feet, its velocity is said to be twenty feet per second.

When a motion is invariable, it is said to be *uniform*; if it be gradually increasing, it is said to be *accelerated*; and if it gradually decrease, it is said to be *retarded*. A force is said to be *accelerating* or *retarding*, according as it produces an accelerated or retarded motion.

Forces are either *instantaneous* or *continued*. The former is an impulse, like a stroke; the latter acts without intermission. When a continued force remains always of the same intensity, it is called a *constant* force. Other continued forces are said to be *variable*.

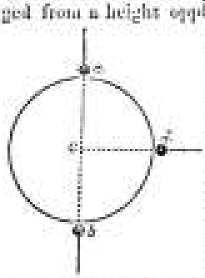
A body, in moving, possesses a force which is called its *momentum* or *moving force*. Momentum is very different from velocity. A light body and a heavy body may move at the same velocity, but the momentum of the light body will be small in comparison with that of the heavy one. The light one, on coming to a state of rest, will perhaps fall harmlessly on the ground, while the other, by its momentum, will strike *forcibly* on the earth, or destroy any object which opposes it. Momentum is proportionate to the mass and velocity of bodies, and by multiplying the weight by the number of feet moved over per second, we find that the momentum is the product. Thus if a body of twelve ounces move with a velocity of twenty feet per second, its momentum is (twelve times twenty) two hundred and forty. In ordinary language, the term *impetus* is used to signify the violent tendency of a moving body to any point.

Before entering upon a consideration of motion as produced by ordinary forces, it will be appropriate to describe the effects produced upon bodies when simply falling—that is, moving downwards towards the earth, when the supports which upheld them are withdrawn.

PHENOMENA OF FALLING BODIES—WEIGHT.

Attraction, as already explained, is a force inherent in nature, by which particles and masses of matter are drawn towards each other. This force, it has also been stated, increases in proportion to the quantity of matter which the attracting body contains, and it also increases as the bodies approach each other. Further, it has been mentioned that this powerful and subtile quality in matter is the cause of the falling or drawing of bodies downwards towards the earth, and thus produces what is termed *weight* or *gravity*. Gravity, then, is simply the tendency which any substance has to press downwards in obedience to the law of attraction, as exemplified in the phenomena of bodies falling from heights to the ground, when the supports which upheld them are removed.

All falling bodies tend directly towards the centre of the earth (*c*) in a straight line from the point where they are let fall. If, then, a body be let fall in any part of the world, the line of its direction will be perpendicular to the earth's centre. Consequently, two bodies (*a b*) falling on opposite sides of the earth, fall towards each other. Suppose any body to be disengaged from a height opposite to us, on the other side of the earth, its motion in respect to us would be upward, while the downward motion from where we stand would be upward in respect to those who stand opposite to us, on the other side of the earth. In like manner, if the falling body (*d*) be a quarter, instead of half the distance round the earth from us, its line of direction would be directly across or sidewise—that is, at right angles with the lines already supposed.



It will be obvious, therefore, that what we call *up* and *down* are merely relative terms, and that what is down in respect to us, is up in respect to those who live on the opposite side of the globe. Consequently, *down* everywhere means towards the centre of the earth, and *up* signifies from the centre of the earth. The velocity or rapidity of every falling body is uniformly accelerated or increased in its approach towards the earth, from whatever height it falls, if the resistance of the atmosphere be not reckoned. If a rock be rolled from the summit of a steep mountain, its motion is at first slow and gentle; but as it proceeds downwards, it moves with perpetually-increased velocity, seeming to gather fresh speed every moment, until its force is such that every obstacle is overcome; trees and rocks are dashed from its path, and its motion does not cease until it has rolled to a great distance on the plain.

The same principle of increased velocity in bodies as they descend from a height, is illustrated by pouring treacle, honey, or any thick sirup from an elevated vessel. The bulky stream, which is perhaps two inches in diameter where it leaves the vessel, is reduced to the size of a straw or thread on reaching its destination; but what it wants in bulk is made up in velocity, for the small thread-like stream at the bottom will fill a vessel just as soon as the large and slow-moving stream at the outlet; the velocity is indeed so great, that the stream has not time to sink at once into the mass below, but falls in overlaying folds. From the same principle, a person may leap from a chair without danger; but if he jump from the house-top, his velocity becomes so much increased before he reaches the ground, as to endanger his life by the fall.

It is found by experiment, that the motion of a falling body is increased, or accelerated, in regular arithmetical progression. In other words, in every second of time during its descent, it acquires an additional rate of speed, the rate regularly increasing by the accumulation of the preceding additions. A dense or compact body, when falling freely, passes through a space of 16 feet 1 inch during the first second of time. Leaving out the odd inch for the sake of even numbers, we find that the space fallen through in a given time is determined by the following arithmetical computation:—Ascertain the number of seconds which a body occupies in falling. Take the square of that number (that is, the number multiplied by itself), and multiply the square by 16, which is the number of feet fallen during the first second, and the result is the amount of feet which the body altogether falls. For example, if a ball occupy 3 seconds in falling, we take the square of 3, which is 9; then we multiply 9 by 16, which gives 144 as the result, and that is the number of feet fallen. Again, if we find that the ball occupies 4 seconds in falling, we take the square of 4, which is 16, and multiplying 16 by 16, the result is 256, which is the number of feet fallen. And so on in every other case.

It is not always easy, by the above mode of calculation, to arrive at a correct result as to the height fallen by bodies, and all that can be expected is an approximation to a true result. This arises from bodies being of different bulks, and receiving different degrees of opposition from the atmosphere in their descent. It is a common supposition that large and heavy bodies fall more quickly than small and light ones. This opinion, which was maintained even by philosophers, until Galileo rectified the mistake, perhaps originates in the error of confounding *momentum* with *velocity*. Be this as it may, it is now an established truth in science, that all bodies, of whatever density, fall with the same velocity. Thus a ball containing a pound of lead falls with the same velocity as a ball containing an ounce. This equality in the rate of falling is, however, disturbed by the quality of figure and bulk of bodies. A solid ball of gold will fall more quickly than the same quantity of gold beat out into a thin leaf, because, in the case of the leaf, the resistance from the atmosphere on a large surface impedes the descent. Thus bulky and porous substances are prevented from falling with the same velocity as those which are compact.

If the atmosphere were removed, all bodies, whether light or heavy, large or small, would descend with the same velocity. This fact is ascertained by experiments performed with the air-pump. When a piece of coin, for instance a guinea, and a feather, are let fall at the same instant of time, from a hook which has held them at the top of the exhausted receiver of an air-pump, they are observed to fall at an equal rate, and to strike the bottom at the same moment. Hence it is demonstrated, that were it not for the resistance of the atmosphere, a bag full of feathers, and one of coins, would fall from a given height with the same velocity, and in the same space of time.

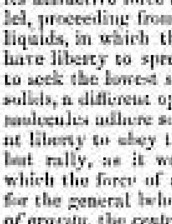
It has been stated that the attraction of gravitation increases in proportion to the quantity of matter which the attracting body contains. Thus the mass of our planet, the earth, exerts a force of attraction which produces the phenomena of weight, and the falling of bodies with a certain velocity. In consequence of the different size and density of the sun and planetary bodies, attraction is much stronger in some of them than others, and consequently the weight of bodies differs in each. On the surface of the sun, our pound would weigh upwards of 27 pounds, and a body would fall upon it 434 feet the first second; on the surface of Jupiter, our pound would weigh about 2 pounds 4 ounces; and on the moon, it would weigh only the fifth part of a pound.

As a body, in descending to the earth, receives increasing accessions to its velocity during every successive second, so when a body is projected upwards from the surface of the earth, its velocity decreases in the same proportion, till it comes to a state of momentary rest, when it instantly begins to descend with a gradually-increasing velocity, which at any point in the descent is equal to its velocity at the same point when ascending. In this calculation, however, we omit the influence of the atmosphere, which would cause the final velocity in the descent to be less than the original velocity with which the body was projected upwards.

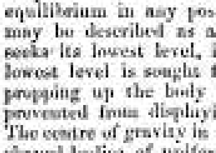
THE CENTRE OF GRAVITY.

Terrestrial gravitation, as already explained, does not act on the mere surface of bodies, or according to their bulk, but is exerted in reference to all the particles or atoms individually which compose the mass of a body. As the earth is nearly of a spherical form, its attraction is the same nearly as if it proceeded entirely from the centre. On account of the great size of the earth, compared with that of any ordinary body at its surface, its attractive force acts in straight lines, sensibly parallel, proceeding from the earth's centre. In the case of liquids, in which the atoms slightly cohere, the atoms have liberty to spread themselves over the earth, and to seek the lowest situation for repose. In the case of solids, a different operation is observable. In them the molecules adhere so closely together, that they are not at liberty to obey the law of gravitation individually, but rally, as it were, round a common centre, upon which the force of attraction may be considered to act for the general behoof. This centre is called the *centre of gravity*, the *centre of inertia*, or the *centre of parallel forces*.

Every solid body or dense mass possesses a centre of gravity, which is the point upon or about which the body balances itself, and remains in a state of rest or equilibrium in any position. The centre of gravity may be described as a point in solids which always seeks its lowest level, in the same manner that the lowest level is sought for by water; for it is only by propping up the body that the centre of gravity is prevented from displaying the same mode of action. The centre of gravity in round, square, or other regular-shaped bodies, of uniform density in all their parts, is the centre of these bodies. When a body is shaped irregularly, or when there are two or more bodies connected, the centre of gravity is the point about which they will balance each other.



Any square or angular body which we may place on the ground will remain stationary, or safely at rest, provided an ideal line, drawn from its centre of gravity, and passing to the ground in a direction perpendicular to the earth's surface, fall within its base, as in the annexed fig. A point below A is the centre of gravity; and from that point the line of direction goes downward to B, which is within the edges of the base. An object of this form, and so placed, will stand. If the line of direction from the centre of gravity fall without the outer edge of the base, as from A to B, in the next fig., then the object will not remain balanced on its base; it will fall over, and attain some position in which the line of direction falls within the boundary of the base on which it stands. By keeping this simple principle in view, stability and safety will generally be secured in the erection of objects of art, such as houses, monumental edifices, spires, and obelisks, as well as in the lading of coaches, carts, and other vehicles, and the piling of timber or any kind of goods in heaps. In every instance, the base ought to be sufficiently broad to admit of the line of direction from the centre of gravity falling within it.



A small amount of experience seems to point out the propriety of erecting all kinds of structures with a base wide enough to secure stability; nevertheless, in opposition both to experience and the simple principles of science, we often find that stage-coaches are laden in such a manner, that their centre of gravity is liable to too great a change of position, and that they are overturned, to the personal injury, and even loss of life, of the passengers. The error in these instances consists in raising the centre of gravity too high. At first, perhaps, the centre of gravity is so comparatively low, that, in the case of swaying to a side, the line of direction would fall within the edge of the wheel, and no danger would ensue; but it is common to go on piling masses of goods or luggage, or placing a number of passengers, on the roof of the vehicle, so that the centre of gravity becomes considerably elevated; so high, indeed, that when the carriage is swayed, or jolts to one side, the line of direction is thrown beyond the wheel, and the vehicle will consequently fall over. In the annexed cut, a loaded vehicle is represented crossing an inclined plane, or we may suppose that its wheel on one side has come in contact with a stone S, which has raised it above the level of the other wheel, so as to incline the body of the vehicle very considerably from the horizontal. The centre of gravity is represented in two different positions—a lower, with the line of direction L C; and a higher, with the line of direction U C. Had the vehicle not been high laden, the line of direction would have remained as L C, and as it falls within the wheel or base, the vehicle would have maintained its balance; but being now laden to a considerable height, the line has risen to about the place where it is marked descending from C to U, beyond the base; consequently the vehicle must overturn.

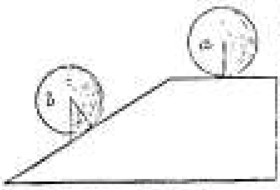
There are instances in which bodies will not be overturned, although the line of direction falls considerably beyond the base. These exceptions to a common rule are observable in the case of rapidly and smoothly moving bodies, in which centrifugal force acts as a counterpoise to the weight of the body. A familiar example of this kind occurs in the case of skaters, in making their circular turns on the ice, in which they bend, or lean greatly, beyond the perpendicular without falling. This peculiarity in moving bodies will engage our attention under the head Centrifugal Force. The tendency which leaning bodies have to fall, may also be counteracted in some measure by the cohesion of parts. Thus there are many instances of walls, steeples, and towers inclining sensibly from the vertical line, and yet, by the strength of the cement which binds them, they have stood for ages.

Whatever raises the centre of gravity, or narrows the base, allows the line of direction to pass more easily without it, and diminishes the stability. Hence the imprudence of rising up in carriages or boats, when in danger of being upset; and hence, as we have just mentioned, the danger of high-loading of vehicles. Lately, an improvement has been effected in stage-coach building, by which a chief part of the load is placed as low as the axle of the wheels; and by this means the danger of overturning is almost entirely averted.

The centre of gravity of a body is not always in the substance of the body. Thus the centre of gravity of a circular ring is in the centre of the circle; of an elliptic or oval ring, in the centre of the ellipse; and of a hollow cylindric tube, it is in the imaginary axis of the tube.

In a drum, for instance, the centre of gravity is a point in the centre of the drum, where there is nothing but air.

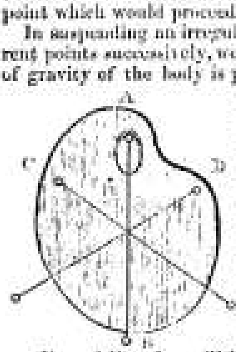
When a circular object (*a*) is placed on level ground, or a horizontal plane, it remains at rest on a point of its surface, because the line of direction from its centre, which is its centre of gravity, falls perpendicularly to the point on which it is in contact with the earth and at rest; and because it could not possibly get its centre of gravity nearer the earth by changing its position. When a similar circular object (*b*) is placed on an inclined plane, it will not remain at rest, but roll over, because the line of direction from its centre of gravity falls perpendicularly downwards in front of the point on its surface which touches the plane. On this account it rolls over, as if it were seeking a spot on which it might have the line of direction from its centre of gravity passing through its point of contact with the earth. Hence a circular body continues rolling down an inclined plane till it find a level spot on which the line of direction passes through its point of rest.



In a bar of iron six feet long, and of equal breadth and thickness, the centre of gravity is just three feet from each end, or exactly in the middle. If the bar be supported at this point, it will balance itself, because there are equal weights on both ends. This point, therefore, is the centre of gravity. If a bar of iron be loaded at one end with a ball of a certain weight, then the centre of gravity will not be at the middle, but situated near the heavy end of the bar. But if we attach a ball of the same weight to both ends, the centre of gravity is again in the middle of the bar.

A remarkable illustration of the principles now detailed is exhibited in the case of the earth and moon. The earth revolves round the sun in consequence of a cause already explained—namely, the sun's attraction; but instead of the centre of the earth describing the oval or elliptic orbit round the sun, it is the centre of gravity of the earth and moon that describes it. We shall briefly explain the reason for this. The earth, in its course, is encumbered with the moon, a body of about the seventieth of its mass; in other words, the moon is like a small ball stuck at one end of a bar, having the earth or a larger ball at the other end—the bar between being the mutual attraction of the earth and moon. On this account, the centre of gravity of the earth and moon is at a point somewhere between the centres of the earth and moon. This point lies not far below the earth's surface. Therefore, if the earth were to fall towards the sun, it would be this point which would proceed most directly towards it.

In suspending an irregularly-shaped body from different points successively, we may learn where the centre of gravity of the body is placed, by observing that the line of direction in each case passes through the same point, which point is the centre of gravity. For example, let a painter's palette, which is an irregularly-shaped body, be suspended from the thumb-hole, as in the annexed cut, and the line of direction will necessarily be from A to B. Next suspend it from a point at D, and a new line of direction will be obtained, crossing the line A B. The place where the two lines intersect is thus the centre of gravity. The point of suspension, on being removed to C, will give the same place of intersection in the original line of direction; and so on with every other point of suspension.

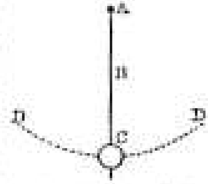


In the various natural structures displayed in the animal and vegetable kingdoms, the centre of gravity is always so situated, as to produce a just equilibrium and a harmony of parts. Every animal is properly balanced on its limbs, and every tree has a tendency to grow in a direction perpendicular to its base, whether it grow from a level or an inclined plane. Some animals are enabled to move in opposition to the law of gravity, as, for instance, flies creeping on the ceiling of a room; but in such cases, other powers in nature are exerted to preserve their secure footing.

THE PENDULUM.

Gravity, which causes bodies to fall, also causes them to swing backwards and forwards, when suspended freely by a string or rod from a point, and when once moved to a side, to give them an occasion of falling. A body suspended in this manner is called a *Pendulum*.

Pendulums usually consist of a rod or wire of metal, at the lower end of which a heavy piece or ball of brass or other metal is attached. When a pendulum swings, it is said to oscillate or vibrate; and the path which its ball pursues in swinging, from its resemblance in figure to an inverted arch or bow, is called its arc. In the accompanying cut, a pendulum of the most common construction is represented. A is the axis or point of suspension. B is the rod. C is the ball, or a round flattish piece of metal, which is fastened to the rod by a screw behind, and by which screw it can be raised or lowered on the rod. D D is the path or arc which the ball traverses in swinging. When the pendulum is at rest, it hangs perpendicularly, as here represented, and the place which the ball is seen to occupy is called the point of rest.



The pendulum remains at rest till its ball is drawn aside to allow it an opportunity of swinging on its axis. Being raised to any height on one side, and set at liberty, the ball, by the force of gravity, has a tendency to fall to the ground; but being confined by the suspending rod, it is compelled to make a sweep to that point where it was formerly hanging at rest, immediately beneath the point of suspension. But it does not stop here; it has acquired a velocity sufficient to carry it onward in an ascending course to nearly as high a point on the opposite side as that from which it was let fall. Of its own accord, it again falls downwards in the same arc, and rises to near the point where it set off; and thus, of itself, continues to vibrate for a certain length of time, till its force is expended, and it finally comes to a state of rest in its original situation under the point of suspension.

At every sweep of the pendulum (when not meddled with, or assisted by any external force), the length of the path or arc traversed by the ball is in a small degree diminished. This arises from two causes—the obstruction offered by the atmosphere, and the friction on its axis or point of suspension. These causes, therefore, sooner or later, bring the pendulum to a state of rest, unless external force of some kind continues to be applied to urge it to sustain its action.

The ball of a pendulum in swinging, as has been mentioned, describes the figure of an arc. This arc is a certain portion of a circle. The extent of this portion depends on the force exerted in setting the pendulum in motion, or in drawing it aside to let it fall. A circle being divided by mathematicians into 360 degrees or parts, the ball may be made to swing over five, ten, twenty, or any other number of degrees under 180, which is half a circle. The extent of the arc traversed is usually from ten to twenty degrees.

A pendulum with a long rod vibrates slower than one with a short rod. The time does not become longer, however, in exact proportion as we extend the rod. The vibration, it must always be recollected, is analogous to the falling of bodies. The spaces fallen through by a body in 1, 2, 3, or 4 seconds, are not in proportion to 1, 2, 3, 4, and so on, but in the proportion of 1, 4, 9, 16, 25, and so on, or the squares of the time occupied in falling. In the case of pendulums, it is found that their lengths are as the squares of the times of vibration. Thus if the times occupied by one vibration of two pendulums be 1 and 2 seconds respectively, the lengths of the pendulums will be as 1 and 4; so if the time of one vibration of several pendulums be as 1, 2, 3, 4, their lengths are as 1, 4, 9, and 16.

The vibrations of the pendulum being produced by terrestrial gravitation, it follows, as a natural result, that if the force of gravitation be weakened, so will the tendency of the ball of the pendulum to fall or swing be weakened. This result is distinctly observable in different parts of the earth. At the equator, the earth, as formerly mentioned, bulges out to a thickness of about 26 miles on the diameter, or 13 miles from the surface to the centre; and as the attraction of gravitation proceeds from the centre, the force of this attraction is consequently weaker at the surface at the equator than it is at the surface at the poles. At every part of the surface between the equator and poles, there is a proportionate increase of gravity. Besides the effect produced by the greater distance of the surface from the centre at the equator, centrifugal force, which is strongest at the equator, assists in weakening the attractive force at that place. In consequence of these combined causes, a pendulum of a given length vibrates more slowly at the equator than at the poles. In proportion as we advance on the surface of the earth from the equator towards the poles, so does the pendulum swing or vibrate more quickly. To preserve uniformity of speed, therefore, in pendulums at different parts of the globe—that is, to make them all vibrate in one second—their length must be regulated according to the distance of the places from the equator. Thus each degree of latitude has its own length of pendulum.

From a knowledge of these laws, we are enabled, by this instrument, not only to detect certain variations in that attraction in various parts of the earth, but also to discover the actual amount of the attraction at any given place. To compare the force of gravity in different parts of the earth, it is only necessary to swing the same pendulum in the places under consideration, and to observe the rapidity of its vibrations. The proportion of the force of gravity in the several places will be that of the squares of the velocity of the vibration. Observations to this effect have been made at several places by Biot, Kater, Sabine, and others.

The uniform vibration of the pendulum has rendered it useful in regulating the motion of clocks for measuring time. In the common clock, a pendulum, connected with the wheelwork, and impelled by weights, or a spring, regulates the motions of the minute and hour hands on the dial-plate, by which the time of day is pointed out. If no pendulum were employed, the wheels would go very irregularly. The pendulum is regulated in length, so as to vibrate sixty times, each time being a second, in the space of a minute. At each vibration, it acts upon the tooth of a wheel, which turns the rest of the machinery. In order that the pendulum may vibrate neither quicker nor slower than sixty times in a minute, in the latitude of London it must measure 39 inches and about the 7th of an inch from the point of suspension to the centre of oscillation. A pendulum at Edinburgh would require to be a small degree longer. The greatest nicety is required in the adjustment of the length, for a difference amounting to the 1000th part of an inch, would cause an error of about one second in a day. Therefore, to make a pendulum go slower by one second a day, it must be lengthened by the 1000th part of an inch; and to make it go quicker, it must be shortened in the same proportion. It is possible to cause short pendulums to regulate the movement of clocks the same as long pendulums; and this is done in cases where long pendulums would be inconvenient, or inelegant in appearance. This is accomplished by shortening the pendulum to a fourth of its ordinary length, by which it beats or vibrates twice instead of once in a second.

The pendulums of clocks being made of a rod of metal, they are liable to be extended by the heat of summer, and shortened by the cold of winter; and by this means the uniformity of their motion is destroyed. Various contrivances have been adopted in order to compensate this effect on the motion of the clock, and pendulums constructed for this purpose are called *compensation* pendulums. The parts of the rods of these pendulums are so constructed and arranged, that when one of them expands downwards, another at the same time expands upwards, by which any variation from temperature is counteracted on the whole. See No. 16.

LAWS OF MOTION.

Motion, as already mentioned, is the changing of place, or the opposite of rest. According to the general explanations which have been given, it appears that motion in bodies is as natural as rest, and that matter passively submits to remain in either of these states in which it may be placed, provided no external force or obstacle interfere to cause an alteration of condition. These and other fundamental laws of nature, in relation to rest and motion of matter, are laid down by Sir Isaac Newton in the following three propositions:—

1*st*, Every body must persevere in its state of rest, or of uniform motion in a straight line, unless it be compelled to change that state by forces impressed upon it.

2*d*, Every change of motion must be proportional to the impressed force, and must be in the direction of that straight line in which the force is impressed.

3*d*, Action must always be equal and contrary to reaction; or the actions of two bodies upon each other must be equal, and their directions must be opposite.

In the first of these laws, there are three points requiring consideration—namely, the permanency, the uniformity, and the straight line of direction of motion in bodies.

As was formerly observed, it is impossible to show either permanency or uniformity of motion in bodies upon or near the earth; for all moving bodies are sooner or later brought to a state of rest by the force of attraction, friction, and the opposition of the atmosphere. It is only, therefore, in the case of the great works of nature, or planetary bodies, that the laws of motion are most clearly and fully illustrated.

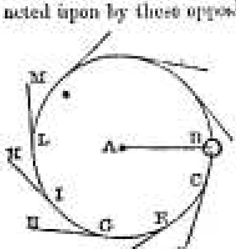
The tendency of a body to move in a straight line from the point whence it set out, is as much a property of matter as the uniformity of motion. If we conceive the idea of a body impelled into a state of motion by any given force, and at the same time conceive the idea that there is no obstacle to interrupt it, no attractive force to bend it aside, we shall then fully understand that a moving body must, as a matter of necessity, from its property of inertia, proceed in a straight line of direction—it must go on in an even path for ever.

CENTRIFUGAL FORCE AND CIRCULAR MOTION.

Bodies, in flying round a centre, have a tendency to proceed in a straight line, and this principle of motion, as already mentioned, is termed *centrifugal force*. Examples of this tendency are very familiar to our observation. When we whirl rapidly a sling with a stone in it, and suddenly allow the stone to fly off, it proceeds at first sensibly in a straight line, but is gradually drawn to the earth by attraction. In turning a circular grinding-stone rapidly with water in contact with it, we perceive a rim of water first rising on the stone, and next flying off; and the more rapidly we turn the stone, so does the water fly off with the greater force. In grinding corn by two rapidly-turning stones playing on each other, the grain poured in at an opening at the centre is quickly shuffled towards the edges of the stones, and expelled in the condition of meal or flour. If we put some water in a vessel, and rapidly turn it in one direction, we shall find that the water endeavours to escape, and rises up to the edges of the vessel, leaving a deep hollow in the middle. The tendency to fly off from a centre is made use of in the manufacture of pottery. Soft clay being placed on a revolving wheel, it quickly spreads towards the circumference of the machine, and is guided or moulded by the hand of the potter into the required form. In forming common crown or window glass, advantage is also taken of the principle of centrifugal force. A mass of glass, softened by heat, and fixed at the middle on an iron rod, being made to turn rapidly round, first in one direction, and then in the opposite, and continuing this alternating rotatory motion till the glass becomes cool, is found to spread out into a large, thin, circular plate, from which square panes of glass are afterwards cut.

In the same manner as solid bodies laid on a whirling table are thrown off, so water in a vessel which is caused to spin round in any way, as on the centre of a horizontal wheel, instead of lying at the bottom, is raised all round against the sides of the vessel. Equestrians, in performing their feats of horsemanship, always incline their bodies inwards when standing on a horse which is running round a circle. Centrifugal force having a tendency to impel them outwards, is thus counteracted by the inward leaning, and forms a species of support to their overhanging bodies. A horse running in a circle, or quickly turning a corner, naturally adopts the same counteracting posture, and leans inwards. A skater, in moving in a circular or curvilinear path on smooth ice, also leans inwards, so much so, that if he were to stand still in this posture, he would inevitably fall on his side; but centrifugal force, which has a tendency to impel his body outwards from the curve, or in a straight line of motion, sustains him, as it does the equestrian, and he therefore moves gracefully and safely in the circular path which his fancy directs. In this and other instances, we find the force of gravity overcome by centrifugal force. It is in obedience to this principle that the earth bulges out to the thickness of 26 miles upon the circumference at the equator, where the whirling motion is most rapid.

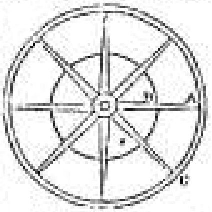
Thus centrifugal force is the tendency to fly off in a straight line, or at a tangent, from motion round a centre; and the power which prevents bodies from flying off, and draws them towards a centre, is, as already mentioned, called *centripetal, or centre-seeking* force. All bodies moving in circles are constantly acted upon by these opposite forces, as may be exemplified by the annexed cut.



A is a point to which a string with a ball at the end of it (B) is attached. On forcing the ball B into motion, it will describe a circle round the point A, in which case the string is the centripetal force. The ball, in whirling, however, having a continual tendency to fly off, if it be disengaged from the string at C, will go in a straight line C D; if at E, it will go in the line E F; if at G, in the line G H; and so on at every point in the circle.

The mutual action of centrifugal and centripetal forces, in the case of circular motion, proceeds according to a certain ratio. If the mass of the revolving body be increased, its distance from the centre and velocity remaining the same, its centrifugal force will be increased in the same proportion. If the distance from the centre be increased, while the mass and the time of revolution remain the same, the centrifugal force will also be increased in the same proportion. If the number of revolutions performed in a given time be twice as many, the distance and mass being unchanged, the centrifugal force will be four times as great; if three times as many, the force will be nine times as great; if four times as many, it will be sixteen times as great; and so on in the same proportion. The masses of the planets, and their distances from the sun, being various, the forces which affect them are also similarly varied.

The line round which a body performs a motion of rotation is called an *axis*. This axis may be only imaginary, like that of the earth; or real, as the axle of a wheel. The body may revolve about two projecting pins or pivots resting in sockets, in which case its axis is a straight line joining the pivots; or it may turn on a cylindrical rod of small diameter, passing through the body, like a wheel on its axle. It is evident that every point of the body, during its revolution, will describe a circle, the centre of which is a point in the axis of the body. In the turning of a wheel on its axis, that part which is at the greatest distance from the centre has the greatest velocity; and at this extremity of the circumference the centrifugal force is greatest. For example, in the annexed representation of a wheel with arms radiating from a centre, the velocity is greater at the extremity of the arm, at A, than it is at B, half the distance from the centre. But the point B goes round as often as the point A, having a smaller circle to traverse. In this manner, the velocity of revolving bodies must always, as a matter of necessity, increase in proportion to the distance from the centre of motion; hence a comparatively small centrifugal force near the centre is prodigiously increased towards the circumference. By increasing the force, and adding to the velocity of a revolving body, the centrifugal force becomes so great, that it will in some cases overcome the cohesiveness in the material of the body, and cause it to break and fly off in pieces. When large grinding-stones are thus whirled with great rapidity, they are apt to fly in pieces, to the extreme danger of those using them.



Bodies movable on an axis of rotation are submitted to different kinds of forces. They are generally distinguished by the duration of their action into instantaneous and continued forces. If the body which sustains an action of the former kind be quiescent and free, it will move in the direction in which the impulse is given with a uniform motion. If, however, the force impressed upon it be incapable of setting it in motion, then it receives a shock, the effect of which is called *percussion*. A continued force produces a continued effect. If the body be free, and previously quiescent, this effect is a continual increase of velocity. If the body be so restrained that the applied force cannot put it in motion, the effort is a continued pressure on the points or lines which sustain it.

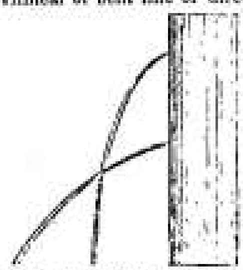
A solid body which is movable upon a fixed axis, is susceptible of no motion, except one of rotation upon the axis. If it be submitted to the action of instantaneous forces, one or other of the following effects must ensue:- 1*st*, The axis may resist the forces, and prevent any motion. 2*d*, The axis may modify the effect of the forces, sustaining a corresponding percussion, and the body receiving a motion of rotation. 3*d*, The forces applied may be such as would cause the body to spin round the axis, even were it not fixed, in which case the body will receive a motion of rotation, but the axis will suffer no percussion.

What has been just observed of the effect of instantaneous forces, is likewise applicable to continued ones. 1*st*, The axis may entirely resist the effect of such forces, in which case it will suffer a pressure which may be estimated by the rules for the composition of force. 2*d*, It may modify the effect of the applied forces, in which case it must also sustain a pressure, and the body must receive a motion of rotation which is subject to constant variation, owing to the incessant action of the forces. 3*d*, The forces may be such as would communicate to the body the same rotatory motion if the axis were not fixed. In this case the forces will produce no pressure on the axis.

The power of centrifugal force in rapidly-whirling bodies may be rendered so great, as to overcome the force of gravity. In whirling a sling with a stone in it, the stone does not fall out of its place in the sling. The following is a more striking example:—Place a jug of water on the inside of the rim of a wheel a few feet in diameter; then, beginning gradually, set the wheel in rapid motion, and it will be observed that the jug retains its place, whirling round in a perfectly stable manner, and that even the water in it is not spilled. Thus gravity, or the tendency to fall downwards, is overcome by centrifugal force. If the jug were placed in a situation in the wheel near the centre of motion, where the centrifugal force is weak, it would at once fall to the ground.

LAWS OF PROJECTILES.

Bodies, on being projected by any impulsive forces, are called *projectiles*, and are observed to pursue a curvilinear or bent line of direction in their motion. The bending from the straight line is produced by the force of gravity, and 'the change is proportional to the impressed force.' A ball projected from a cannon, a stone thrown by the hand, and water spouted from a vessel (see fig.), furnish familiar examples of curvilinear motion.



It is a remarkable law of motion, that whether the force which projects a body be great or small, the body, if thrown horizontally, will reach the surface of the earth from the same height, in the same space of time, not calculating resistance of the air. For example, if two guns are fired from the same spot, at the same instant, and in a horizontal direction, one of the balls falling half a mile, and the other a mile distant, it will be found that the ball which proceeds the greatest distance, takes precisely the same time to reach the ground which the other does. The time of flight, as it is called, of two balls will be the same in whatever directions, and with whatever velocities, they are fired, provided they reach the same height. The reason for the same length of time being occupied in falling by both balls is, that they are both carried downward at the same rate by gravity. Hence a ball dropped perpendicularly from the top of a high tower, does not reach the ground sooner than a ball shot from the same height to the distance of one or more miles in a horizontal direction.

In projecting bodies through the atmosphere, great advantage, in point of distance, is gained by impelling them from heights, because a ball thrown from a high situation to a lower, reckoning its whole course, is more aided than retarded by gravity. When the ball is projected from a lower situation to a higher, it is in the first place retarded by gravity in its ascent, and the acceleration afterwards by gravity being less than this previous retardation, it consequently does not go so far as if projected from a height.

We are now prepared for the consideration of one of the most important principles in dynamics—namely, the law of motion which governs a body after receiving a projectile impulse. A projectile exhibits a composition of motion—namely, a horizontal motion forward, when thrown in that direction, produced by the impressed force; and a descending motion, produced by gravity, or the earth's attraction. These two motions are unequal; they are not at the same velocity. The horizontal motion is uniform, while the descending motion, according to the law of gravitation in relation to falling bodies, is accelerated. The consequence is, that the projectile, as already mentioned, pursues a curved line of direction, the convex side of the curve being uppermost. The degree of curvature of the line of motion depends on the amount of the original projectile force. The law is, the greater the projectile force, or the greater the original velocity of the object, so is the sweep of the curve proportionally greater.

Let us suppose that the projectile force is sufficient to carry a cannon ball ten miles; this will give a very wide curve, allowing that the ball is shot from a lofty situation. But let us add to the projectile force, and send the ball double the distance, and the curve is now exceedingly wide. If we in this manner go on adding to the projectile force, we at length give the ball such a motal force, that it will go quite round the world; instead of describing portions of curves, it will describe a whole circle.

This conducts us to a most extensive result. We have at once placed before us a reason why the planetary bodies should have assumed curvilinear paths in relation to the sun. The original projectile force which they received in connection with the force of gravitation, has obliged them to pursue curved lines in their motion; and once being disengaged, they have, by a balance of centrifugal and centripetal forces, continued to travel in circular, or, properly speaking, elliptical orbits—the ellipticity being caused by a want of exact uniformity between the forces which affect them.

ACTION AND REACTION.

According to the third proposition of Newton—'Action must always be equal and contrary to reaction.' Action is the impression of force. A blow is action; pressure is action. Reaction is resistance; but the word resistance does not fully convey the meaning of reaction, which properly signifies the action of striking or pressing back, even although the body struck or pressed upon do not move. When a man strikes a hammer upon a fixed stone, the stone strikes the hammer at the moment of contact as much as the hammer strikes it. But if the stone be not fixed, and be liable to be easily upset, then its reaction is less, and it acquires a momentum. When a boy throws his ball against the wall of a house, the wall reacts on the ball, and causes it to rebound; but if the boy throw his ball at a pane of glass with the same force, the glass, having the power to resist only a portion of the force, gives way before it. In this case, if we suppose the ball to possess the action or force of 4, and the glass to possess the reaction of 2, the ball, in passing through the glass, loses 2 in its force, and retains the remaining 2. If it then came against another pane possessing a reactive power of 2, it would not break the glass, and, its force being now spent, it would fall to the ground. Thus 'action and reaction are equal.'

A story is told of a person who, from his knowledge of the law of action and reaction, betted that he would lie down on the ground and allow an anvil to be placed upon his breast, and that any one might strike the anvil with as much force as he was pleased to exert. In this case the person who made the offer was quite safe, provided he could support the weight of the anvil; for if a blow were given with the utmost force by a comparatively light body, as a hammer, though it would communicate nearly double its momentum to the anvil, yet the anvil, being so heavy, would acquire so small a velocity, that the shock given to the person would be insensible. Were a freestone of the same weight as the anvil used, it would give a still less shock, for the action and reaction of perfectly elastic bodies are twice as great as that of inelastic bodies. Iron has more elasticity than freestone.

It is by reaction acting contrary, or in opposition to action, that the movements of living objects are rendered effectual. When we walk on the ground, the ground resists the pressure, and we feel ourselves steadied. A bird in flying, pushes itself onward by the flapping of its wings against the partially-resisting medium of the atmosphere. A sailor in rowing a boat causes the oars to push against the water; and the water partially resisting the force, motion is communicated to the boat. In pushing a boat from the shore, the firm ground has such a power of reaction, that we are able to give the boat much greater momentum than if we pushed only against water. If we go into the boat, and try to move it by merely pressing against some part of its fabric, no motion whatever is produced, for the action and reaction are equal. The whole force employed must be rendered greater than the reaction, otherwise no motion can be communicated to the body.

When two bodies come into collision with each other, as in the case of two bodies moving in a straight line, but opposite course, to each other, the law of action and reaction being equal, will not be clearly illustrated, unless the collision be in the direction of the centre of gravity or inertia of the two—in common language, unless the blow be *fair*. The centre of gravity, in cases of this kind, is called the *centre of action*, or *percussion*. For example, when we strike a ball with a club, fairly against its side opposite to its centre of gravity, it is impelled to a considerable distance; but if we strike it above this central point, a part of the force is expended in vain, or lost, and the ball moves but a comparatively short distance. Experience has demonstrated that the centre of action in hammers should be in the head or striking part; and therefore, in striking with these instruments, the blow may be given with every advantage. But when an attempt is made to strike with an object in which the centre of action is at a place short of its extreme point, for instance, a common iron poker, a part of the action is expended towards the hand of the person who strikes, and he feels a disagreeable jarring sensation in his arm.

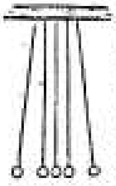
This definition of the centre of action applies only to the motion of bodies in a straight line. In the case of revolving bodies, the centre of action or percussion is a point in it, to which, if an immovable obstacle be applied, the body will remain at rest without any tendency to move in any direction, and the axis will receive no shock. In straight rods or bodies of any form, suspended as pendulums, the centre of oscillation is the same as the centre of action in revolving bodies.

MOTION IN ELASTIC BODIES.

In reference to the effects of collision, bodies are divided into three classes—hard, soft, and elastic. A hard body is one that suffers no change of form by the action of any force. A soft body is one that undergoes a change of form by this means. An elastic body suffers a momentary change of form by the action of any force impressed upon it, and immediately springs back, or recovers its original form. The first two classes are styled *inelastic* bodies.

If two equal inelastic bodies be moving with equal velocities in opposite directions, and come in collision, each will destroy the onward motion of the other, and consequently both will be reduced to a state of rest. If there be any elasticity in the bodies, they will, according to their degree of elasticity, rebound from each other, and a positive process of reaction will be exhibited. By this means there will be at once a counteraction and transmission of force. As above stated, when the bodies are perfectly elastic, the action and reaction are double that of inelastic bodies.

An example of the transmission of force or motion from one body to another, while the transmitting bodies remain at rest from their mutual counteraction of the force communicated, may be seen in the case of a row of billiard balls, which possess a certain elasticity. Place six billiard balls in a row on a smooth plane, and let them be all pretty close to each other, or even in contact. Then give a smart blow to the first ball, or, as we may call it, No. 1; it will instantly strike against No. 2, which will communicate the force to No. 3, and from 3 it will be given to 4, and from 4 to 5, and from 5 to 6. None of the balls, however, will sensibly move from the spot in which it rests, except the last of the row, which, having no ball to impinge upon, will roll away, and thus expend the force communicated by the blow upon No. 1.



An experiment of this kind is generally performed upon a number of elastic balls of a small size, suspended in a row by threads, as in the preceding fig., in which case there is no friction to interrupt the process of action and reaction.

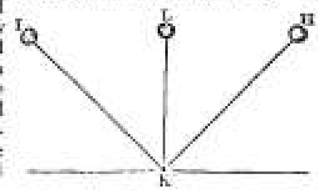
REFLECTED MOTION.

A body projected by a single force proceeds in a straight line till a new force act upon it, and send it on a new line of direction. When a moving body is thus impelled into a new line by striking against some body, its motion is said to be *reflected*.

Examples of reflected motion are very common—as, for instance, when a rolling ball encounters an opposing stone in its path, in which case it flies off obliquely in a new direction; when we throw a thin piece of slate along the surface of a river, and make it skip from point to point; or when an apple, in falling from a tree, touches a lower branch in its descent, and rebounds in a slanting direction to the ground.

It is found by experiments that moving bodies observe certain laws in respect to the line of direction they pursue in rebounding, or being reflected from any impediment with which they happen to come in contact. In the accompanying cut, the line A B is a level marble slab, C is an ivory ball, which being thrown towards the slab in the direction of C E, is reflected in the direction E D. Thus the two angles F and G are exactly equal; and it is demonstrated that a perfectly elastic ball striking a smooth wall or floor, makes the same angle in leaving the point where it strikes that it does in approaching it.

Whatever be the angle at which the ball strikes the smooth fixed surface, the same rule will be observed to be followed. This is exemplified in the next fig. If the ball be dropped perpendicularly from L to K, it will rebound and return to L. If sent in the line H K, it will rebound or be reflected to I. The angle which a ball makes with the perpendicular line in going from H to K, is called the *angle of incidence*; and the angle which it makes in rebounding from the point at K to I, is called the *angle of reflection*. These angles are always equal.



A calculation of the angles of reflected motion is necessary in the case of presenting a shield or other object to ward off a missile or blow from the person. If the angle be too acute—that is, if the blow be too point-blank—the shielding object may be damaged, or perhaps destroyed; while if the angle be obtuse, the object which gives the blow will slide off harmlessly.

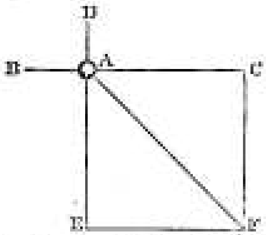
If a billiard player strike a ball perpendicularly against the cushion, it will return in the same direction. If, however, he strike the ball at an angle against the side of the table, it will rebound or fly off at an opposite angle. Suppose a ball to be placed half way up the side of an oblong table, and to receive sufficient force in such a direction as would make it strike the centre of the end of the table, the ball will fly off at an angle, and approach the side of the table opposite to that from which it was put in motion. By a knowledge of these laws, the billiard player often makes a ball fly from one corner, strike the centre of the table, and reach the corner parallel to that from which it was originally struck.

COMPOSITION OF MOTION AND FORCES.

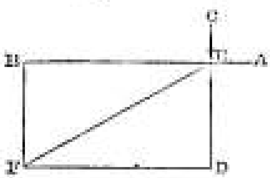
Hitherto we have spoken only of the motion of a body as produced by a single impulsive force, and turned aside or reflected by another force acting upon it; we have now to consider the subject of *compound motion* *and force*, or motion and force produced by two or more forces acting on a body in different directions at the same time.

If two or more forces act on a given point of a body, at certain angles, a single force may be found which would produce the same effect. This single force is technically called the *resultant*, or *equivalent*. For instance, a wind blowing from the north-west, and a current setting from the north-east, both acting on a ship, and tending to carry it with equal velocities in their own directions, the ship will be found to move in an intermediate direction, as if it were acted on by a single force, like a breeze, from due north.

In treating of combinations of mechanical forces, it is usual to represent them by diagrams, the various lines of which are significant of the quantity or intensity of the forces, of the directions in which they act, and of the effects produced by them. Thus, in the annexed diagram, we have an example of motion produced by two forces acting on a body from different directions. A is a ball, which, having received a blow at B, is proceeding onward to C. At the point A, while on its course, it receives a blow equal to the former, which second blow would have been alone capable of carrying it to E in the same time that the first blow would have carried it to C. This new force, by changing the direction of the original motion, causes the ball to move in a line towards F, and the effect is the same as if the ball had been at first sent in the direction of A F by a single force. Practically, it would be difficult to regulate blows with such nicety as to produce this line of motion, but in the theory of forces, the law is as it has been stated. The line A F in the figure is termed the *diagonal*.

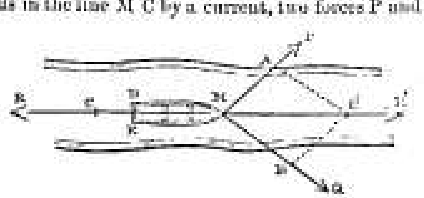


Should the constituent forces be of different magnitudes, then the figure described may be a parallelogram, or oblong, as in the following cut. The force here, in the direction A B, is double that of the cross force C D, by which means the ball describes a diagonal line to F, and so forms a parallelogram, when we draw all the lines connected with the experiment. The parallelogram thus formed is called the *parallelogram of forces*. The two given forces acting in the directions E B, E D, are called *components*, and the single force in the direction E F is the *resultant*. The process of finding a single force equivalent to two or more forces, is called the *composition of forces*.



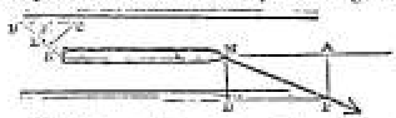
The process of finding forces which will produce a motion equal to that of a single force, is called the *resolution of forces*. The following are examples :—

If a boat D E M floating on a river be pressed downwards in the line M C by a current, two forces P and Q,



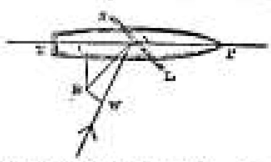
acting in the directions M P, M Q, may be found that will counteract the influence of the current, and keep the boat stationary. For make M C to represent R, the force of the current, and make M C' equal to M C, and find M A and M B as before, they will respectively represent P and Q. If two men, therefore, pull two ropes in the directions M P, M Q, with forces denoted by M A, M B, they would keep the boat at rest. If the ropes be tied to two posts at P and Q, the forces M A, M B, will represent their reactions.

Let H M be a canal boat, M P the rope by which it is drawn by a horse attached to it at P. The force of the draught being denoted by M P, it may be resolved into M A and M B, of which only M A is effective in drawing the boat forward; the other force M B tends to turn the head of the boat in the direction M B. This last force must therefore be counteracted, which is effected by means of the helm H E turned to an oblique position. When the boat is in motion, the water, being at rest, produces a resistance or pressure against the



helm. If C D denote the resistance, it may be resolved into H D and H C, of which H D produces no effect on the helm; therefore C H is the only effective pressure. Again, C H may be resolved into C F and F H, the latter of which tends to turn the stern of the boat in the direction F H, and thus counteracts the force M B, by tending to turn the boat round in an opposite direction; and the part C F tends to move the boat backwards, and thus, counteracting a part of the force M A, it retards the progress of the vessel. The two forces F H, M B, would move the boat sideways, or laterally, to the side of the canal; but this can be prevented by giving the helm a little more obliquity, for, from the length and shape of the vessel, it is much more easily moved in the direction of its length than of its breadth.

Let T P be a ship, S L its sail, W A the direction of the wind and its pressure on the sail. W A can be resolved into A B perpendicular to the sail, and B W parallel to it, the latter of which has no effect in pressing on the sail; therefore A B is the effective pressure on the sail. Were the vessel round, it would move in the direction B A. Let B A be resolved into C A and B C, the former C A acting in the direction of the keel, or length of the vessel, or in the direction C A, and the latter perpendicular to it, or in the direction of the breadth. The former pressure C A is the only pressure that moves the vessel forward, the other B C makes it move sideways. From the form of the vessel, however, this latter force B C produces comparatively little lateral motion; any that it does occasion is called *lee-way*. By turning the helm, the vessel may be made to turn round in any direction by the pressure of the water upon it, if the vessel has also at the same time progressive motion.



The suspension of a kite in the air is another illustration of the effect of the pressure of an aërial current, the explanation of which belongs to PNEUMATICS.

COMMON MOTION.

Motion, as has been stated, is called *common*, when participated in by two or more bodies. Thus all things on the earth, including the atmosphere, have a motion in common with the earth; a person riding in a chaise has a motion in common with the chaise; a person in a moving vessel at sea has a motion in common with the vessel. For convenience, we shall, in treating of this branch, use the terms larger and smaller body—the larger being understood to be the body on which the force to produce motion is immediately impressed, and the smaller that which is carried along by the body impressed.

A large body is in motion; it is moving in a certain direction, at a certain velocity; everything on it, or small body connected with it, partakes in its motion, and has a tendency to proceed in the same direction, and at the same velocity.

It appears strange that there should be a communication of motion from the larger body to the smaller, without the immediate intervention of impressed force on the smaller; but a little examination shows that such must necessarily be the case. The larger body has received the impulse to move, and this impulse is transmitted through the whole mass of the body, including all the small objects on its surface, and those which are anyway connected with it in its propulsion. When a man is walking on the deck of a ship, which is moving at the rate of ten miles an hour, he perhaps imagines that he has no more motion than if he were walking on the solid ground. But it would be incorrect for him to think so. His body, and everything about his person, have received an impulse from the vessel; he possesses a velocity of ten miles an hour as much as the planks of the vessel do; and this onward motion he cannot divest himself of, as long as the ship continues to move at this rate of speed, or as long as he continues in connection with it.

On account of this participation of motion in all bodies moving in connected masses, it is observed that all objects whatever keep their proper places in or about the large moving bodies with which they are in contact, and hence no confusion takes place in the relative situation of objects on the earth by its motion. For example, when we leap from the ground, the earth does not slip away from below us; if we ascend in a straight line of direction, we fall down exactly upon the same spot whence we rose. When a man falls from the top of a mast of a moving vessel, he falls upon the deck upon a spot directly under the point whence he fell: the vessel does not leave him. When we are sitting in the cabin of a moving vessel, and let a small object drop from our hand to the floor, it falls on a point on the floor immediately below, the same as if it had been dropped in a house on solid ground: the floor does not leave it behind. When we are sitting in a rapidly-moving coach, and in a similar manner let an object fall, it descends in the same manner to the bottom of the coach. The reason for these phenomena is that already mentioned—the small objects possess a motion derived from the larger; this common motion, or *motal inertia*, as some authors call it, is retained by the small objects during their descent, so that, while descending, they are also going forward.

One of the most beautiful examples of common motion is that which is exhibited by an equestrian standing on a horse which is running round a circle, while he at the same time throws oranges from his hand and catches them in their descent. Notwithstanding his rapid motion, the oranges which are thrown into the air do not fall behind; they return regularly to his hand. To counteract centrifugal force, he leans greatly inward; but this does not alter the law of motal inertia, which causes the oranges to return. He throws them almost sidewise in an inward slanting direction, and yet they come readily back to him. The reason for these phenomena is, that the oranges participate in the forces by which he himself is impelled and sustained.

Small bodies which have derived a motal inertia from a larger, continue to possess this motal inertia after leaving the larger, until they meet with some new impression of force sufficient to alter their condition. If they were not drawn to the earth by attraction, and were not opposed by the atmosphere, they would go on moving in a straight line for ever. When we drop a ball from the window of a moving coach, it continues to go forward, as if it were still in the coach, till it meet the ground, when it is stopped; thus its motal inertia is destroyed. If we attempt to leap from a moving body, such as a coach or a boat, we continue to possess the motion which we previously had, until we touch the earth, when we receive a shock by the destruction of our motal inertia. But if we leap from one moving body to another moving body which is going near it, on the same level, in the same direction, and at the same velocity, we sustain no shock, because the body upon which we leap possesses the same condition of motion as that which we possess.

When a man, standing on the ground, shoots at a bird on the wing, he requires to follow its motion by keeping his gun moving when presented at it; but if he be standing on the deck of a ship sailing at the rate of ten miles an hour, and point his gun at a bird flying in the same direction and at the same velocity as the ship, then he is placed in the same condition as the bird: he does not require to move his gun, as if following the bird. In taking aim at a bird on the wing from the solid ground, it requires considerable skill to prevent the shot from proceeding to a point behind the bird, because the shot is entirely destitute of motal inertia on being fired, unless it be previously put in motion. But a bullet on leaving a gun which is moving at the same rate as the bird, and in the same direction, keeps going on in the direction of the bird, because it retains the motion it had in common with the gun. The bullet in this case does not go in the direction of the gun, but obliquely, so as to keep up with the motion of the bird, so that the same effect is produced as if the shot had been fired from a fixed gun on land to a fixed point in the air in advance of the bird. Should the bullet be fired from a gun in a moving vessel, for instance a ship sailing westward to a fixed point on land, then a certain allowance must be made for the motal inertia of the bullet: it must be fired a little eastward, and the motal inertia will carry it westward to the object.

Objects falling from bodies moving in an onward direction to those which are at rest, are regulated by the same law that governs projectiles. The falling objects, as formerly mentioned, are affected by two motions—one in a horizontal, and the other in a descending direction. When these motions are unequal, the falling body describes a curve in its descent, the convex side of the curve being uppermost. Thus motal inertia, and the motion produced by projectile impulse, are the same thing; hence powerful centrifugal force in the sun, sufficient to disengage a portion of its mass, would be equivalent to a projectile impulse from it as a fixed body.

In consequence of the general participation of common motion in all things connected with a moving body, there can be no consciousness of motion in the living beings carried about by it, provided the motion be perfectly smooth, and there be no means of observing bodies which are at rest. Thus, on account of our possessing a motion in common with the earth, which moves with perfect smoothness, we can neither see nor feel the earth moving. And here we may remark, that although Astronomy assures us we are thus carried through space with the earth, as it revolves round the sun, we cannot say anything definite respecting our *absolute motion*, as we know not whether the sun is an immovable centre of the world. Everything, however, seems to imply that the sun itself is only a planet revolving around another sun, which, in its turn, is not fixed; and therefore we are as yet unable to conjecture what the centre of all motion is. Again, a person sitting in the cabin of a smooth-sailing ship, and not looking out at the windows, cannot, by his mere sensations, tell that the vessel is moving; but if he look at the shore, which he knows to be at rest, he is immediately sensible of the progressive motion of the vessel.

In looking from a moving body, as from a ship to the shore, or from a coach to objects on the wayside, a delusive feeling prevails that it is not the body we are upon, but the body which is at rest, that is really moving—going in a direction contrary to that of the body we are connected with. This is in consequence of our possession of motion in common with the moving body. We are under an influence, or in a condition, that renders us incapable of seeing our own motion; hence the error which the sense of vision leads us to commit, is left to be rectified by the understanding.

MECHANICS—MACHINERY.

THE application of the laws of motion and forces to objects in nature or contrivances in the arts, constitutes the branch of Natural Philosophy usually treated under the head MECHANICS, MECHANICAL POWERS, or ELEMENTS OF MACHINERY.

GENERAL DEFINITIONS.

The original signification of the word *machine*—which is the root of the various terms *mechanic, mechanical*, and so forth—was art, contrivance, ingenuity, or, in general, the means of bringing about an effect; hence a machine, in its widest acceptation, is an engine or instrument devised to produce an effect. When the term 'mechanics,' or 'mechanical,' is applied to the action of forces—as mechanical powers—it is meant that certain powers are exerted, or motion produced, by the action of particles or masses of matter, solid or fluid, one upon another. Thus *mechanical action* is applied to the action of forces that produce no change in the constitution of bodies, and is therefore distinguished from *chemical, vital*, or any other species of action. For example, the pounding of a piece of limestone to powder is strictly mechanical, whether it be effected by the blows of a hammer, or by the silent agency of running water; but the reduction of limestone to a similar state by sulphuric acid is chemical. In the former case, all the elements of the original limestone remain in the powder; whereas in the latter, it is converted by the action of the acid into a very different compound.

In natural philosophy, machines are usually distinguished as *simple* or *complex*. A simple machine is equivalent to a tool or instrument, as a spade or lever; a complex machine is an engine in which different parts, or various tools, combine to produce the required effect. In ordinary language, these distinctions are not very minutely attended to, though indispensable to the precision of science. *Mechanics* is the term commonly employed to comprehend the science which treats of machines, whether theoretically of their powers, or practically of their application and construction.

Machines are, under all denominations or circumstances, only instruments through which power may be made to act. They only convey, regulate, or distribute the force or power which is communicated to them from some source of motion, and never create or generate power. But although a machine does not create power, or give more power than it has received, it practically applies the power which has been communicated to it in so convenient and easy a manner, that a result ensues almost as surprising as if it had actually generated the whole or a portion of the power it exhibits.

The main purpose required in mechanical operations is to overcome, oppose, or sustain a certain resistance or force. This purpose is obtained by applying another species of force. According to the usual phraseology, the resistance or force to be overcome is termed the *weight*, and the force which is applied the *power*.

The ability of applying force by the human hands, without the aid of instruments or machines, is very limited. In almost all our operations of art, it is found necessary to call in the aid of instruments or machines of some kind. All the instruments which mankind have adopted for their use—from the piece of stick with which the savage scratches the ground as a plough, to the most elegantly-finished piece of mechanism—act upon certain fixed principles in nature, which a long course of experience and scientific investigation has developed.

The mechanical powers which exhibit the working of these principles are strictly only three in number—namely, 1, The *Lever*; 2, The *Pulley*; and 3, The *Inclined Plane*. These may be called the Primary Mechanical Powers; and from two of them, the Lever and Inclined Plane, other three are formed, as follow:—1, *Wheel* and *Axle*, from the *Lever*; 2, *Wedge*, from the *Inclined Plane*; 3, *Screw*, from the *Inclined Plane*. These may be called the Secondary Mechanical Powers. The six altogether form the most usually-occurring elements of complex machinery.

THE LEVER.

The lever is one of the most important and extensively-used of all the mechanical powers, and its operation exhibits some of the leading principles in mechanics. A lever is a rod, or bar of iron, wood, or any other material, which is movable upon or about a prop or fulcrum, or about a fixed axis. It is called a *lever*, from a French word signifying to raise, and has been applied to instruments for raising or lifting weights.

Three elements contribute to the operation of the lever—the *power*, the *fulcrum*, and the *weight*. The power is the force applied, the fulcrum is the prop or support, and the weight is the resistance or burden to be lifted. The terms *power* and *weight* have merely a reference to the manner in which the machine is used; strictly, both the power and weight are *forces* the same in character and action. The distance of the point of application of a force from the fulcrum is called the *arm* of the lever.

There are three kinds of levers, differing according to the relative situation of the power, fulcrum, and weight. Each of these consists of a straight bar, and, in theoretical calculations, is supposed to be in itself destitute of any gravity or degree of heaviness. In theory, also, the forces which are applied are supposed to act at *right angles* to the fulcrum. In the *first*, or most simple kind of lever, 'the fulcrum is disposed between the power and the weight;' in the second, 'the weight is disposed between the power and the fulcrum;' and in the third, 'the power is disposed between the weight and the fulcrum:'—

In the first kind of lever, 'the fulcrum is disposed between the power and the weight.' Fig. 1 is an example. A to B is a straight bar, resting on a prop or fulcrum F. From A to F is the long arm of the lever, and from F to B is the short arm. P is the power, or a certain force drawing down the extremity of the long arm at A. W is the weight suspended from the extremity of the short arm at B. The object is to cause P, which is supposed to be a small weight, to balance or overcome W, which is supposed to be a much heavier. Practically, the force of a man pressing upon the extremity of the handle of the lever at A, will effect with ease, in lifting the heavy weight W, what it would require a much greater force to accomplish by pressing upon the long arm at a point nearer the fulcrum.

Fig. 1.

This is more clearly exemplified in fig. 2, which represents a lever placed conveniently for raising a square block W, which is the weight. On pressing down the extremity of the long arm of the lever at A, the point of the short arm B raises the block. F is an object lying on the ground to press against as the fulcrum. As in the case of fig. 1, 'the

Fig. 2.

force of a man pressing upon the extremity of the handle at A, will effect with ease, in lifting the weight W, what it would require a much greater force to accomplish by pressing upon the long arm at a point nearer the fulcrum.'

The principle in mechanics which produces this phenomenon is very simple, and is explained by what is called the Law of Virtual Velocities, or, from its general application, the Golden Rule of Mechanics.

This fundamental law or rule is—*That a small weight, descending a long way in any given length of time, is equal in effect to a great weight descending a proportionally shorter way in the same space of time.* In other words, what is gained in velocity or time is lost in expenditure of power.

Another way of stating this important law is as follows:—*In the case of equilibrium, if a motion be given to the mechanical power, then the power multiplied by the space through which it moves in a vertical direction, will be equal to the weight multiplied by the space through which it moves in a vertical direction.*

This principle, which applies to every mechanical movement in the case of equilibrium, has been illustrated by a reference to the property of attraction of gravitation. What is called weight, is only an effect of gravity on the atoms of matter. In figurative language, every atom is drawn towards the earth by an invisible line or cord of attraction; and when one atom rises or falls ten inches, the same quantity of attraction is drawn out from, or sent back to the earth, as if ten atoms were to rise or fall only one inch.

Thus, by a proper mode of applying the power, we may cause a weight of one pound, by moving through a space of ten feet, to raise another weight of ten pounds, moving through a space of one foot; or (the reverse) by a weight of ten pounds, moving through the space of one foot, we may make a single pound move through the space of ten feet. But by none of the mechanical powers shall we be able, by moving a weight of ten pounds through one foot, to move a single pound through eleven feet; nor, by a single pound moving through a space of nine feet, shall we be able to raise a weight of ten pounds through one foot.

Neither by the power of the lever, therefore, nor by any other of the mechanical powers, can we make any absolute increase of the power which is applied. In other words, the quantity of power expended in any great and instantaneous effort, is exactly the amount of the power which has been previously accumulated. All that we can do to procure mechanical advantage, is to accommodate the velocity, force, or direction of the applied power to the purposes we have in view.

To apply this principle to the lever: in fig. 1 or 2, a small force at A is equal to double the force exerted at a point half way betwixt A and the fulcrum; yet in both cases the same amount of mechanical power is expended. A slight push downwards at A, by being continued for one minute, is equal to a push of double the force at a point half way towards the fulcrum, continued for the same time. Any amount of force, therefore, can be exerted with ease at the extremity of the long arm of the lever, provided we choose to make the arm long enough and strong enough.

It may possibly be said that it would be as expeditious to push down the extremity of the long arm of the lever, as to push down the arm at a point nearer the fulcrum. Practically, in small levers this may be the case; but when levers of considerable length have to be used, and a succession of depressions and raisings are necessary, it will be found that more time is spent in working with a long than a short lever. For when the sweep of the lever is inconveniently long, the person using it has to move his body quickly up and down over a larger space, and is sooner fatigued. For this reason, although a boy with a long lever may balance as great a weight as a man with a shorter one, yet, in raising weights successively by it, the boy would be sooner fatigued.

It is a general rule that 'the force of the lever increases in proportion as the distance of the power from the fulcrum increases, and diminishes in proportion as the distance of the weight from the fulcrum increases.' In making calculations to ascertain the proportions to be observed betwixt the power and the weight, regard must be paid to the respective lengths of the long and short arms of the lever. We must also fix what are to be the units of weight and distance, and let them be the same on both ends. If we state inches to be the unit of length of the short arm, inches must be the unit of length of the long arm; and if ounces be made the unit of weight of the short arm, ounces must be made the unit of power of the long arm.

Rule.—Multiply the weight by its distance from the fulcrum; then multiply the power by its distance from the same point; and if the products are equal, the weight and the power will balance each other.

Example 1.—Suppose a weight of 100 pounds on the short arm of a lever, at the distance of 8 inches from the fulcrum, then another weight or power of 8 pounds would be equal to this, at the distance of 100 inches from the fulcrum. Because 8 multiplied by 100 produces 800, and 100 multiplied by 8 produces 800—and thus the weight and the power would mutually counteract each other.

Example 2.—Suppose we wish to calculate what power should be employed at the end of the long arm of a lever to balance a given weight at the end of the short arm. We multiply the weight by the length of its arm: this gives us a product; then divide that product by the number of inches in the long arm, and the result or quotient is the power. Thus a weight of 10 pounds, multiplied by 10 inches, as the length of the short arm, gives a product of 100. If the length of the long arm be 20, we find how many twenties are in 100; and there being 5, consequently 5 pounds is the power. In this instance the mechanical advantage is two to one—that is, the power is twice as small as the weight.

The common spade used in delving offers a similar example of simple lever power, when employed in raising the earth from its place to turn it over. Fig. 3 represents an equally familiar example—namely, a

Fig. 3.

wood-sawyer or carpenter moving a log of timber from its place, by means of a long pole or beam of wood. Stone masons use a lever of iron of this description, called a crow-bar.

The power of the first kind of lever is frequently seen to operate in machines or instruments having two arms. The most common examples of this nature are pincers, scissors, and similar instruments. In the pair of scissors here represented, the two limbs are seen to be joined together by a rivet at the centre, which becomes the fulcrum of both.

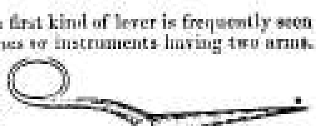


Fig. 4.

A common scale-beam for weighing, used by shopkeepers, is an example of the first kind of lever, formed with two arms of equal length, and suspended over the centre of gravity, so that the two extremities balance each other. (See fig. 5.) S is a string or line suspending the beam A B at a central point F, which is the fulcrum. The point of suspension, or pivot, is sharpened to a thin edge, so as to allow the arms to rise or fall with as little friction as possible when any weight is put in the scales.

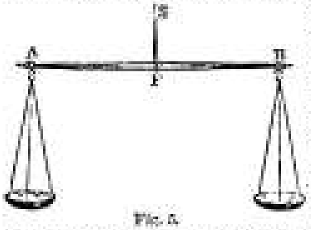

Fig. 5.

There is another kind of balance, called a *steelyard*, which consists of a lever with arms of unequal length, and acts upon the principle of distance from the fulcrum on the long arm compensating for weight on the short arm, as already defined. Fig. 6 is a representation of the steelyard balance:—C is the fulcrum or pivot by which the beam is suspended, and freely plays as on an axis. A is the short arm, and the opposite end is the long arm. W is the scale for the reception of the article to be weighed. The long arm is graduated into divisions by marks, each mark denoting by a figure a certain number of pounds or ounces. P is a weight of a certain heaviness, and being movable

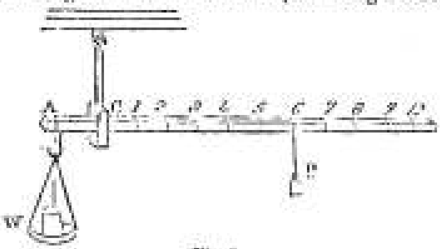

Fig. 6.

by a ring, it can be slipped along the bar to any required point. The same weight is always used, and thus constitutes one of the principal conveniences of this kind of balance. In proportion as the article to be weighed in the scale W is heavy, so is the weight P slipped along to a greater distance from the fulcrum; and when it is brought to a point where it balances the article, the figure on the bar at that point indicates the amount of the weight. If P be one pound, and if, when suspended from the division at 6, it balance the weight at W, it is evident that the weight will be six times P, or 6 pounds. And so on with all the other divisions.

The steelyard, though not so ancient as the common balance, is of considerable antiquity. It was used by the Romans, and has long been in use among the Chinese. Neither the common balance nor the steelyard is suitable for showing the varying weight or heaviness of an article at different latitudes of the earth's surface, because the weights employed are equally affected with the attraction of gravitation and centrifugal force, as the article to be weighed. For this reason, the difference of weight resulting from the causes mentioned, can only be demonstrated by a balance formed of a spring of elastic metal. By suspending the article from the spring, it pulls it out to a certain extent, and so indicates the weight on a graduated scale on the instrument. As the spring acts the same in all latitudes, it serves as a fixed or unalterable power, while the article to be weighed is liable to an alteration in its weight or heaviness according as it is brought near, or carried from, the equator. [See Laws of Matter.]

In the lever of the second kind, the weight is placed between the power and the fulcrum, as in fig. 7. The line from A to F is the long arm, B to F is the short arm. W is the weight, and P is the power. The object required by this lever is to lift the weight W by raising

Fig. 7.

the extremity of the lever at A. In this, as in the case of the first kind of lever, the power is increased in proportion to its distance from the fulcrum.

Examples of this kind of lever-power are common. One of the most familiar is that of a man pushing or lifting forward a bale of goods, as represented in fig. 8, in which the bale or weight W presses against the lever between the power P and the fulcrum F.

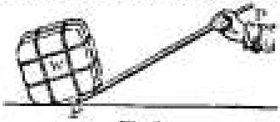

Fig. 8.

Another example of this lever is that of a man using a wheelbarrow, as represented in fig. 9. A point in the wheel of the barrow, where it presses on the ground, is the fulcrum. The body of the barrow, with its load, is the weight. And the two handles, lifted or held up by the man, form the power. In proportion as the man shortens or lengthens the handles in holding them, so does he increase or diminish the weight he has to sustain; increasing, however, by another law, the difficulty of pushing forward the barrow, according to the weight on the fulcrum.

Fig. 9.

Two men carrying a load between them on a pole is also an example of the second kind of lever. The load may either rest upon, or be dependent from, the pole. In the case of two porters carrying a sedan chair by means of two poles, the load or weight is partly above and partly below the line of the lever. In the case of porters carrying a barrel slung from a pole, as in fig. 10, the weight is altogether below the lever. In both instances the principle is the same. Each man acts as the power in moving the weight, and at the same time each man becomes a fulcrum in respect to the other. If the weight hang fairly from the centre of the pole, each man will bear just a half of the burden; but if the weight be slipped along to be nearer one end of the lever than the other, then the man who bears the shorter end of the pole supports a greater load than the man who is at the long end. The weight increases precisely in proportion as it advances towards him. Sometimes, when a man and a boy are carrying a hand-barrow between them, the man, in order to ease the weight as much as possible to the boy, holds by the arms of the barrow near to where they join the loaded part. In yoking horses to the extremities of cross bars in ploughs, coaches, or other vehicles, care should be taken to hook the cross bar to the load at its centre, otherwise one horse will have to pull more than the other.

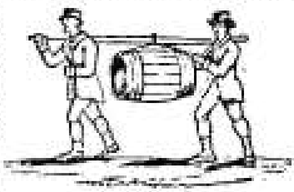

Fig. 10.

An inflexible beam, resting on supports or fulcra at its two extremities, acts similarly as a lever of the second kind. Should no weight be appended to its centre, the weight of the material itself, when the extension is considerable, will be enough to bend it down, and even to break it. Extended flexible cords or chains are from this cause always bent down in the middle, no power of extension being able to overcome the gravity of the materials, which will give way before they can be rendered perfectly straight. The bent string of a boy's paper kite is an example of this powerful influence of gravity of materials.

The instrument used for cracking nuts (fig. 11) is an example of the second kind of lever with two arms or limbs. The fulcrum is the joint which connects the two limbs; the nut between them is the weight or resistance; and the hand which presses the limbs together, in order to break the nut, is the power. As each limb is a lever, a double lever action takes place in the operation. The oar of a boat in rowing is also a lever of this kind. The hands of the sailor who pulls constitute the power; the boat is the weight to be moved; and the water against which the blade of the oar pushes, the fulcrum.

Fig. 11.

The second kind of lever is sometimes employed as an instrument of pressure. The point of the short arm is, for example, pushed into a crevice or hole in a wall, the fulcrum is the object to be pressed, and at the extremity of the long arm a heavy weight is applied. In this rude but efficacious manner are cheeses pressed in some parts of the country.

In the lever of the third kind, the power is placed between the weight and the fulcrum (fig. 12). The fulcrum is at the extremity of the short arm at F; the weight W is dependent from the extremity of the long arm at A; and P is the power. In this lever, the power acts with considerable disadvantage, or with small effort; but this disadvantage is compensated by an opposite advantage, which is frequently of great importance in the operations of both nature and art. The advantage consists in the velocity with which a small power will cause the extreme point of the long arm of the lever to move over a great space. This lever, therefore, whether in nature or art, is used only when a great space has to be traversed quickly by the long arm; but in this case the power must always be greater than the weight.

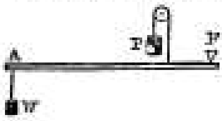

Fig. 12.

An example of this kind of lever is found in the foot-board of the turning-lathe (fig. 13). The foot of the workman presses lightly on the board or plank near the end which rests on the ground, or fulcrum, and causes the opposite extremity of the board to move in a downward direction over a considerable space. A spring overhead, or a crank, pulls the board up again by means of a string S; the workman again presses it downward, and so a constant action of the string or cord which works the lathe is easily produced.

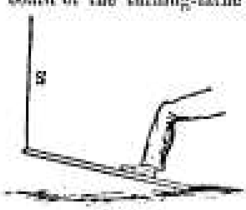

Fig. 13.

A man wielding a flail with two hands, and similar instances of using weapons, are also examples of the third kind of lever action. A similar action is observable when we use fire-tongs; a small motion of the fingers near the joint of the instrument causes the legs, which are two levers, to open or shut over a considerable space.

Before the peculiar advantages of this species of lever became known, or were appreciated, it was called the *losing lever*.

The movements in the limbs of animals are generally produced by the action of this kind of power.

Compound Levers.

When several levers of the simple kinds are connected together, and are made to operate one upon the other, the machine so formed is called a *compound lever*. In this machine, as each lever acts with a power equal to the pressure on it of the next lever between it and the power, the force is increased or diminished, according to the number or kind of levers employed. Fig. 14 represents a compound lever, consisting of three simple levers of the first kind, placed in a line, and each working on its own fulcrum. The desired object of the machine is for a small force or power at P to move or balance a large weight at W. The same rule applies, in calculating the action of this combined lever, which has already been given for the simple lever—namely, 'Multiply the weight on any lever by its distance from the fulcrum; then multiply the power

Fig. 14.

by its distance from the same point; and if the products are equal, the weight and the power will balance each other.' Or, for the form of lever in the figure, 'Multiply the length of the long arm by the moving power, and multiply that of the short one by the weight or resistance.'

It is supposed that the three levers in the figure are of the same length, the long arms being six inches each, and the short ones two inches each; required—the weight which a moving power of 1 pound at P will balance at W. In the first place, 1 pound at P would balance 3 pounds at E; we say 3, because the long arm being 6 inches, and the power 1 pound, 6 multiplied by 1 is 6; and the short one being 2 inches, we find that there are 3 twos in 6, therefore 3 is the weight. The long arm of the second lever being also 6 inches, and moved with a power of 3 pounds, multiply the 3 by 6, which gives 18; and multiply the short arm, being 2 inches, by a number which will give 18; we find that 9 will do so (9 twos are 18); therefore 9 is the weight borne at the extremity of the short arm of the second lever at D. The long arm of the third lever being also 6 inches, and moved with a power of 9 pounds, multiply the 9 by 6, and we have 54; and multiply the short arm, being 2 inches, by a number which will give 54; we find that 27 will do so (twice 27 is 54); therefore 27 is the weight borne at the extremity of the short arm of the third lever. Thus 1 pound at P will balance 27 pounds at W; or 1 ounce at P will balance 27 ounces at W—the proportions being always alike, whatever denomination of weight we employ.

In this instance, the increase of power is comparatively small, because the proportion between the long and short arms is only as 2 to 6, or 1 to 3. If we make the proportions more dissimilar, as 1 to 10, or 1 to 20, the increase of force becomes very great. For example, let the long arms be 18 inches each, and the short ones 1 inch each, and 1 pound at P will balance 18 pounds at A, and the second lever would be pushed up with a power of 18 pounds. This 18 being multiplied by the length of the lever 18, gives 324 pounds as the power which would press down the third lever. Lastly, multiply this 324 by the length of the lever 18, and the product is 5832 pounds, which would be the final weight at W which 1 pound at P would raise.

The following is a general rule for calculating the advantages of a compound lever consisting of any number of levers, whether equal or not:—Call the arms of the different levers next the power the *arms of power*, and the other arms the *arms of weight*; then, if the lengths of the arms of power and the power itself be multiplied together, the product will be equal to the continued product of the arms of weight and the weight, when the power and weight are in equilibrium.

A similar result to that of a combination of levers might be produced by only one lever, provided it were long enough; but the operation would be both clumsy and inconvenient. By combining levers, and making them act one upon another, great weights may be balanced within a small compass, and with an exceedingly small power. On this account, machines are constructed with combinations of levers for weighing loaded carts and other heavy burdens. The cart is wheeled upon a sort of table placed level with the ground, beneath which the levers are arranged; and a small weight placed on a scale attached to the extreme point of the first lever balances the load, which rests on the table above the last lever. This species of weighing-machine is often to be seen at toll-bars.

Bent Levers.

In the foregoing examples of lever powers, the levers or bars are supposed to be straight, and the powers and weights, or forces, are supposed to act at right angles with them. Levers, however, are frequently *bent* in their form, for purposes of convenience, and the powers and weights often act *obliquely*, or not at right angles.

In calculating the mechanical advantage of bent levers, the chief matter for consideration is *obliquity* in the direction of the applied power and weight. Obliquity in the action of the forces generally diminishes the mechanical advantage. Whatever be the form of the lever, or the direction of the power and the weight, the mechanical advantage of the power or the weight is always represented by *a line drawn from the fulcrum, at right angles to the direction in which the forces are respectively exerted.*

Fig. 15 is a bent lever, with the power P hanging from A, and the weight W hanging from B. In this case, both the power and the weight act at right angles to an ideal line, drawn as from E to G across the fulcrum, which strikes the lines of direction of the forces at right angles.

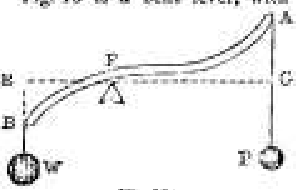

Fig. 15.

The adjoining fig. (16), representing a pronged hammer in the act of being employed to extract a nail, is another example of a bent lever. The hand of the workman is the power exerted on the long arm of the lever; the head of the hammer, where it presses on the flat surface beneath it, is the fulcrum; the prongs are the short arm of the lever, and the resistance of the nail is the weight.

Fig. 16.

THE WHEEL AND AXLE.

A lever has been defined to be 'a rod or bar of iron, wood, or any other material which is movable upon or about a prop or fulcrum, or about a fixed axis.' The illustrations which have been given show the lever only in its character of a simple bar, which is movable in some part 'upon or about a prop or fulcrum.' It is now to be shown how it acts when movable upon or about a fixed axis. When a lever is movable upon an axis, and is susceptible of being turned completely round, it assumes the character of the diameter of a wheel. In fig. 17, the simple rudiments of a wheel are represented. A and B are the two arms of a bar or lever playing upon a fixed axis at F, and which axis is the fulcrum. If we push down A, we raise B, or if we push down B, we raise A. In this manner the situation of the power and the weight is transferable from one end to the other, as in the beam of a common balance, without altering the equilibrium.

Fig. 17.

Fig. 18 is a representation of a wheel in a state more advanced to completion. Here the arms A B are connected with the arms D C, both at the centre F, and by means of the circumference or rim of the wheel. By reason of this union of parts, the central axis at F becomes the common fulcrum for every portion of the wheel; therefore, from the centre to any point of the circumference is an arm of a lever, although the line of that lever be not marked or seen, as in the case of a distinct spoke. Besides wheels with axes in the centre, there are others with axes not in the centre, called eccentric wheels. At present, however, we are treating only of those having their axes in the centre.

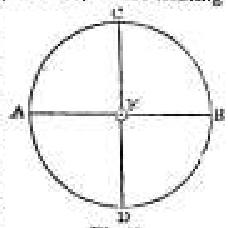

Fig. 18.

Wheels with a central axis may be rendered available as levers in various ways, according to the placing of the weight or resistance. The plan commonly pursued consists in giving to the wheel an axle, which is fixed to its arms, and placing a weight near the axle or fulcrum, to work against another weight at the circumference. Thus a machine is formed called the Wheel and Axle, which constitutes one of the simple mechanical powers founded on the lever.

The machine termed the Wheel and Axle consists of a wheel fixed upon an axle or spindle, which axle turns horizontally on its two ends in upright supports. See fig. 19. The fulcrum of the machine is common to both the wheel and the axle, and is the centre of the axle. A is the wheel, B is the axle, and H is a handle with which the machine may be turned. By turning the wheel, the axle is also turned, and a rope being fixed to the axle, with the weight W hanging at its extremity, the turning of the wheel causes the axle to wind up the rope, and so lift the weight. If, instead of turning the wheel with the hand, we wind a rope round the circumference of the wheel, in a contrary direction from that in which the axle-rope is wound, and also hang a weight of a certain heaviness, P, to its extremity, then the draught, or pulling of the wheel-rope in unwinding, will turn the axle, and so wind up the axle-rope with its weight. In this manner one power works against another, exactly as in the case of the lever. By properly apportioning the two powers in correspondence with the diameters of the wheel and the axle, the one power or weight may be made to balance the other power or weight, so as to produce an equilibrium of the machine.

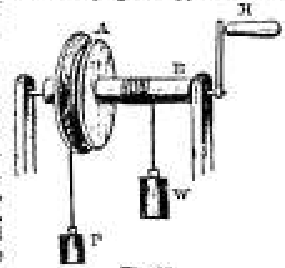

Fig. 19.

The wheel and axle form what is called a *perpetual lever*. Common simple levers act only for a short space, or by reiterated efforts, so as to be adapted for lifting an object from one place to another on the ground. The perpetual lever, formed by the wheel and axle, turns round without intermission, and is therefore suitable for lifting weights attached to a rope through any space upward from the ground without stopping.

Fig. 20 is a representation of the machine endwise, and shows how the lever operates. The line going across the machine from A to B represents the line of the lever. A is the situation of the power, F is the centre or fulcrum, and B is the situation of the weight; therefore from A to F is the long arm, and from F to B is the short arm of the lever. In other words, the long arm is half the diameter of the wheel, and the short arm is half the thickness or diameter of the axle. By widening the wheel, and so lengthening the long arm of the lever, the smaller will be the power necessary to overcome the weight on the axle or short arm; but what is gained by this mechanical advantage, is lost by the circumstance, that the power must descend

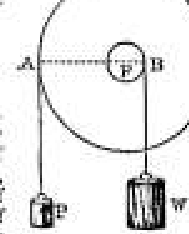

Fig. 20.

through a proportionally greater space, in order to raise the same weight through the same space in the same time.

To find what forces will balance each other, let the same rules be followed as those formerly given for the simple lever. Multiply the weight by its distance from the fulcrum (that distance is half the diameter of the axle), then multiply the power by its distance from the same point (that is, half the diameter of the wheel), and if the products be equal, the weight and the power will balance each other. Thus a power of one pound at or depending from the circumference of a wheel of twelve inches in diameter, will balance a weight of twelve pounds at or depending from the circumference of an axle one inch in diameter.

Note.—No allowance is made in these calculations for the overlaying of the rope in winding, which affects the length of both the long and short arm; but this is a matter of practical, not of theoretic import.

The principle of the wheel and axle, or perpetual lever, is introduced into various mechanical contrivances which are of great use in many of the ordinary occupations of life. One of the simplest machines constructed on this principle is the common windlass for drawing water by a rope and bucket from wells. Coal is lifted from the pits in which it is dug by a similar contrivance, wrought by horse or steam power.

The capstan in general use on board of ships for hauling or drawing up anchors, and for other operations, is an example of the wheel and axle constructed in an upright or vertical, instead of a horizontal position. In fig. 21, one of these capstans is represented. The axle is placed upright, with the rope winding about it, and having a head pierced with holes for spokes or levers, which the men push against to cause the axle to turn. This is a powerful and convenient machine on shipboard: when not in use, the spokes are taken out and laid aside.

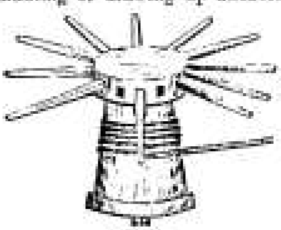

Fig. 21.

The common crane affords an excellent illustration of the wheel and axle in a combined form.

PULLEYS.

The pulley and cord is one of the primary mechanical powers. A pulley is a wheel, with a groove in its circumference, and is suspended by a central axis. In fixed pulleys, a flexible cord, which is made to pass over and hang from the upper part of the groove, has at one extremity a certain weight to be raised, and at the other extremity a power is attached for the purpose of pulling. There are two kinds of pulleys—the *fixed* and *movable*.

The annexed cut, fig. 22, represents a fixed pulley. A is the wheel, B is a beam or roof from which the wheel is suspended. P is the power hanging at one end of the rope, and W is the weight at the other end. This kind of pulley is called a fixed pulley, because it does not shift from its position. It possesses no mechanical advantage. The wheel is merely a lever with equal arms, and therefore the cord which passes over these arms gains no advantage. To raise a pound weight from the ground at the one end of the cord, the power of one pound must be exerted at the other. The object of the single fixed pulley is not to save power, but to give convenience in pulling. For instance, by pulling downwards, a weight may be raised upwards; or by pulling in one direction, a load may be made to proceed in another. The same object might be gained by drawing a cord over a fixed post or pivot, but in this case the friction of the cord would chafe or injure it; the wheel or pulley is therefore a simple contrivance to prevent friction, for it turns round along with the cord.

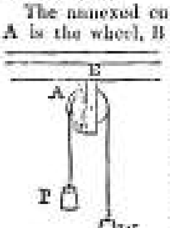

Fig. 22.

The movable pulley is in form the same as the fixed pulley, but instead of being placed in a fixed position from a beam or roof, it hangs in the cord which passes under it, and from it the weight is suspended. In fig. 23, a movable pulley is represented. A is a hook in a beam to which one end of a cord is fixed. B is the movable pulley, under which the cord passes, and proceeds upwards to C, a fixed pulley, from which it depends to P, the power or the hand pulling. The fixed pulley C is of no further use than to change the direction of the power. W is the weight hanging from B. The movable pulley possesses a mechanical advantage. The first point to be observed is, that the weight hangs in the cord; second, that the weight presses down each side of the cord equally—that is, it draws as hard at A as at C or P; third, that the consequence of this equal pressure is the halving of the weight between the two ends of the cord. The *halving of the weight* is therefore the mechanical advantage given by the movable pulley.

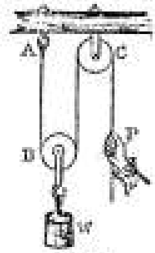

Fig. 23.

Example.—If the weight W be ten pounds, five pounds is borne by A, and five pounds by P. The case is precisely the same as that of two boys carrying a basket between them. The basket is the weight, and each boy, with his hand upholding the handle, bears only half the load, whatever it may be. If, instead of holding by the handle, the boys slip a cord beneath it, and each take an end of the cord, the case is the same.

In order to save expenditure of power in lifting weights by pulleys, it is always contrived to cause some inanimate object, as, for instance, a beam or roof, to take a share of the weight, leaving only a portion to be borne by the person who pulls. But in this, as in all cases of mechanical advantage, the saving of power is effected only by a certain loss of time, or a longer continuation of labour. To lift a weight one foot from the ground by the movable pulley, a man must pull up the cord two feet; therefore, to lift a weight, it will take double the exertion to draw it up a given height in a given time without the pulley, that it would require with the intervention of the pulley.

As the power which a man can exert by his hands is able to overcome a weight greater than the weight of his own person, this circumstance may be taken advantage of in a very peculiar manner, through the agency of the fixed pulley. As represented in fig. 24, a man may seat himself in a loop or seat attached to one end of a cord, and passing the cord over a fixed pulley above, may pull himself upwards by drawing at the other end of the cord. By adding a movable pulley and another fixed pulley to the apparatus, the exertion of pulling would be diminished one half. An apparatus of this nature, having two fixed pulleys and one movable pulley, is used by masons and other artisans in making repairs on the fronts of buildings.

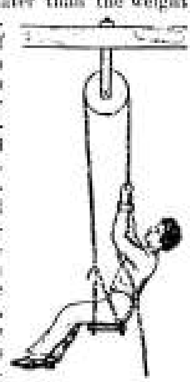

Fig. 24.

The principle upon which pulleys act is the distribution of weight throughout the different portions of the cord, so as to lessen the power necessary to be exerted by the operator. And along with this principle is the changing of the direction of the power for the sake of convenience in pulling.

According to ordinary language, the mechanical power of which we are treating is called the power of the pulley; but, in reality, as has been just shown, the pulley has no power in itself. The power of the machine is in the cord. *It is in the equal tension of the cord through its whole length, by which the weight is distributed upon intervening points, that the machine offers any mechanical advantage.*

In all cases in which cords are drawn tightly, so as to hold objects in close contact, the same species of power or mechanical advantage is exemplified. For instance, in drawing a cord in lacing, or a thread in sewing, this distribution of power is observable. If all the power which is distributed throughout the sewing of a single pair of strong shoes were released and concentrated in one main draught, it would in all likelihood be a power sufficient to lift one or two tons in weight.

Technically, the wheel of a pulley is called a *sheave;* for protection and convenience, this sheave is ordinarily fixed with pivots in a mass of wood called a *block;* and the ropes or cords are called a *tackle*. The whole machine, fully mounted for working, is termed a *block and tackle*. By causing a wheel and axle to wind up the cord of a block and tackle, the power of the lever is combined with that of the pulley in the operation.

There is no assignable limit to the power which may be exerted by means of pulleys. The machine may be constructed to raise with ease any weight which the strength of materials will bear, provided the combination is not so complex as to exhaust the power by the friction produced.

The power of pulleys is increased by a combination of wheels or sheaves in one tackle. There are different kinds of combinations or systems of pulleys. In some there is only one fixed pulley, and in others there are several. The following are examples of different combinations of pulleys:—

Fig. 25 represents a compound system of pulleys, by which the weight is distributed through four folds of the same cord, so as to leave only a fourth of the weight, whatever it may be, to be raised by the operator. In this illustration, the cord number 1 bears one fourth of the weight; the cord number 2 bears a second fourth; the cord number 3 bears a third fourth; and the cord number 4 bears a fourth fourth. Here the mechanical advantage ceases. For although the cord number 4 passes over the topmost fixed pulley down to the hand of the operator, no more distribution of power takes place; this topmost pulley being of use only to change the direction of the power. The person who pulls has thus only a quarter of the weight to draw. If the weight be one hundred pounds, he has the labour of pulling only twenty-five pounds.

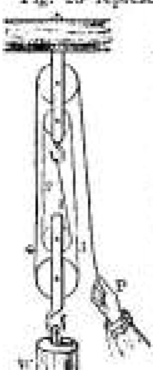

Fig. 25.

Thus it is observable that the diminution of weight is in proportion to the number of movable pulleys. To calculate the expenditure of power or diminution of weight, therefore, we have only to multiply the number of movable pulleys by two, and the product shows the power to be exerted. Two movable pulleys multiplied by two, gives 4; therefore a fourth of the weight is the power required; and so on. The addition of a single movable pulley to any system of pulleys, at once lessens the apparent weight one-half, or, in other words, doubles the effect of the power; but every such addition causes more time to be spent in the operation, there being at every additional fold of the cord more cord to draw out, and also more friction to overcome.

In the annexed system of pulleys (fig. 26), a series of movable pulleys, with different cords, are made to act successively on one another, and the effect is doubled by each pulley. At the extremity of the first cord, a power of one pound depends. This cord, marked 1, by being drawn below a movable pulley, supports two pounds—that is, 1 pound on each side. The next cord, marked 2, in the same manner supports four pounds, or 2 pounds on each side. The next cord, marked 4, supports eight pounds, or 4 pounds on each side. Thus 1 pound at P supports 8 pounds at W. If another movable pulley were added, the 1 pound at P would support 16 pounds; and so on.

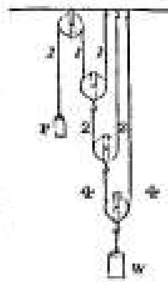

Fig. 26.

In working pulleys, the power must be applied in a line perpendicular to, or parallel with, the weight—that is, straight above the weight—in order to produce the full efficacy of direct force. If the power be applied obliquely—do not draw fair up—there will be a loss of power in proportion as the line of draught departs from the perpendicular.

Pulleys are used chiefly on board of ships, where blocks and tackle are in constant requisition for raising and lowering the sails, masts, and yards. They are likewise in considerable use by house-builders and others, in connection with the wheel and axle, for raising or lowering heavy masses of stone and other articles.

Fig. 27 is a representation of a system of pulleys commonly used in practical operations. Three movable pulleys are enclosed in the block A, and three fixed pulleys are enclosed in the block B. Suppose, therefore, that the weight W, in this case, is six hundred pounds, the hand P pulls it upwards by exerting a force of one hundred pounds. A combination of pulleys resembling this is used in turning kitchen jacks. The weight in sinking draws off the cord from a spindle, by which motion the jack is turned. In order that a considerable weight falling slowly through a comparatively small height may keep the jack in motion for a long time, as many as ten or twelve movable and fixed pulleys are used.

Fig. 27.

THE INCLINED PLANE.

A horizontal plane is a plane coinciding with that of the horizon, or parallel to it; when the plane is not level or horizontal, but lies in a sloping direction, with one end higher than the other, it is said to incline, or is called an *inclined plane*. In fig. 28, A B is the *horizontal*, and A C the *inclined* plane.

Fig. 28.

The inclined plane, as already stated, is a primary mechanical power. The object which is accomplished by it is the raising of weights to considerable elevations, or the overcoming of resistances by the application of lesser weights and resistances; or, making a small power overcome a greater.

To raise a load of a hundred pounds to an elevation of fifty feet by a direct perpendicular ascent, and without using any mechanical advantage, the power exerted must be a hundred pounds, or equal to the weight to be overcome. If, instead of raising the load directly upwards, we raise it by the gradual ascent of an inclined plane, the power required is less than a hundred pounds, and the diminution is in proportion to the smallness of rise in the inclined plane. But this saving of power, as in all other instances of mechanical advantage, is accomplished only by a corresponding loss of time.

In drawing a load, as, for instance, a loaded carriage, along a horizontal plane, the resistance to be overcome is chiefly the friction of the load upon the plane. If there were no friction or impediment from inequalities of surface, and if the load were once put in motion, it would go on moving with the smallest possible expenditure of power.

In drawing a load up an inclined plane, ordinary friction has to be overcome, and also the gravity of the body, which gravity gives it a tendency to roll down to the lowest level. In this constant impulse to descend, it is not at liberty to pursue the same line of descent as bodies falling freely from heights. It falls or rolls down as much less speedily than a free falling body (omitting the loss by friction), as the length of the inclined plane is greater than its height. A freely descending body falls about 16 feet in the first second; and a body rolling down an inclined plane, rolls just as many feet the first second as the number of feet of inclination is in sixteen feet. If the inclination be one foot in sixteen, the body rolls down one foot; and so on.

Any body, in being drawn up an inclined plane by a power parallel with the plane, presses at right angles with the plane. The common expression is, that the reaction of the plane upon the object is perpendicular to the plane. When an object, as a ball, rests upon a horizontal plane, its pressure is at right angles with the plane; or, what is the same thing, the reaction or resistance of the plane is at right angles with it. This is seen in fig. 29, in which a ball is represented lying on a level plane, with the line of pressure A passing down to B, which line is at right angles with the plane. Suppose, then, that the end of the plane at C is elevated to D, as in fig. 30, so as to form a slope; in this case the line of pressure of the ball on the plane is also moved, so as still to be at right angles with the inclination.

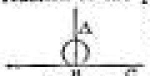

Fig. 29.

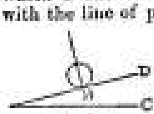

Fig. 30.

The power which is required to be sustained for the purpose of overcoming friction or inequalities of surface on level planes, is for the purpose of drawing the load up or over the inequalities.

The amount of power corresponding to different weights and inclinations of the plane has been correctly ascertained; hence the following rules:—

First.—The quantity of weight is great in proportion to the inclination of the plane; consequently, so is the difficulty of raising greater, and the rate of elevation or motion slower.

Second.—To overcome the weight or resistance, and the slowness of movement, a corresponding increase of power must be given.

Third.—The smaller the inclination, so is the pressure of the weight on the plane the greater.

Fourth, or Special Rule of Calculation.—Whatever is the unit of inclination in a given length, the same is the unit of weight that can be lifted, and the unit of power to be exerted.

If the inclination of a road be one foot in ten, *one-tenth* is called the unit of inclination; hence, *one-tenth* part of the nominal weight of the load has to be lifted; and a power to draw this one-tenth part of the load has to be exerted. Or, to put the case in other words:—If the road rise one foot in ten, there is in the ten only one foot of perpendicular height to be lifted through; and the weight at any point of the ten feet is only a tenth of what it would be if it were to be lifted through a perfect perpendicular ascent of ten feet.

The reason is now perceived why a small power overcomes a greater in the case of draughts upon inclined planes. The load is, as it were, lifted by instalments. Partly supported as it advances, and always supported more completely the smaller the inclination, the weight of the burden is apparently lessened by merely taking the rise gradually and slowly. If we suppose a case of two roads, the first rising one foot in twenty, and the second rising one foot in fifty, a loaded carriage will be found to go over the fifty feet of the one with precisely the same expenditure of power that would be required to make it go over the twenty feet of the other—that is, always providing that friction and other circumstances are alike.

Fig. 31 represents a supposed case of two inclined planes of the same height, but different slopes, meeting together at the top, with a weight resting on each, P and Q, hanging by a string, which passes over the pulley M. If the length of the longest plane from A to M be two feet, and that of the shorter from B to M be one foot, then two pounds at Q, on the short side, will balance four pounds at P, on the long side; and so on in this proportion, whether the planes be longer or shorter. In this manner, weights moving on two adjoining inclined planes may be adjusted so as to balance each other, although the inclinations be different; and they are so made to act on various sloping railways connected with public works, where one wagon descending on one plane is made to draw up another wagon on another plane.

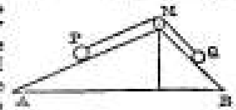

Fig. 31.

An inattention on the part of our forefathers to these exceedingly simple principles of mechanical science, led them to form roads over steep hills, pursuing, as it was imagined, the best routes, because they were the straightest in a forward direction. In modern times, this error has been avoided by enlightened engineers, and roads are now constructed with as few risings and fallings as possible. When roads have necessarily to be carried to the summits of heights, they are very properly made either to wind round the ascent, or to describe a zig-zag line of direction. The drivers of carts are aware of the saving of labour to their horses by causing them to wind or zig-zag up steep roads instead of leading them directly forward.

The inclined plane is resorted to for a saving of labour in many of the ordinary occupations of life. By it loaded wheelbarrows are with comparative ease wheeled to considerable elevations in house building and other works of art; hogsheads are rolled out of or into wagons, and ships are launched into or drawn from the water, the inclined plane being as useful in giving facilities for letting down loads as in drawing them up. It is also by inclined planes that we reach the higher floors of a house from the ground, or attain other elevations. For all such purposes, the inclined plane is formed with steps to insure our safe footing. All stairs or flights of steps are inclined planes. A ladder forms a steep inclined plane.

THE WEDGE.

The inclined plane has been described as being fixed or stationary—as, for instance, a common ascending road, or a sloping plank, upon which the weights are moved. It has now to be viewed as a *movable plane*, in which form it suits many useful purposes.

When an inclined plane is movable, and the load or weight which it affects is at rest, it is called a *wedge*. The wedge is therefore a mechanical power, founded on the principle of the inclined plane.

The wedge is an instrument or simple machine, consisting of a solid body of wood, iron, or some other hard material, and is triangular in form. (See fig. 32). Here the wedge is seen to taper from a thick end or head at B to a thin edge or point at A. This, however, is only the more common form of the wedge. It is made with sides of various angularities or degrees of slope; and in some cases it possesses a flat and a sloping side. When it slopes on both sides, it consists of two inclined planes joined together; and when one of its sides is flat, it acts as only one inclined plane. The wedge is employed as an instrument for cleaving solid masses asunder, to compress bodies more closely together, and to move great weights through small spaces. Fig. 33 is a front view of a wedge in the act of splitting asunder a piece of timber. The power employed to

Fig. 32.

force the wedge forward, is either repeated blows with a mallet or hammer, or the gradual pressure of a weight. In general, the power is applied by rapid strokes, or quick applications of some kind of external pressure.

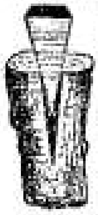

Fig. 33.

The rules for calculating the power of the wedge are similar to those for the inclined plane. In proportion as the inclination or angularity is great, so is the resistance greater, and the power must be greater to overcome it. Thus, if the wedge be of short dimensions, and thick at its head, it will require a greater power to move it than if it be long, and thin in its form. The resistance offered to the wedge of equal sides, when the pressure is equally applied, is, as in the case of the inclined plane, at right angles with the sides. See fig. 34, in which the oblique cross lines represent the direction of the pressure passing at right angles through the sides, and meeting at the centre.

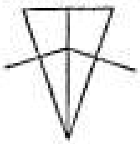

Fig. 34.

It is difficult to calculate the precise power of the wedge, for much depends on the force or the number of blows which may be given to it, together with the obliquity of the sides, and the power of resistance in the object to be split. In the splitting of timber, for instance, the divided parts act as levers, and assist in opening a passage for the wedge.

The wedge is the least used of the simple machines, but the principle upon which it acts is in extensive application. Needles, awls, bodkins, and driving nails are the most common examples. Knives, swords, razors, the axe, chisel, and other cutting instruments, also act on the principle of the wedge; so likewise does the saw, the teeth of which are small wedges, and act by being drawn along while pressed against the object operated upon.

The principle of the inclined plane, which is the basis of that of the wedge, is particularly observable in the action of the razor and the scythe, both of which cut best by being drawn along the materials against which they are applied. When the edge of a scythe or razor is examined with a microscope, it is seen to be a series of small sharp angularities of the nature of the teeth of a saw.

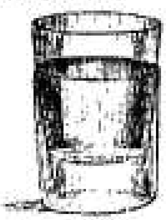

Fig. 35.

The principle of the wedge operates in the case of two glass tumblers, one placed within the other, as in fig. 35. A very gentle pressure applied to the uppermost tumbler would be sufficient to burst the lower. At every little advance of the uppermost tumbler, it acts more and more as a lever power on the rim of the lower, and at last overcomes the resistance, and fractures the vessel.

THE SCREW.

The screw is the fifth, and usually the last mentioned mechanical power. Like the wedge, it is founded on the principle of the inclined plane.

The screw consists of a projecting ridge winding in the form of an inclined plane, and in a spiral direction, round a central cylinder or spindle, similar to a spiral road winding round a precipitous mountain. Fig. 36 is a representation of a common strong screw used in various mechanical operations. The projecting ridge on the spindle is technically called the *thread*. The thread is not always made in this square projecting form; it is frequently sharpened to a single thin edge, as in fig. 39, but this does not affect the principle of the machine.

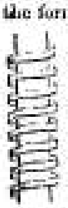

Fig. 36.

One circumvolution or turn of a thread of a screw is, in scientific language, termed a *helix* (plural *helices*), from a Greek word signifying winding or wreathing. The spiral winding of the thread is called the *helical line*.

The helices of a screw do not necessarily require to have a central spindle. They may form a screw of themselves, and do so in the case of the common cork-screw (fig. 37). A screw of this pointed or tapering form, in penetrating a substance, possesses the advantage of the inclined plane in three ways—first, by the gradual thickening of the substance of the thread from a sharp point; second, the gradual widening; and third, the gradual ascending of the thread.

Fig. 37.

The screw acts on the principle of the inclined plane, and this is obvious from the consideration of the nature of the threads. If we were to cut through the turns of the threads straight from top to bottom, and draw them out to their full extent, each separate and retaining its own inclination, we should find that they were so many inclined planes. In the annexed cut, fig. 38, one entire turn of the thread is thus drawn out, reaching from *b* to *a*, and is seen to form an inclined plane. If not drawn out, it would wind down to *c*; therefore, while a weight is raised by one turn of the screw over the limits of one thread, or from *c* to *b*, it has actually been carried up the inclined plane from *a* to *b*.

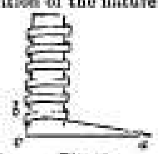

Fig. 38.

The screw has no power by itself. It can operate only by means of pressure against the threads of another screw which overlaps it and holds it. This exterior screw, which is technically called a *box* or a *nut*, consists of a block with a central tube cut out in spiral grooves so as to fit with perfect exactness to the screw which has to work in it. Fig. 39 represents both screws in combination. M is the box or nut through which the screw passes; L is a lever inserted into the head of the screw, for the purpose of turning it.

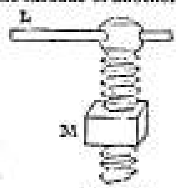

Fig. 39.

The object required by the use of the screw is to apply force or pressure. To produce the intended effect, either the outer or inner screw—that is, either the nut or the screw—must be fixed. If the screw be fixed at one extremity, say at the top, to a solid body, the nut may be turned round it so as to move from the bottom to the top; and if the nut be fixed, held fast by some solid body, the screw in the same manner may be turned round till it reach its extremity. Thus either the screw or the nut may be forced in such a way as to squeeze or press any object presented to it.

Practically, the screw is never used as a simple machine; the power being always applied by means of a lever, passing either through the head of the screw or through the nut. The screw therefore acts with the combined power of the lever and inclined plane; and in investigating the effects, we must take into account both these simple mechanical powers, so that the screw now becomes really a compound machine.

In the inclined plane, as has been seen, the less it is inclined, the more easy is the ascent, though the slower is the process of rising to a certain elevation. In applying the same principle to the screw, it is obvious that the greater the distance is betwixt the threads, the greater or more rapid is the inclination, and consequently the greater must be the power to turn it under a given weight. On the contrary, if the thread inclines downwards but slightly, it will describe a greater number of revolutions in a given space, so as to diminish the distance betwixt the threads, and the smaller will be the power required to turn the machine under a given weight; therefore the finer the screw, or the nearer the threads to each other, the less the power will require to be for a given resistance.

Suppose a case of two screws, one having the threads one inch apart, and the other half an inch apart; then the force which the first screw will give with the same power at the lever, will be only half that given by the second. The second screw must be turned twice as many times round as the first, to go through the same space. At the lever of the first, two men would raise a weight to a given height by making one revolution; while at the lever of the second, one man would raise the same weight to the same height by making two revolutions.

It is apparent that the length of the inclined plane up which a body moves in one revolution is the circumference of the screw, and its height the interval between the threads. The proportion of the power would therefore be—'as the circumference of the screw is to the distance between the threads, so is the weight to the power.' By this rule, the power of the screw could alone be found, provided the action of the machine was not affected by the lever which works it. As that is the case, the circumference described by the outer end of the lever employed is taken instead of the circumference of the screw itself.

The rule by which the true force of the screw is calculated, is by multiplying the circumference which the lever describes by the power. Thus—*The power multiplied by the circumference which it describes, is equal to the weight or resistance multiplied by the distance between the two contiguous threads.* Hence the efficacy of the screw may be increased, by increasing the length of the lever by which it is turned, or by diminishing the distance between the threads. If, then, we know the length of the lever, the distance between the threads, and the weight to be raised, we can readily calculate the power; or, the power being given, and the distance of the threads and the length of the lever known, we can estimate the weight which the screw will raise.

Suppose the length of the lever to be forty inches, the distance of the threads one inch, and the weight 8000; required—the power, at the end of the lever, to raise the weight. The lever being 40 inches, the diameter of the circle which the lever describes is double that, or 80 inches. Reckoning the circumference at thrice the diameter (though it is a little more), we multiply 80 by 3, which gives 240 inches for the circumference of the circle. The distance of the threads is one inch, and the weight 8000 pounds. To find the power, multiply the weight by the distance of the threads, and divide by the circumference of the circle.

$$8000 \times 1 = 8000 \div 240 = 33\tfrac{1}{3}$$

Thirty-three and a third is the product, and it would require that power or number of pounds to raise the weight. This, however, is only in theory. In practice, a third of the amount of power would require to be added to overcome the friction of the machine.

In the ordinary working of the screw, velocity is incompatible with great power. This is a truth, however, which applies only to a screw with one thread. There is a way of making a screw by which great velocity and power may be combined. This is done by forming the screw with two, three, or more threads. To understand how this is accomplished, we have only to conceive the idea of a screw with one thread, very wide betwixt its turns, and then imagine one or two other threads placed so as to fill up the intervals; thus composing a fine close screw. And as by this means all the threads descend with equal rapidity, we have a screw which will not only descend with great velocity, but which will apply a very great degree of pressure. A screw of this nature is used in the printing press, by which a pressure of a ton weight is applied instantaneously by a single pull of a lever.

The most common purpose for which the screw is applied in mechanical operations, is to produce great pressure accompanied with constancy of action, or retention of the pressure; and this quality of constancy is always procurable from the great friction which takes place in the pressure of the threads on the nut, or on any substance, such as wood, through which the screw penetrates.

The common standing-press used by bookbinders for pressing their books affords one of the best examples of the application of the screw to produce great pressure (fig. 40). The screw A has a thick round lower extremity B, into holes in which the lever is inserted. This extremity B is attached by a socket joint to the pressing-table C, so that when the screw is turned in one direction, the table sinks, and when turned in another, the table rises. The books D lie upon a fixed sole S, and are thus between the table and the sole. H is a cross beam above, in which is the box or overlapping screw, to give the necessary resistance.

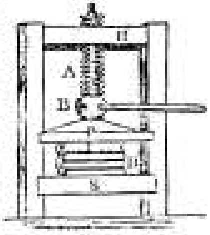

Fig. 40.

MECHANICAL COMBINATION AND STRUCTURE.

Mechanical action is applied to the action of forces that produce no change in the constitution of bodies, and is therefore distinguished from chemical or any other species of action, in which change of constitution is less or more effected. Great changes are continually taking place in nature and art by mechanical action. Mechanical action generally implies movement or change of place, and in most cases alteration of external features and circumstances. The whole of the planetary movements are mechanical; the motions of water and winds are mechanical; and the new appearances produced in art by placing different objects together are mechanical.

The action of forces upon solids, or mechanical action, is taken advantage of by mankind for the production of numerous useful results in the arts. And success in attaining these results depends in a great measure upon the knowledge we have of the principles of mechanics, and the skill and care we use in applying them. When skill, care, and ingenuity are brought fully into operation for these results, very great wonders are in many instances achieved. But where there is ignorance or negligence, the object in view may not only be defeated, but very mischievous consequences may take place.

Example first.—If a tall mast or beam break through at two-thirds of its height, and the two fractured ends be simply placed together and tied with a rope, the upper piece will, by the action of a small force, again fall. It will act like *the arm of power of a lever* against the rope, which is the *weight*; and as this weight is inconsiderable, the arm of power will preponderate. But if we take the two pieces and saw each of them lengthwise, so as to make four pieces, and then, as represented in fig. 41, lay a short piece alongside of a long piece, and another long piece on the top of the first short piece, with the second short piece opposite to this second long piece, the whole will be effectually *spliced* together; in such a case, with the aid of an overlapping rope, the beam will in all likelihood be stronger than it was before it was fractured. The cause of its being stronger, at least of its remaining firm, is, that the weaker part at one side is supported by a stronger part on the other side. Thus, by skilfully taking advantage of certain forces acting in connection with solids, we are able to rear a structure of the utmost possible strength.

Fig. 41.

Example second.—If a man, in making repairs upon the outside of a building, project a plank from a window for the purpose of standing upon it, and if he proceed to place himself near the outer extremity of the plank, without having placed a sufficient counterbalancing weight at its inner extremity, he will assuredly be precipitated to the ground, and perhaps killed; because the *gravity* of his body acted like a *power*, on the arm of a lever, while the lever was without a sufficient *weight* to preserve the apparatus in equilibrium. From such neglects of the operation of forces in nature dreadful consequences frequently ensue.

The study of the operation of mechanical forces, along with experience, teaches that there are certain bulks, positions, and forms of bodies which produce the greatest strength for purposes of art:—

The strength of beams or masses of the same kind and bulk, and fixed in the same manner, in resisting a transverse force which tends to break them, is simply as their breadth, as the square of their depth, and inversely as their length—that is, the thicker and shorter they are, they are the stronger. Thus if a beam be twice as broad as another, it will also be twice as strong; for the increase of breadth doubles the number of the resisting particles. By making the beam double the depth, the strength is four times as great; because the number of fibres is doubled, and the lever by which they act is also increased.

But this increase of strength, by increasing bulk, has a practical limit. It is found that in increasing the dimensions of a body, or combination of bodies, preserving all proportions the same, *the weight increases more rapidly than the increase of strength, or power of endurance*. This is one of the most important principles in mechanical science, and ought to prevent undue extension in structural arrangements.

Take a block of stone, and fix one end of it into a wall, leaving its other end projecting. By this arrangement of position, each particle of matter in the block acts as a weight pulling downwards as with a lever, the fulcrum of the lever being at the point of support, and the particles of matter in the mass forming at once the arm of power and the weight. Hence every particle we add to the length of the block adds to the length of the arm of the lever, and increases the weight. If we add to the block beyond a certain length (whatever may be its constitutional strength), we shall certainly cause the mass to break, and fall, from the effect of gravity, upon the outer extremity.

A similar lever action takes effect in the case of blocks or beams supported at both ends, the only difference being, that, in extending them to an undue length, they will break in the middle, or at the weakest point between the two supports. The strength of a beam supported at both ends is twice as great as that of a beam of half the length, which is fixed only at one end; and the strength of the whole beam is again increased if both ends be firmly fixed, as into a wall.

In the case of fibrous or grained materials—as, for instance, wood—the body sustains the greatest pressure when the weight is applied to the grain endwise, or to the beam longitudinally. The nearer that the pressure can be applied to any beam endwise, the better. Thus a beam supports most weight on its upper end, the other end being fixed to the ground, and its strength is next greatest when the pressure is applied to it leaning at top against another beam. This is exemplified in the angular roofs of houses, in which two beams lean against each other like the two sides of the letter A. In arranging beams to support great weights, as in building bridges, each beam is made to push obliquely upward with one end, while it pushes obliquely downward with the other, and thus an extensive combination of beams is firmly supported.

In rearing structures consisting of beams, it is an important point to convert, as far as possible, by mode of erection, cross or transverse strains into longitudinal strains, or into forces acting on the ends of beams in the direction of their length.

Nature appears to have designed that strength of structure should be accomplished with the least expenditure of material. It is obvious that, if trees and animals were made many times larger than we now find them, and of the same kinds of substance, they would be borne down by their own weight. Small animals endure greater comparative violence, and perform greater feats of strength, in proportion to their size, than large ones. The largest bulk which a human being can possess in his person, at the same time retaining activity of motion, is not more than is usually seen in well-grown men.

The same principles relative to mechanical strength apply to contrivances in the arts. As already stated, the strength or power of endurance in a material does not increase in proportion as the weight increases; hence there is a practical limitation of the magnitude of machines and other structures. For example, a bridge or roof of beams may be very strong when of small or moderate size, but if the dimensions be extended beyond a certain limit, the structure will fall, by not being able to support its own weight.

The strength or power of endurance of pressure upon a fixed body is greatly increased by giving the body a certain form. The strongest form in nature or art is that of an *arch*, which is a skilful disposition of parts, forming a convex and concave side, the convex side being that upon which the pressure is applied. The arch, which takes its name from *arcus*, a Latin word signifying a *bow*, may be either a portion of a circle or ellipse, or entirely rounded in form. Whether shaped like a bridge, a round tube, or the shell of an *egg*, the principle which causes the power of endurance of pressure is the same. The principle of endurance consists in the particles of the arched body bearing upon each other like a series of wedges (see fig. 42),

Fig. 42.

thus causing a compression of particles on the concave side of the circle, which enables the mass to bear an enormous pressure on the convex side. Indeed the greater the pressure is (to a certain extent) perpendicular to the convexity, so also the compression and power of resistance become the greater.

PRACTICAL MACHINERY.

Machines are usually formed of wood, iron, steel, brass, or other durable materials, with sometimes leather and cordage as part of the apparatus. In the construction of every machine, four objects are particularly desirable—*1st*, Strength or durability of materials; *2d*, Simplicity of arrangement of parts; *3d*, Exactness of fitting of one part to another; and *4th*, Easiness and correctness of motion. It is a general and well-recognised principle in mechanics, that the *fewer the parts* are in a machine, and the *more simple its construction*, the better.

Machines act from the impression of a certain power or force communicated to them. Whatever be the amount of power they receive, that amount they expend in their action. They cannot in the smallest degree increase the power. They can only convey, regulate, and distribute the quantity of power which has been communicated to them.

The power communicated to machines is derived from various sources—as human labour, the power of horses or other animals, the force of wind, water, or steam, or any other active agent which may be found suitable. Sources of power are technically called *moving forces*, or *first movers*.

Of the original impressed power, each moving part of the machine uses a certain portion. If the whole power which enters a machine be supposed to consist of 1000 parts, this large quantity is dispersed in various small quantities through the mechanism; some wheels taking perhaps 10 parts, others 5 parts, a third kind 1 part, a fourth a fractional part, friction another part, and so on, till the whole 1000 parts are expended. In some large cotton, flax, or silk-spinning establishments, a single water-wheel or steam-engine turns several thousands of spindles; each spindle, consequently, consumes a minute fraction of the originally-impressed power.

Whatever be the nature of the moving forces, it is generally sufficient for all purposes that they produce in the first instance *rotatory* or *circular motion*, and either in a horizontal or vertical direction. It is, however, indispensable that the power be of that magnitude which will cause each part of the machine to fulfil its assigned office. If the power be too small or weak, the machine will move languidly and ineffectually; and if too great, it will either cause the machine to move too rapidly, or at least power will be expended uselessly. In the application of moving forces, it is always a matter of importance to regulate the power to the precise wants of the machinery.

The circular motion communicated in the first instance to a machine is, by means of certain contrivances, diffused through the whole organisation, and changed into every conceivable direction; some parts being caused to revolve, others to rise and fall, a third kind to move horizontally to and fro, and so forth, in all possible ways. The various parts may also be made to move with any degree of velocity; there being methods of transforming quick into slow motion, or slow motion into quick. Most minute and complex operations are thus performed by machines with a precision which often exceeds the skill of the most expert artisan; but these operations are all necessarily marked by the quality of *uniformity of action*. As machines cannot reason, or act arbitrarily in stopping, moving, or altering their process, according to circumstances, they proceed in a blind routine, whether right or wrong, *mechanically* as it is called, and in every case less or more require the superintendence of reasoning beings. This apparent defect, however, is really advantageous. A machine, by being composed of inanimate matter, proceeds unswervingly in its assigned duty, and may be forced to accomplish tasks which it would be both inhuman and impolitic to demand from living creatures.

The purpose of machinery, therefore, is to *lessen and aid human labour*. At an inconsiderable expense, and with a small degree of trouble in supervision, a machine may be made to do the work of ten, fifty, or perhaps as many as five hundred men; and the work so simply effected by inanimate mechanism, serves to cheapen and extend the comforts and luxuries of life to the great body of the people. The following are the chief elementary parts of machinery:—

WHEELS.

A wheel moving on a central axis is a lever with equal arms radiating from the fulcrum at the centre, and is thus called a perpetual lever.

Wheels may be used in machines simply to transmit power from one point to another. This is done by means of toothed wheels. Projecting teeth or *cogs* are placed all round the circumference of a wheel, and when the wheel is turned, these teeth work upon or press against the teeth of another wheel, and so cause it to turn also, but in an opposite direction. Fig. 43 represents two wheels so working upon each other. As both of these wheels are of the same size, and consequently are levers with equal arms, they do not alter the effect of the power communicated to them. The motion of the axle in the wheel B is the same as the motion of the first axle in the wheel A. Thus power may be *transmitted* from one point to another.

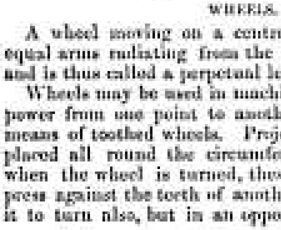

Fig. 43.

A long and large axle, in wheelwork, is called a *shaft*, and shafts of small dimensions are termed *spindles*. The terminating points of axles, shafts, and spindles, where they rest and turn upon supports, are called their *pivots* or *gudgeons*. The *sockets* upon which the gudgeons bear in turning are sometimes termed *bushes*.

WHEELS AND PINIONS.

When power has to be *accumulated* or increased in its effect in the course of its transmission, a large wheel is made to play upon a small wheel, by which means there is a diversity in the lengths of the levers. Fig. 44 is a representation of a large wheel W, working on a small wheel or pinion P. The wheel is turned by the handle C. In all arrangements in which large wheels are moved by small wheels, or small wheels by large, the small wheels are called *pinions*; and when these pinions are broad in their dimensions, they are termed *trundles*.

Fig. 44.

In this combination of a wheel and pinion, a long perpetual lever works against a short perpetual lever, by which a considerable mechanical advantage is gained. The wheel may be supposed to possess 48 teeth, and the pinion 6 teeth; hence, by one revolution of the wheel, the pinion turns 8 times, which gives the axle of the pinion eight times the velocity of the axle of the wheel; and if we suppose that the diameter of the wheel is ten times the diameter of the pinion, the power is increased in effect ten times.

Any degree of velocity greater than that of the first rotatory motion, may be imparted to the parts of a machine, by making these parts so much smaller than the primary moving parts. Thus if a large wheel, having a thousand teeth in its circumference, work upon and turn a small wheel having only ten teeth in its circumference, the small wheel will go round one time for every ten teeth of the large wheel which it touches; or in other words, it will go round one hundred times for one time of the large wheel. The respective velocities of wheels in a machine are in this manner always proportionate to their diameters or size, unless when specially arranged to be otherwise.

A combination of wheels acting as perpetual levers is represented in fig. 45. Three wheels are placed in a row close to each other, and it is supposed they are fixed by three axles to some upright object. On the side of the first wheel A, there is attached a small toothed pinion or wheel F, which, by the pressure of its teeth on the teeth of the second wheel B, causes this second wheel to turn round. The power applied to produce this motion is at the circumference of the first wheel at D. From D, then, to the centre of the pinion F, is the long arm of a lever, of which the centre of the pinion is the fulcrum; and from the centre to the ends of the teeth of the pinion is the short arm. The second wheel B having received its motion, the toothed pinion G, which is similarly attached to its side, presses against the teeth of the third wheel C, and so causes it also to turn. In this way a second lever is put in action. And the third wheel, from its circumference to the point from which the weight W depends, is a third lever. As the power or small weight P falls, therefore, from the circumference of the first wheel, the resistance W is raised, with the accumulated force of three levers acting on each other. The line across the figure represents the three levers in action.

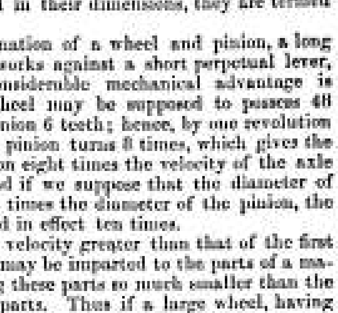

Fig. 45.

To calculate the power or mechanical advantage to be gained by such a machine—suppose the number of teeth on the first wheel to be six times less than the number of those on the circumference of the second wheel, then the second wheel would turn round only once, while the first wheel turned six times. And in like manner, if the number of teeth on the circumference of the third wheel be six times greater than those on the axle of the second wheel, then the third wheel would turn once, while the second wheel turned six times. Thus the first wheel will make 36 revolutions, while the third wheel makes only one. The diameter of the first wheel being three times the diameter of the axle of the third wheel, and its velocity of motion being 36 to 1, three times 36 will give the weight which a power of 1 pound at P will raise at W. Three times 36 being 108, one pound at P will balance 108 pounds at W.

WORKING OF TOOTHED WHEELS.

In the working of toothed wheels one upon another, or of wheels working on pinions, it is essential to set them in opposition with such exact adjustment, that the teeth of one will fall into the hollows betwixt the teeth of the other. When the teeth of each do not work with this nicety, they are apt to jar upon and break each other, and so damage the machine. In some cases teeth are made of a round or pointed form at their extremities, by which a very small degree of grinding or pressing on each other takes place. Fig. 46 is an example of a wheel and pinion with rounded and pointed teeth. From the centre of the axis of the pinion L to the centre of the wheel C, a dotted line is marked, called by mechanics the *line of centres*. The dotted circle OO round the pinion, and the dotted circle PP round the wheel, indicate the true point of working or contact of the teeth upon each other. These two circles are seen to join with exactness at A.

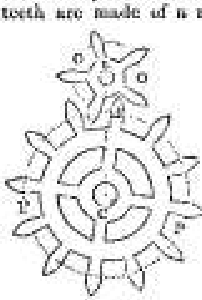

Fig. 46.

ALTERING THE DIRECTION OF MOTION.

Motion often requires to be *altered in its direction* in the course of its transmission. For example, rotatory horizontal motion requires to impart rotatory vertical motion, or rotatory vertical to impart rotatory horizontal. By means of a peculiar mode of setting the wheels, and a corresponding peculiarity in the shape of their teeth, any alteration may be effected in the direction of the motion. Fig. 47 represents a plan of changing the direction of motion. A is a pinion or trundle working with its shaft horizontally on a wheel B, whose shaft is turning vertically. As the case may happen to be, the horizontal movement is causing the vertical movement, or the vertical movement is causing the horizontal movement.

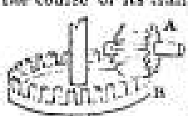

Fig. 47.

Fig. 48 represents a more common plan of changing the direction of motion. The wheels in this case are bevelled. A *bevel wheel* is one with teeth placed in a sloping or oblique direction on its circumference. When two bevel wheels are placed at right angles to each other, their respective teeth work against each other, and so a harmonious joint motion ensues. This is exemplified in the figure, in which a horizontal shaft with a bevel wheel is seen turning a smaller bevel wheel above it, placed on a vertical shaft.

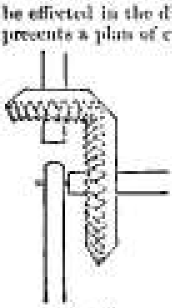

Fig. 48.

TRANSMISSION OF POWER BY BELTS.

A common mode of transmitting power from one point to another, when the interval is considerable, is by a flat leathern band, strap, or belt, communicating from a wheel at the source of power to a wheel connected with the machine. The wheels upon which straps work are usually called *pulleys*. They have flat and broad rims, and these rims have sometimes narrow ledges, to prevent the belt from slipping off. The rims must also be rather rough on the surface, so as to give the belt a sufficient friction or power of pulling in performing its revolutions.

Fig. 49 represents the transmission of power by a belt. A is the first pulley, which has received the power from its source, and C is the second pulley, moved by a belt, which passes over both pulleys. In this case, the motion of A is transmitted by the belt to C, which it causes to turn in the same direction as A. If these two pulleys were of precisely the same diameter, and the belt did not relax or slip, the second pulley would unavoidably go at the same velocity as the first, because the belt has exactly the property of a toothed wheel, and simply transmits the power it has acquired. As C appears to be somewhat smaller than A, it would consequently turn more frequently; therefore we have here an example of the mode of increasing the velocity while transmitting power. Fig. 50 represents two pulleys moving in different directions by means of a belt. The large pulley is supposed to be that which has received the power from its source. The belt, after leaving it, is crossed, and thereby causes the small pulley to move round in a direction contrary to that of the first.

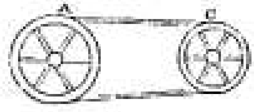

Fig. 49.

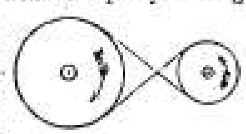

Fig. 50.

SHAFTS AND PULLEYS.

When power requires to be carried to a distance beyond that which belts can conveniently manage, the transmission is effected by a long shaft; and if it be necessary to change and rechange the direction of the motion, bevel wheels are added. Or the transmission may take place by a long flat chain acting like a belt, but caused to travel over small wheels or pulleys, to prevent the chain hanging down in any part of its course. A chain of this nature is called an *endless chain*.

Motion is often required to be communicated to many different machines, *at different points*, from one source of power. This is effected by means of a shaft and pulleys. From the pulley which receives the first motion, a belt is sent to a pulley fixed upon a shaft, which shaft is generally hung horizontally from the roof over the machines. As the shaft turns through its whole extent, it is able to turn pulleys fixed at any point upon it, and from these pulleys belts are sent down to pulleys at the respective machines.

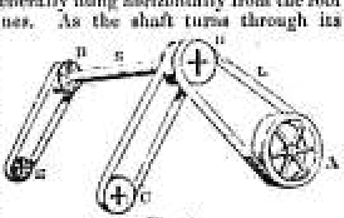

Fig. 51.

Fig. 51 represents an apparatus of a shaft and pulleys. A is the pulley receiving motion from the source of power, and, by means of the belt L, turns the pulley B on the end of the shaft S. At the same time, the pulley D at the opposite end of the shaft is turned. From a pulley on the shaft situated close to B, a belt descends to turn C, and from D another belt descends to turn E. Thus an extended axle or shaft from C will turn a machine, and an extended axle or shaft from E will turn another machine.

Shafts with pulleys, working on the plan now stated, are to be seen at almost every manufactory in which machinery is employed; and the power, by means of bevel wheels and upright connecting shafts, is carried upwards from storey to storey in a building, giving motion to hundreds of wheels, spindles, and other parts of the mechanism.

CHANGING VELOCITY.

It is sometimes necessary that a machine, or part of a machine, should be propelled with a velocity which is not equable, and is continually changing from fast to slow, and slow to fast. This happens in cotton-mills, where it is necessary that the speed of certain parts of the machinery should continually decrease from the beginning to the end of an operation. To effect this, an apparatus is used as represented in fig. 52. Two cones, or conically-shaped drums, are used, having their larger diameters in contrary directions. They are connected by a belt, which is so governed by proper mechanism, that it is gradually shifted along from one extremity of the cones to the other, thus acting upon circles of different diameter, causing a continual change of velocity in the driven cone with relation to that which drives it. The shifting of bands from large to small wheels, and from small to large, has similar effects.

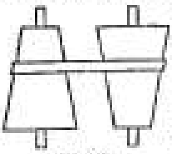

Fig. 52.

PRESERVING REGULARITY OF MOTION BY A VARIABLE FORCE.

In some mechanical contrivances, the force which is applied varies in its intensity, while the wheels of the machinery require to be kept at a uniform speed. This is generally the case when the force is communicated from a steel spring, which, after being wound up, is suffered to relax. *Fig.* 53 is a spring suited for operations of this kind. It is represented in a state of relaxation, and is wound up into a compact form by means of a spindle fixed to its inner extremity. The coiling of a strip of paper round the finger, and allowing it to unwind itself, is a familiar illustration of the action of a spring of this description. The force communicated by the relaxing of the spring varies in its intensity. The force is greatest when it begins to relax, and gradually weakens till its expansive energy is exhausted. To compensate this defect, a very ingenious plan is adopted in the apparatus of the common watch.

Fig. 53.

Fig. 54 represents the apparatus of motion of a watch, somewhat magnified. The spring is confined in a brass cylinder or barrel B. To this barrel the spring is attached by a slit at its outer extremity. The inner extremity of the spring is fixed by a similar slit to the central axis or spindle. F is a brass cone, broad at bottom, and narrow at top, with a path winding spirally round it as an inclined plane. This cone is called the *fusee*, and has also a central axis or spindle K, to which it is fixed. To a point on the lower inclined path of the fusee a small steel chain C is attached, and the other extremity of this chain is attached to the top part of the barrel. When the spring is relaxed, the chain is almost altogether round the barrel. To set the apparatus in motion, the watch-key is made to turn the spindle K, by which the chain is drawn from the barrel to the fusee, filling up the inclined path to the summit. The chain, in leaving the barrel, causes it to turn, and consequently to wind up the spring inside. The process of unwinding or relaxing ensues, and now the ingenious plan for regulating the motion is to be remarked. At first, when the force of the spring is greatest, the chain acts upon a small round of the fusee; in other words, it pulls with a small lever—for, as already explained under the head Wheel and Axle, a wheel or round object on an axis is simply a perpetual lever. In proportion as the intensity of the force weakens, and the barrel takes off the chain from the fusee, and winds it about itself, so does the chain act upon a longer lever, or so does it gain a greater lever advantage, by drawing at a wider part of a cone. Thus the gradual loss of force is counterbalanced by a gradual increase of lever advantage.

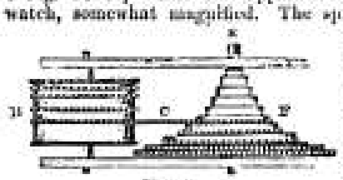

Fig. 54.

ALTERNATE OR RECIPROCATING MOTION—ECCENTRIC WHEELS.

Alternate or reciprocating motion is applied to movements which take place continually backwards and forwards in the same path. In most complex machines, both rotatory and reciprocating motion occur, and these motions may be converted into each other by various contrivances.

A common plan for gradually raising and depressing an object by machinery is that of an *eccentric wheel*; that is, one with an axis not in its centre. *Fig.* 55 represents the action of a wheel of this kind. W is the wheel, and A the axis upon which it is fixed. When the axis turns, the wheel turns with it. As the axis never moves out of its place, the wheel necessarily describes a path of gradual rising and falling in its revolutions. Suppose an object, as T, pressing upon the upper edge of the wheel, so as to accommodate itself to the motion, it is obvious that, by the action of the wheel, this object will be alternately raised and allowed to fall. Or suppose that a rod is hung from a point of the wheel near where T rests, it is similarly obvious that the rod would be raised or depressed according as the wheel turned. Thus a rising and falling motion may be effected by an eccentric wheel.

Fig. 55.

Eccentric wheels are made of different forms. According as they may be required to act, they are circular, oval, heart-shaped, or pointed at one end, and so forth—the object in each case being to produce alternate motion, by continually altering the distance of some movable part of the machine, from the axis about which they revolve. Technically, the projecting parts of eccentric wheels are called *cambs*.

In some cases eccentric wheels are not required to perform entire revolutions on their axes. It is perhaps sufficient for the purpose of the mechanism if they gradually rise to the height of their power, and then, without turning round, gradually descend by retracing their course.

When alternate rising and falling is required *thrice* by only one revolution of an axle, an eccentric wheel is used having three projecting cambs on its circumference, and as each camb comes round, it lifts and lets fall any object presented to it. An example of this apparatus is given in fig. 56. The object required is to work a heavy hammer upon an anvil for beating iron. W is the wheel with the three cambs, and it turns by an axle in upright supports. In turning, each camb, with its rounded or convex side, presses down the end of the handle of the hammer, so as to raise the heavy head H at the opposite end. After pressing down the handle and escaping, the head of the hammer falls with a heavy blow on the anvil A. There it remains till raised up and let fall by the next camb; and so on.

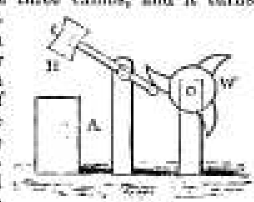

Fig. 56.

OBLIQUE ACTION.

A mechanical advantage, which is frequently of a very serviceable nature, is obtained by causing the points of two straight bars to meet each other, but fixed loosely, so as to be free to move from an oblique to a straight direction, and the reverse. The power consists in bringing the bars to the straight, by which they force asunder or press hard upon any object presented to their outer extremities. In the adjoining fig. (57), the bars are seen first in their oblique position, and next when brought towards a straight. Betwixt the two points a small hollowed piece of metal is inserted, in which the points work, and against which the power is exerted to produce the action. The straightening and bending of the apparatus resemble the action of the knee-joint in animals. The pressure produced by the forcing downwards of the outer extremity of the lower bar (the upper working against a fixed beam) is very easily and rapidly accomplished, and is almost unlimited; and these advantages, as well as the extreme simplicity of the mechanism, have led to the application of the power to the printing-press wrought by the hand, instead of screw pressure.

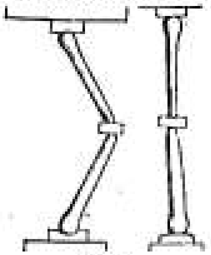

Fig. 57.

CRANKS.

The crank affords one of the simplest and most useful methods of changing an alternate rising and falling motion into rotatory motion. A crank resembles a common handle or winch for turning a machine by the hand; the chief difference being, that a rod or shaft jointed to the handle, and going up and down, works the machine. If the crank be made double, it will turn two wheels or machines.

Fig. 58 represents a double crank in action. S is the rod or shaft ascending and descending, and attached by a joint to the lower part of the crank C, which it alternately pulls up and pushes down, so as to cause the axles W W to turn a wheel at each side. Take away one of the sides of the crank and its support, and the apparatus becomes a single crank.

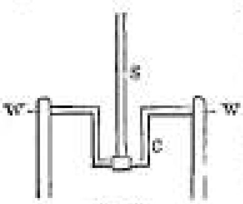

Fig. 58.

Turning-lathes, knife-grinders' machines, and similar apparatus, are usually turned by cranks wrought by an alternate pressing and raising of the foot of the operator; a rod going upwards from the foot-board to the crank causing the wheel or spindle to go round. The crank has been hitherto indispensable in the action of the steam-engine.

ACCUMULATION OF POWER.

Power is susceptible of accumulation—that is, of increasing little by little—and of being extended either gradually or in one or more violent efforts; the efforts being entirely the concentrated amount of the previous accumulation. The apparently wonderful powers displayed through the agency of levers and other simple machines are all a natural consequence of an accumulation of any degree of force into a small space; by which effects take place that could never have been accomplished by the original force. In consequence of this convenient accumulation of power, plans have been devised for establishing *reservoirs of power*, as they may be called, in connection with moving machinery.

A well-known method of accumulating power consists in suspending a heavy body by a chain or strong rope of considerable length—forming what is called by young persons a *swing*. This body may be put in motion by a very small degree of power, and will acquire a vibrating motion like a pendulum. By continuing the impulse as the body returns, it will continually acquire greater and greater force, the arcs through which it moves becoming continually larger, until at last it might be made to overcome almost any obstacle. Upon this principle, the battering-rams or engines for beating down the fortifications of towns in ancient times were constructed. The forcible expenditure of accumulated power in the swing apparatus resembles that which is observable in the case of a person occupying several minutes in bending a spring—that is, accumulating power—and then allowing the spring to unbend itself by one violent effort, which effort is nothing more than the giving out of the accumulated power.

A boy taking a race to gain force before making a leap, is another familiar example of accumulating power and expending it instantaneously. The boy is gathering up power at every step he runs, and the force of his leap corresponds exactly with the quantity of power he has acquired. In the same manner, the lifting of a hammer, axe, or other instrument to an elevation as far as our arm can reach, in order to give a blow with good effect, is a method we naturally pursue to gain an accumulation of power.

In contrivances in the arts, power is sometimes accumulated in order to be given out in the form of a rapid and effective blow. This may be done by means of a horizontal bar or lever, poised on a central axis, and loaded at each end with a heavy ball of lead or iron. After communicating to the machine a sufficient power of rotation, it will proceed with an enormous accumulated energy and momentum, till it expend its force either by friction in turning, or upon some fixed obstacle presented to it.

EQUALISATION OF POWER.

In most machines, both the moving force and the resistance to be overcome are liable to fluctuations of intensity at different times during the operation of working. For instance, when a man turns a winch or handle of a piece of machinery, he is apt to relax in his efforts for an instant from loss of strength, or from an inability to keep his attention closely and uniformly fixed to the labour he has to perform. These relaxations cause an irregularity of motion alike detrimental to the machine and to the work performed.

The irregularities in the motion of machinery, from whatever cause they rise, are remedied by giving to each machine a *reservoir of power*, from which force may be given at all times to equalise the motion according as it may be required. These reservoirs of power are usually in the form of *fly-wheels*. A fly-wheel is generally made of iron, and consists of a heavy rim or circumference, joined to a central axis by cross bars or spokes. In most cases it is placed in close connection with the first moving force, the effect of which it equalises in its passage to the machine.

OBSTACLES TO MOTION—FRICTION.

Moving bodies, as machines and wheel carriages, are less or more retarded in their velocity by friction, and the resistance of the atmosphere, while vessels moving through water are retarded by the resistance both of the atmosphere and of the liquid in which they are buoyant.

Friction is an effect of the action of rubbing of bodies against one another. This effect is produced by inequalities of surface. No such thing is found as perfect smoothness of surface in bodies. In every case there is, to a lesser or greater extent, a roughness or unevenness of the parts of the surface, arising from peculiar texture, porosity, and other causes; and therefore, when two surfaces come together, the prominent parts of the one fall into the hollow parts of the other. This tends to prevent or retard motion. In dragging the one body over the other, an exertion must be used to lift the prominences over the parts which oppose them, and this exertion is similar to that of lifting or drawing of bodies up inclined planes or over upright protuberances.

Friction acts as a retarding influence in the action of all mechanical contrivances, and a due allowance must in every case be made for it. In many instances it destroys more than a half of the power employed, and seldom destroys less than a third. However small it may be, it sooner or later causes the wearing down and destruction of mechanism, and therefore forms an insurmountable obstacle not only to the lasting duration of bodies, but to the perpetuity of motion. It is found to depend on the following circumstances:—1. The degree of roughness of the surfaces in contact; 2. The weight of the body to be moved; 3. The extent of the surfaces in contact—that is, the amount of surface presented to the action of friction; 4. The nature or molecular constitution of the bodies in friction-contact; 5. The degree of velocity of the motion; and 6. The manner of the motion.

Roughness.—It is of the utmost importance to smooth the surfaces. An apparently insignificant piece of matter, or even particles of dust, will greatly retard the motion of a body. But there is a limit beyond which it would be imprudent to smooth the surfaces of bodies having a close texture. If the surfaces be highly polished and levelled, the bodies will adhere by the effect of attraction of cohesion, even when the atmospheric air is not entirely expelled from between them, and more forcibly when the air is completely expelled. Practically, roads and similar surfaces cannot be made too smooth.

Weight.—Friction from weight differs in different bodies, and depends on concurring circumstances—as nature of surface, and so forth. Friction always increases in exact proportion as the weight increases, when all other circumstances remain the same. The parts of machinery, therefore, should be made as light as possible, consistent with strength and durability.

Extent of Surfaces.—Rough bodies are more easily drawn along when their surface of contact is narrow than when they are broad. For example, it is easier to draw two narrow brushes across each other, than two broad ones of the same weight. Friction may therefore be diminished in rough bodies by lessening the extent of surfaces in contact. But there is a limit to this diminution. If the moving surface be very thin, and that over which it moves be in any degree softer, the thin or edge surface will plough a groove in the soft one, and thus the friction will be increased, and the machine injured.

Nature of Bodies.—It is a remarkable truth, that two bodies which are of the same nature, or homogeneous, produce greater friction in movement than bodies which are different in their nature, or heterogeneous. Thus iron working against iron, steel against steel, or brass against brass, causes in each case greater friction and wearing of parts than when iron or steel is made to work against brass. This circumstance is always attended to in the construction of machinery.

Degree of Velocity.—Friction is a uniformly retarding force, except in the case of small velocities, when it is greater in proportion. The reason for its being greater in small velocities is, that in these cases time is allowed for the prominences of the moving body to sink deeply into the hollows of the surface on which it is moving, which has a retarding effect.

Manner of the Motion.—The least advantageous manner in which one body can be moved upon another, is to cause it to slide or drag. The most advantageous manner is to cause it to roll or turn. The causing of a body to roll instead of to slide, is one of the chief means of diminishing friction. The opposition presented by inequalities of surface to a rolling wheel, is overcome with ease, in proportion to the extent of diameter of the wheel. On a perfectly horizontal plane, the friction of wheels on the plane is very inconsiderable; the chief seat of friction in such cases being in the axles working in their sockets.

Friction is greatly diminished by lubricating the rubbing surfaces with an oily or greasy substance, which substance forms a medium of smooth incompressible or but slightly elastic molecules betwixt the bodies, and so prevents the tendency to grind or wear down the surfaces. Water, or any similar fluid, will also act as a medium to prevent friction; but the effects are only temporary, and would frequently be injurious, as the substance speedily evaporates and corrodes metals. Practically, fine pure oil is found to be the best lubricant for machinery.

One of the first considerations on the part of contrivers of mechanism, should be how to provide for and diminish the effects of friction in their machines. For want of forethought on this important point, thousands of ingenious schemes, which seemed perfect in the form of models and drawings on paper, have been completely frustrated when attempted to be brought into use.

Whatever may be the retarding and frequently inconvenient effects of friction in reference to the action of mechanism, it is certain that friction is indispensable in the economy of both nature and art, and serves as an essential auxiliary to gravitation. It is a property which is frequently necessary, to allow one kind of matter to possess a hold upon another, without actual cohesion. We walk and maintain our erect posture by means of gravitation and action and reaction; in other words, we are held to the earth by gravitation, and our pressure with our feet exemplifies action and reaction: but if there was no such property as friction, we should either stick to the earth by attraction of cohesion, or slide along it as upon the smoothest ice. In order to keep our feet from sliding when on ice, if we received any impulse, we either tie rough substances on our shoes, or scatter ashes in our path; and thus we receive the benefit of friction. It is by friction that rains wear down hills, and that rivers wear away their banks, by which ceaseless process the external configuration of the globe is constantly undergoing a change. The operations in art of washing, cleaning, scouring, sharpening, polishing, cutting, bruising, beating, and so forth, are all effected less or more by friction. The hold which one fibrous substance has on another, or mutual friction, permits the operations of weaving cloth, twisting ropes and threads, and the tying of one body to another. Thus friction is of universal service; and the only known instances in nature in which it seems not required, and therefore not present, are the movements of the heavenly bodies, which, as far as yet known, revolve in vacuity, and are consequently not impeded in their motions.

RESISTANCE OF AIR AND WATER.

Atmospheric air and water are fluids of different densities, and both present an obstacle to the motion of solid bodies through them.

There is a rule in respect to the resistance presented in moderate velocities which applies both to air and water. It is, that *the resistance is proportional to the square of the velocity.* For example, a velocity of twenty miles an hour causes a resistance four times greater than a velocity of ten miles an hour, for the square of twenty (which is 20 times 20, or 400) is four times the square of ten (which is 10 times 10, or 100). Thus, by increasing the velocity of bodies through air or water, we must increase the motive power in a greater proportion, in order to compensate the loss caused by resistance.

Although the above rule is nearly correct for moderate velocities, it deviates considerably from what is observable in the case of great velocities, such as that of a cannon ball. When the velocity is upwards of 1000 feet per second through the air, the quick passage of the body is supposed to cause a partial vacuum behind it, which causes a retardation of its motion.

Resistance to motion in fluids is greatly modified, also, by the form of the moving body. The form that gives least resistance is nearly that of a parabola, or a form somewhat resembling the breast of a duck, the head of a fish, or the rounded bow of a vessel, sharpened to cleave the fluid through which the body passes.

HYDROSTATICS—HYDRAULICS—PNEUMATICS.

GENERAL DEFINITIONS.

MATTER exists in three principal states—*solid*, *liquid*, and *aëriform*. These states respectively, and the various modifications of them, are the immediate result of certain principles of attraction and repulsion operating on the atoms or particles of which matter is composed.

The solid, liquid, and aëriform varieties of matter assume a position on our globe corresponding to their heaviness or density in a given volume: the solid sinks lowest, and composes the chief mass of the earth; above the solid lies the liquid variety, in the form of the ocean, lakes, and rivers; and above all is the atmosphere, consisting of an expanse of aëriform matter, which wraps the whole earth round to an elevation of from forty to forty-five miles above the highest mountains. In this great ocean of air, loaded less or more with particles of moisture from the liquids beneath, animals live, breathe, and move, and plants grow and receive an appropriate nourishment.

Though differing both in substance and appearance, the liquid and aëriform varieties of matter resemble each other in many of their properties and tendencies, and constitute the class of bodies termed *fluids*. Fluids signify bodies which will flow, or whose component particles are easily moved among each other. Some fluids are so thick and viscous, or sticky, that they can scarcely flow—as tar, honey, and some metals in a state of fusion; others flow with ease—as water and distilled spirits; while others are so light and volatile, as to be impalpable to the touch and invisible to the eye—as pure atmospheric air and various gases.

It is common to divide fluids into two kinds—*non-elastic* and *elastic*; that is, fluids which cannot be compressed into a smaller bulk, and those which are susceptible of compression. The non-elastic fluids are water, and all other varieties of liquid bodies; but recent experiments prove that the term is not strictly applicable to them. It has been found that water may be compressed in a confined vessel, to a small extent, by means of a very great pressure; and it is certain that water at a considerable depth in the ocean is more dense or compressed than at the surface: water, consequently, is an elastic substance; but as it can be compressed only with very great difficulty,* the term non-elastic fluid is not altogether inappropriate. Atmospheric air, and all gases, are elastic. They can, with little difficulty, be compressed into a much smaller volume than they ordinarily possess; and when the pressure is removed, they return to their original bulk. Some gases (as carbonic acid gas, for example) may be compressed to such an extent, as to assume the form of liquids and solids; in other words, from the condition of being perfectly invisible to the eye, they can be made to appear as a piece of solid matter, which may be touched and handled.

In treating the subject of fluids, it is convenient to refer in the first place to those which are of the liquid form, and afterwards to those which are elastic or aëriform. Pure water, at an ordinary temperature, furnishes the most suitable example of liquid bodies. Water also gives the name of the department of science which includes the laws of liquids. Thus *Hydrostatics*, from two Greek words signifying *water* and *to stand*, treats of the weight, pressure, and equilibrium of liquids in a state of rest; and *Hydraulics*, from two Greek words signifying *water* and *a pipe*, treats of liquids in motion, and the artificial means of conducting liquids in pipes, or raising them by pumps.

* The compressibility, and consequently the elasticity, of water, have been rigorously determined by the experiments of Professor Oersted. This compressibility, however, is all but inappreciable in the ordinary economy of nature; common spring water yielding only about 46·65 millionths of its bulk to the pressure of the atmosphere.

HYDROSTATICS.

In ancient times, water was believed to be an element or simple substance in nature. It is now ascertained by experiment that water is not an elementary body, but is a substance composed chiefly of two gases (oxygen and hydrogen) in a state of chemical union, and into these gases it can be resolved by an artificial process. The investigation of this subject belongs to the science of CHEMISTRY.

As a liquid, water consists of exceedingly small particles or atoms of matter in mechanical combination. The exact nature and form of the atoms composing water are not satisfactorily known, in consequence of their excessive minuteness. They may be compared to very small particles of sand, cohering slightly, and easily slipping or sliding over each other. Whatever may be the nature and form of these exquisitely fine atoms, it is certain that they can adhere firmly together, so as to assume the form of a solid, as in the case of ice; and be made to separate from each other, and disperse through the thinner fluid of the atmosphere in the forms of steam, clouds, or mist.

Thus *imperfect cohesion of atoms or particles* is a property common to all fluids. The atoms composing water being in closer union than those of air, are observable as a mass, and palpable to the touch. When the hand is dipped into them, and then withdrawn, a certain quantity is brought away on the surface of the skin; and this adhesion of the particles of water (caused by attraction of cohesion) is what what we in ordinary language call *wetness*. Certain substances, as is well known, absorb water to a great extent; in such cases the molecules of the water merely penetrate and fill up the crevices in the substance.

Solid bodies, as a stone, or piece of metal, or wood, have a natural tendency to press only in one direction—that is, downwards, or in the direction of the earth's centre—in obedience to the law of terrestrial attraction. Water has a similar natural tendency to press downwards, and from the same cause; as, for example, when a jug of water is spilled, the water is seen to fall in a stream to the ground. Water, however, is governed by a law of pressure, independently of this general law of gravitation. This peculiar or independent law consists of a tendency in the particles of any mass of water to press equally in all directions.

I. *Pressure equally in all directions* may be considered as the first or great leading law in reference to water, and generally all fluids, liquid or *gaseous*. This pressure is a result of the exceeding smallness of the individual particles, and of the perfect ease with which they glide over or amongst each other.

To exemplify equal pressure, fill a leathern bag with water, and then sew up the mouth of the bag so closely, that none of the water can escape. Now squeeze or press upon the bag so as almost to make it burst. The pressure so applied does not merely act upon the water immediately under the point of contact, but acts equally upon every particle of water in the mass—the particles at the centre being as much pressed upon as those at the outside; and it will be observed that the water will squirt out with equal impetuosity at whatever part in the surface a hole may be made. In this, as in all similar cases, there is a transmission of pressure throughout the mass. Each particle presses on those next it; and so, by the force communicating from particle to particle, the whole are equally affected. In the case of water lying at repose in an open vessel, the tendency to press equally in all directions is not observed to act upward, because the gravity of the mass keeps the water down; but on pressing upon the surface of the liquid, we observe that it rises against the compression, or tries to escape in any way it can.

To take another example—if we plunge our hand into a vessel of water, we displace so much liquid, and cause it to rise higher up the sides of the vessel. In this case the water is observed to rise without any reluctance; it as readily presses upward as downward. Although it is a property in fluids to press equally in all directions, the degree of intensity of pressure in any mass of fluid is estimated by the vertical height of the mass, and its area at the base.

II. *Pressure of water in proportion to its vertical height, and its area at the base*, is therefore a second leading feature in the laws of water. In other words, the pressure of a column of water does not depend on the width or thickness of the column, but on its height, and the extent of its base or lower part. The whole of any fluid mass may be imagined to consist of a number of columns of an inconsiderable thickness, which stand perpendicularly on the horizontal base of the containing vessel, and press the base of the vessel with their respective weights. The pressure, then, if the height of the fluid be the same throughout, is as the number of columns, and this number is according to the area of the base. Consequently, in vessels whose bases differ as to area, and which contain fluids of the same density, but different heights, the pressure will be in the compound ratio of the bases and heights.

If the columns of which a fluid mass was supposed to consist were formed of particles lying in perpendicular lines, the pressure of the fluid would be exerted on the bottom of the vessel only; but as they are situated in every irregular position, there must, of consequence, be a pressure exerted in every direction, which pressure must be equal at equal depths. For if any part of the whole mass were not equally pressed on all sides, it would move towards the direction in which the pressure was least, and would not become quiescent till such equal pressure was obtained. The quiescence of the parts of fluids is therefore a proof that they are equally pressed on all sides.

Several interesting experiments may be made to prove that the pressure of water is in proportion to its height and width of base:—Fig. 1 represents a vessel with a broad top EE, tapering to a narrow base CD. The dotted enclosure ABCD represents an ideal column of water the width of the base. The vessel is supposed to be filled with water to the surface EE. Yet the base or bottom sustains no more pressure than that described by the ideal column ABCD; for the other parts of the contained fluid can only press the column ABCD, and also the sloping sides, laterally, and therefore do not contribute to the increase of the pressure on the bottom CD. Again, if we take a vessel of the same capacity, but with a broad base, as in fig. 2, the pressure on the bottom is very different. In this case the base EF sustains a pressure equal to the weight of a column whose base is EF, and height equal to AC; for the water in the central column ABCD presses laterally, or sidewise, with the same force as it does on the part on which it stands; and thus a uniformity of pressure is established over every part of the bottom.

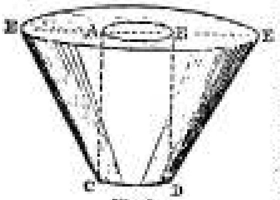

Fig. 1.

Fig. 2.

From these two cases combined, the reason is evident why fluids contained in the several parts of vessels remain everywhere at the same height; for the lowest part where they communicate may be regarded as the common base; and the fluids which rest thereon are in equilibrio then only, when their heights are equal, however their quantities may vary.

We may prove the truth of these propositions in various ways. Let ABCD, fig. 3, represent a cylindrical vessel, to the inside of which is fitted the cover G, which, by means of leather at the edge, will easily slide up and down in the internal cavity, without permitting any water to pass between it and the surface of the cylinder. In the cover is inserted the small tube EF, open at top, and communicating with the inside of the cylinder below the cover at G. The cylinder is filled with water, and the cover put on. Then, if the cover be loaded with the weight, suppose of a pound, it will be depressed, the water will rise in the tube to E, and the weight will be sustained. In other words, a very small quantity of water in this narrow tube will press with a force as great as if the vessel were of the dimensions KLCD, instead of ABCD. By filling the tube to F, a force will be gained sufficient to balance additional pound weights on the cover G, and as great as could be conferred by a vessel of equal breadth all the way up to F.

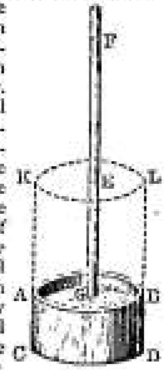

Fig. 3.

Water, in its pressure equally in all directions, presses upwards as well as downwards. This is seen in the above experiments. Take fig. 3 as an example. The water in the vessel ABCD, when the tube is filled, presses, as has been said, with a force equal to that of a column of water of equal breadth all the way up to F. This can only be in consequence of the water in the vessel ABCD pressing violently upwards against the cover G, which violence causes a corresponding reaction on the bottom of the vessel. This reaction, then, is equivalent to vertical height. To use a figure of speech, the water in the vessel is in the condition of a man pressing equally upwards with his shoulders and downwards with his feet at the same time; and the more he is acted upon by weight above, the more powerfully does he exert his pressure in both directions.

An instrument called the *hydrostatic bellows* has been constructed to exemplify the effect produced by the pressure of a small column of water. As represented in fig. 4, it consists of two circular stout boards connected together with leather, in the form of a pair of strong bellows, B; a tube A communicating with the interior between the boards. Supposing the instrument to be strong enough, a person standing on the upper board may raise himself by pouring water into the tube, and filling it along with the bellows. It is usual to estimate the pressure by means of weights, W. If the tube hold an ounce of water, and has an area equal to a thousandth part of the area of the top of the bellows, one ounce of water in the tube will balance a thousand ounces placed on the bellows.

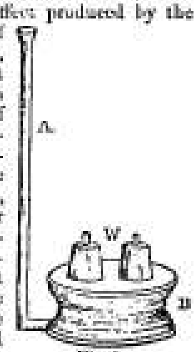

Fig. 4.

This remarkable property in liquids, which is called the *hydrostatic paradox*, is analogous in principle to that which in mechanics is called the Law of Virtual Velocities. According to this fundamental rule, a small weight descending a long way, in any given length of time, is equal in effect to a great weight descending a proportionally shorter way in the same space of time. The rule, as applied to liquids, may be stated thus:—A small quantity of water descending in a long column is equal in effect to a proportionately great pressure exerted by a large volume of water in a short column.

The law of pressure in proportion to height of column is shown in the annexed representation, fig. 5, of a vessel with a uniformly level base, and full of water. Dividing the depth into 10 equal sections, to represent feet, as marked from 1 to 10, it is found that, at the depth of 1, there is a pressure of one foot of water, at 2, two feet, and so on to 10 at the bottom, where there is a pressure of ten vertical feet of water. The average pressure of the whole is at the middle, at 5. These degrees of intensity of pressure have no reference to the horizontal breadth or length of the mass. The same pressure is sustained whether the vessel be a foot or a mile in breadth.

Fig. 5.

As in this example, whatever deficiency of pressure there is upon the perpendicular sides of a vessel of water *above* the middle or point of average pressure, is compensated by a corresponding excess of pressure *beneath* the middle; consequently, the entire pressure diffused over the sides is equal to that at the middle or point of average pressure. A perpendicular side of a cubical vessel, according to this statement, sustains a lateral pressure precisely equal to the half of that which is endured by the bottom.

We may calculate the degree of lateral pressure in vessels having perpendicular sides and flat horizontal bottoms, by first finding the number of square feet in the sides below the surface of the liquid; then multiplying that by the number of feet in half the depth of the liquid; by which calculation the product will express the number of solid feet of the liquid, whose weight is equal to the lateral pressure. We may find the number of square feet in the sides, by multiplying the number of feet in the circumference of the bottom by the number of feet in the depth of the liquid:—

Example.—To find the degree of pressure on the perpendicular sides of a vat 24 feet deep from the surface of the liquid, and 40 feet in circumference—Multiply the 24 by 40, and the product 960 gives the area of the sides; then multiply the 960 by half the height—that is, 12—and the product is 11,520 cubic feet of water, or the volume of liquid whose weight is equal to the pressure on the sides. We next find the weight per cubic foot, which is reckoned to be 1000 ounces; then 11,520, multiplied by 1000, gives 11,520,000 ounces, which is the pressure of the water on the sides.

In consequence of the pressure of liquids being as the vertical height and area of the base, it may happen that the lateral pressure on the sides of a containing vessel is greater than the whole weight of the liquid; this will be the case when the surface of the sides in contact with the liquid exceeds the ratio of double the magnitude of the bottom—at double the magnitude, both lateral and perpendicular pressures are alike, and each is equal to the weight of the liquid.

The circumstance of pressure increasing in proportion to depth, suggests the valuable practical lesson of greatly increasing the breadth of embankments for dams and canals from the top downwards, so as to give much greater strength to the base than the summit; also of increasing the strength of the lower hoops of large vats, to prevent their bursting. It likewise demonstrates the propriety of making dams, ponds, canals, and vessels for liquids generally, as shallow as is consistent with convenience or their required purpose. In each case, it is important to recollect that the degree of pressure on the sides is irrespective of shape or size of the contents, and depends exclusively on the height of the liquid from its upper surface to its base.

That pressure in water is not according to the volume, but the height above the point of pressure, is obvious from many facts both in nature and art. Whether we plunge an object a foot deep in the ocean or in a jar of water, the pressure upon it is the same. The mere extent of the volume of liquid is of no consequence. Therefore, a precipitous shore pressed upon by the sea to the height of any given number of feet, suffers no more pressure (supposing the sea to be at rest) than the side of a canal of the same number of feet in height.

If the law of pressure of fluids were otherwise than that now stated, no species of embankment could withstand the pressure of the ocean, particularly in a high state of the tide. In consequence of the law of pressure being simply as the vertical height, we are enabled by artificial means to stem the volume of a far-spreading ocean, and to secure the dry land from its invasion. A knowledge of this important law might induce the attempt to secure many thousand acres of land which are now covered by the tide.

If a vessel—as, for instance, a tall glass jar—be filled with water, and three apertures be made in its side, at different heights, as in fig. 6, the liquid will pour out with an impetuosity corresponding to the depth of the aperture from the top. The jet from the orifice A will issue with a comparatively small velocity; that from B with a greater; and that from C with the greatest. The expression of this fact is known as the theorem of Torricelli, and may be stated thus: 'Particles of fluid, on issuing from an aperture, possess the same degree of velocity as if they had fallen freely, *in vacuo*, from a height equal to the distance of the surface of the fluid above the centre of the aperture.' For instance, in the annexed diagram, the jet from A will possess the same velocity as if the particles of water had fallen, *in vacuo*, from H to A; that from B the same velocity as if the particles composing it had fallen from H to B; and that from C as if from H to C. The velocity of fluids thus escaping from orifices is, other things being equal, as the square roots of the depths of the orifices below the surface of the fluid; and when fluids escape from lateral orifices, they describe parabolic curves, and obey the laws of projectiles. [See LAWS OF MOTION.]

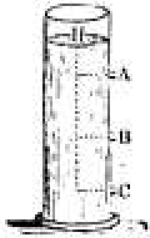

Fig. 6.

Practically, the discharge of liquids from apertures is partly affected by the shape and width of the aperture; for water is retarded by friction, and by its own impetuosity or cross currents in a small channel. It is reckoned that the pressure of water on any body plunged into it, or on the bottom or sides of the containing vessel, is about one pound on the square inch for every two feet of the depth.

Pieces of wood sunk to great depths in the ocean, become so saturated with water by the pressure of the superincumbent mass, that they lose their buoyancy, and remain at rest at the bottom. The depth to which divers can descend, is limited by the increased pressure they experience in their descent. If a bottle be firmly corked and sealed, and sunk to a great depth in the ocean, the cork will either be forced in, or the bottle broken by the pressure. An air-bell rising from a depth, expands as it approaches the surface. At the depth of a thousand fathoms, water is estimated to be about a twentieth part more dense, or compressed, than at the surface.

The great effects which may take place by the action of a small but high column of water, are sometimes exemplified in the rending of mountains. In fig. 7, a mountain or high rocky knoll is represented, with a small vertical crevice A reaching from the summit to an internal reservoir of water near the base. If there be no means of outlet to the liquid, and if rain continue to keep the crevice and its terminating reservoir full, the lateral force exerted by the upright column will be very considerable. Supposing the crevice to be an

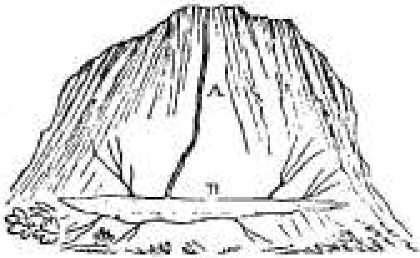

Fig. 7.

inch in diameter, and 230 feet deep, the pressure would be equal to nearly half a ton on every square inch: such a force continually acting on the sides of the mountain (laying out of view the great additional force given by expansion of the liquid in freezing during winter) would probably in time overcome the cohesiveness of the mass, and burst the whole asunder. In this property in water, therefore, we see one of the many provisions of nature for producing changes on the surface of the earth. Effects of a similar character, but on a less scale, are observable in the bursting of walls behind which earth has been piled, and in which no proper outlets for water have been provided; also in the bursting upwards of drains upon a declivity, when they become choked.

The easy motion of the particles among each other causes them to accommodate themselves to the shape of any vessel. The force of gravity also causes them to seek the lowest level for repose—each particle tries to get as low as it can. The result of this general tendency throughout the mass is a perfect levelness of surface—the top of the water is smooth.

III. *A uniform levelness of surface* takes place in every connected mass of water, whatever be its magnitude or its shape. This forms the third leading feature in the laws of water, and is the cause of many of the phenomena in nature. One of the most familiar examples of this law is that observable in a common teapot. In the representation of a teapot, fig. 8, the surface of the liquid in the pot is seen to be at A, and also at the very same height at B in the spout. A straight dotted line is drawn from the one to the other, to show that both surfaces are of the same level. It is customary to say that the small column of water in the spout balances the large mass of water in the pot; but, in reality, there is no balancing in the case. The water necessarily possesses the same surface level in all its parts; one portion cannot stand higher than another; all portions, great and small, are only distributed parts of a single mass.

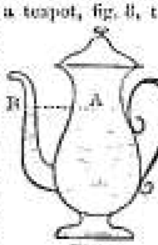

Fig. 8.

The tendency which water has to stand at the same surface level in all parts of its mass is usually referred to by the phrase, 'water finding its level.' It is this inherent tendency in water to find its level that produces the various phenomena of the trickling down of rain and moisture into the ground, the flowing of all kinds of streams, from the small brook to the mighty river, and the shooting of rapids and cataracts over precipices. In each case, the water, in obedience to the natural law or tendency which governs it, is only trying to find its level. In pursuit of this object, the water, by the rubbing force which it exercises, wears down all the solid objects which present an obstacle to it in its course. Thus the substances of which hills and plains are composed, are carried away by streams into the ocean—the ground of continents and islands diminishes in bulk—new land rises in the sea; and so, by the effects of a simple natural cause, great alterations are produced in the external features of the globe.

There are two kinds of levels—the *true level* and *natural level*.* The true level is a perfectly horizontal plane, as, for instance, an even line, thus, ——————; or a perfectly even surface of a floor.

The natural level is a surface, every point of which is at the same distance from the centre of the earth. The surface level of water is always the natural level. The character of a natural level is understood by a reference to the spherical shape of the earth and the pressure of gravitation. The globe is a ball, and any piece of water which lies upon it, lies in the form of a plaster round the ball. Water, therefore, cannot possibly have a true surface level; its level partakes of the sphericity of the ball. Every piece of water, in a state of entire or partial repose, is in this manner convex in its surface.

The degree of convexity of the earth is, as nearly as it can be stated in figures, 7 inches and 9-10ths of an inch, or nearly 8 inches, in each mile. The convexity, however, is somewhat less towards the north and south poles, because the earth is a spheroid, or a sphere flattened at the ends. The annexed diagram, fig. 9, represents a segment of the earth's surface, with the appearance of a true and natural level marked upon it. The curve ES is the earth's surface. PC is a perpendicular line pointing to the centre of the earth. At right angles from this line, a line TL is drawn, representing the true level. Supposing that the line TL is a mile in length, if we draw a line from L to the centre at C, it will cut across the surface of the earth at a point a mile distant from the line at T, which point will be 7 inches and 9-10ths depressed below the part at L.

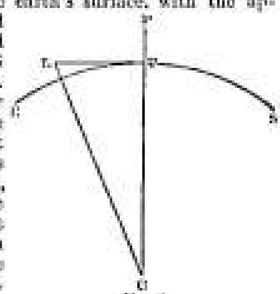

Fig. 9.

The convexity of the earth's surface is not observable in small quantities of water. The surface of a glass of water is not a true level, but the degree of convexity is so small, that it cannot be practically estimated or measured. It is only when a sheet of water is stretched out to an extent of several miles, that the convexity becomes conspicuous. It is very perceptible on the ocean when a ship is seen approaching on the horizon; first the masts and sails of the ship are seen, and lastly the hull. To catch the first glimpse of vessels at sea, the point of outlook for them is placed high above the water. By this means, the person who looks is able to see over a part of the convexity, and give information of the approach of vessels to those placed below. The convexity of the dry land is not so conspicuous, in consequence of the many risings and fallings in the surface. It is only in some extensive alluvial planes in different parts of the world that the convexity can be perceived in the same manner as at sea.

In forming roads, railways, and canals, it is necessary to make allowance for the convexity of the earth's surface. The first thing done in such cases is to survey the land by means of an instrument called a *theodolite*. One of the varieties of the theodolite is a small telescope fixed on a stand, which must, when looked through, be placed perfectly horizontal, or in a true level. To find a true level, an instrument is fixed below it, called a *spirit level*, and by that it is regulated. A spirit level is in universal request in works of art requiring level-

* In mathematics, the term *apparent level* is used instead of true level, and the term *dead level* instead of natural level.

ness of foundation or surface. It consists of a cylindrical glass tube, as in fig. 10, containing a quantity of spirits of wine sufficient to fill it, except a small part in which the air is left.

Fig. 10.

The tube being completely closed or sealed, the small vacancy where the air is left shows an air-bubble at whatever part of the tube is uppermost. The tube being set in a small wooden case with a level bottom, this case is laid upon the block of stone, wood, or other object to be levelled, and when the air-bubble is seen to rest in the middle of the upper side, it signifies that the object on which the instrument lies is a true level. In the accompanying figure, the air-bubble is seen at the middle at *b*; the slightest unevenness would cause the bubble to proceed either towards *a* at the one end or towards *c* at the other.

A true level being found for the theodolite, the surveyor looks through the glass or telescope towards a pole, the lower end of which rests on the ground, and is held in a perpendicular position by a man at (we shall suppose) the distance of a mile, previously measured. The pole having figures marked upon it, a certain figure on a level with the eye is ascertained; 7 inches and 9-10ths are then reckoned down the pole from the figure, and at that depth we have the natural level from which the surveyor makes his subsequent calculations. If a road were to be made on the plan of preserving a true level, it would proceed in its course at a tangent from the earth's convexity, like the line TL in fig. 9, and consequently would reach a point above that to which it was destined to go. It would be impossible to make the water in a canal pursue a true level; in the attempt to do so, it would not remain at rest in the channel prepared for it, but would rush towards the lower end.

As most countries are less or more irregular in surface, canals are usually constructed with different levels, so much of the length being on one level, and so much on another, as the case may be. At every change of level there is a lock, or portion enclosed with gateways, to keep the water at the proper level, and to allow the passage of vessels. The locks of a canal, therefore, are like steps of a stair, one at a greater height than another, and by their means vessels may be made to proceed up or down hill.

SPECIFIC GRAVITY.

The denser in substance that a body is, it is the more heavy or weighty, because it contains more particles to be operated upon by attraction of gravitation. In reference to the density of bodies, the term *specific gravity* is employed to denote the comparison which is made. Thus the weight of a lump of lead is greater than an equal bulk of cork; therefore its specific gravity is greater; and so on with all other substances when compared together. For the sake of convenience, pure distilled water, at a temperature of 62 degrees, has been established as a standard by which to compare the specific gravity or relative weight of solid and liquid bodies. Every such body is said to be of either a greater or less specific gravity than water, bulk for bulk.

We have an example of a difference in the specific gravities of liquids in mercury, water, oil, and spirits. Mercury is considerably more dense or heavy than any of the others; the next in density is water, then oil, and lastly spirits. If we put a quantity of each of these liquids into a glass vessel, one after the other, in the order here mentioned, we shall observe that all keep their respective places, without intermixture, the heaviest at the bottom, and the lightest at the top. Should they even be jumbled together in the vessel, it will be noticed that they in time rectify the disturbance, each assuming its own position. Again, sea or salt water, in consequence of being loaded with foreign matter, is of greater density or specific gravity than pure fresh water of the same temperature. If we therefore pour a quantity of salt water into a glass vessel, and then gently place some fresh water above it, we shall observe the same phenomenon of each kind of liquid retaining its position, the heaviest to the bottom, and the lightest to the top. Or further, if we fill a bottle with water, and dip it with the open mouth downwards into a jar or barrel of spirits, the water, in virtue of its density, will be emptied, and sink into the spirits, and the spirits will immediately rush up into the empty bottle, and supply the place of the water.

The force which liquids exert in opposing each other in a state of equilibrium, corresponds to their specific gravities; in other words, a small quantity of a heavy liquid will balance a much greater quantity of a lighter liquid. For example, take a bent glass tube, as in fig. 11, and pour as much water into it as will extend from the bottom at E to A. This quantity of water will be balanced or kept to its summit level at A by a quantity of mercury measuring from E to B, or by a quantity of oil from E to C, or by a quantity of spirits from E to D. Each of these experiments may be performed one after the other. The pressure of liquids being as the vertical height, and not as breadth, it would make no difference in the result of the experiments if the limb of the tube for the mercury, oil, or spirits, were increased to a foot, a mile, or any other diameter.

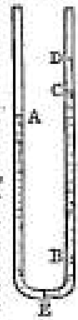

Fig. 11.

Water, at its ordinary temperature of 62 degrees, has a specific gravity of 1000 ounces to the cubic foot. Platinum is 22¼ times heavier, or 22¼ times the specific gravity of water; gold is 19½, mercury 13½, copper 8¾, iron 8, common stone about 2½, and brick 2. Alcohol is a little more than 8-10ths of the heaviness or specific gravity of water, or 0·815; and oil of almonds is a little more than 9-10ths, or 0·915. Atmospheric air at the earth's surface is 1-800th part, or 0·00125; in other words, while a cubic foot of water weighs 1000 ounces, a cubic foot of air weighs one ounce and a quarter. For an ampler list of specific gravities, see Laws of Matter, p. 198.

Though by no means of uniform constitution, the average specific gravity of sea water may be stated at 1·035—that is, to 1000 parts of fresh water there are, in addition, 35 parts of saline substances. Sea water being therefore 35 parts for every 1000 of water more dense than fresh water, it possesses a proportionally greater power of buoying up bodies. A vessel which will carry 1000 tons on fresh water, will thus carry 1035 tons on the sea.

FLUID SUPPORT.

The immersion of solid bodies in liquids develops some important principles in hydrostatics. Any body of greater specific gravity than water, bulk for bulk, will sink on being thrown into water; but a body will float if its specific gravity be less than that of water. The mode of stating the law in reference to the immersion and floating of solid bodies in any kind of fluids is as follows :—

First.—Any solid body immersed in a fluid displaces exactly its own bulk of fluid, and the force with which the body is buoyed up is equal to the weight of the fluid which is displaced; therefore the body will sink or swim, according as its own weight is greater or less than the bulk of displaced fluid. This refers to bodies of less density than water.

Second.—Any solid body of a greater density than water, when wholly immersed in that fluid, loses exactly as much of its weight as the weight of an equal bulk of the water—that is, of the water which it displaces.

It is of great importance that these propositions should be fully comprehended, for they explain innumerable phenomena in nature in reference to the floating or swimming of bodies in water or in the atmosphere. Water, as has been explained, consists of innumerable small particles pressing in all directions, or upwards as well as downwards. Let us fix our attention on a supposed single particle in the mass: while the liquid is in a condition of repose, we may imagine the particle to be sustained between contending forces—the force of a column of particles above, and the equally strong force of particles beneath, pushing to get upward or away from this column.

Let us now substitute any solid object for the supposed particle; for example, the quadrangular object AB represented in a vessel of water, fig. 12. This object, supposed to be of the same density as water, which we see is sunk in a buoyant condition in the water, has displaced a mass of particles, all of which were operated upon in the manner of the supposed single particle. This object, then, by taking the place of the mass of particles, has become subject to the same contending forces, and is consequently floated or sustained to the same extent as they were. If we suppose that the weight of the object is two pounds, liquid to the amount of two pounds is displaced, and the object is pressed upwards with the force of two pounds. Or, to vary the example—suppose that only the lower half beneath the line C is the solid object, and that the space occupied by the upper half is water, the object is still pressed upwards with a force of two pounds; but being one pound weight in itself, and having a pound of water above it, it remains suspended in equilibrium.

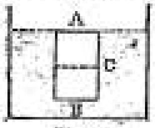

Fig. 12.

These examples refer to bodies which are of the same density or weight as water, bulk for bulk; we shall now take an example of a body specifically lighter than water, by which it will be observed that the buoyancy is governed by the same principle:—Fig. 13 represents a solid object AB half immersed in a vessel of water. In this, as in all cases in which there is a portion of the object above the water, the weight of that portion is borne by, and therefore conveyed to, the portion which is immersed. Thus, in the example before us, the portion B, though less than a pound weight in itself, by supporting A, becomes, we shall say, a pound, and displaces a pound of water; it is therefore buoyed up with the corresponding force of a pound.

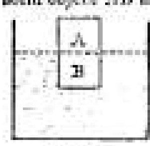

Fig. 13.

Whether a body be large or small in bulk in proportion to its weight, its displacement of water depends exclusively on its weight, so long as it is not heavier than water. A vessel of cork, wood, or any substance lighter than water, weighing a thousand tons, displaces exactly the same weight of water, or is buoyed up with the same degree of force.

From these circumstances, it appears that the entire weight of any *floating* body may be calculated by measuring the quantity of water which it displaces. On immersing a stone, or any other solid object, in water, it is found to be buoyed up in proportion as its specific gravity is less than that of water. If its specific gravity be greater than water, it will sink to the bottom, and if less, it will swim. As the water of the ocean becomes of greater specific gravity the greater the depth, it may happen that an object which sinks at the top of the water, will remain suspended in equilibrium when it descends to a point at which the specific gravity of the water is equal to its own.

Whatever be the weight of any solid object when weighed in air, its apparent weight is lessened when weighed in water. Thus a stone may be moved with comparative ease in water, which cannot be lifted without considerable difficulty on land. The apparent diminution of weight in these cases is caused by the support afforded by the liquid. Attraction of gravitation, which is the cause of what we call weight, is counteracted more in water than in air, because the water has a tendency to buoy up the object. The weight of any object in water is thereby lessened to the extent of the weight of a bulk of liquid equal to the size of the object. If the object displace a pound of water, it will weigh a pound lighter in water than in air.

The circumstance of any solid object displacing its own bulk of liquid, and losing exactly as much of its weight as the weight of that bulk of liquid which it displaces, has led to the use of the *hydrostatic* or *water balance*, for ascertaining the intrinsic value of gold and other precious metals. For example, by knowing, in the first place, how much water a pound of pure gold displaces, and then weighing in water, as in fig. 14, an object said to be a pound of gold, we should observe whether it displaced the proper quantity of water; if it displaced more than was proper, then we should be certain that it contained alloy, or some inferior substance, being too bulky for a pound of gold. Such weights are used by goldsmiths.

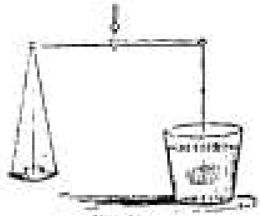

Fig. 14.

Thus if a piece of gold weigh 19¼ ounces in air, it would weigh only 18¼ ounces in water; the ounce of weight thus counteracted being just the weight of the water that the gold displaces. Therefore the weight of the gold would be to that of the water as 19¼ ounces to 1 ounce; that is, the specific gravity of gold is 19¼, if water is taken for the standard.

We may cause an object, such as a light hollow ball or bladder, to displace much more water than what is equal to its own weight; but in doing so, we must press the ball into the water, and that degree of pressure compensates the deficiency of weight in the ball. Thus extraneous pressure on a floating body, and weight in the body itself, are the same thing as respects buoyancy.

The human body, in a state of health, with the lungs full of air, is specifically lighter than water, and more so in the sea than in fresh water. Persons, therefore, on going or falling into water, cannot possibly sink, unless they struggle so as to prevent the liquid from buoying them up. The body will float with a bulk of about half the head above the surface; and thus a person who cannot swim may live and breathe, until chilled, or otherwise paralysed, by simply stretching himself on his back, and lying with his face above the water. By throwing the arms out of the water, the body does not displace so much liquid; its weight is increased, and it naturally sinks. Ignorance of these facts, and want of resolution, cause many deaths by drowning.

There are various kinds of apparatus for preventing drowning, called life-preservers. The most common are those which consist of pieces of cork, or other very light material, attached to the upper part of the body. But air-tight bags are preferable, as they may be said scarcely to encumber the body when empty, and, as danger approaches, they can be inflated with ease by being blown into. Life-boats have large quantities of cork in their structure, and also air-tight vessels made of thin metallic plates; so that, even when the boat is filled with water, a considerable portion of it still floats above the general surface. The bodies of some animals, as sea-fowl, and many other species of birds, are considerably lighter than water. The feathers with which they are covered add very much to their buoyancy. Quadrupeds swim much easier than men, because the natural motion of their legs in walking or running is that which best fits them for swimming. Fishes are enabled to change their specific gravity by means of an air-bag with which they are provided. When the air-bag is distended, they rise to the surface; and when it is contracted, they descend to the bottom.

The buoyant property of liquids is independent of their depth or expanse; for if there be only enough of water to surround an object plunged into it, the object will float as effectually as if it had been immersed in a large mass of water. Thus a few pounds of water may float an object which is a ton in weight. We account for these phenomena by the law of pressure in liquids being as vertical height, not as width of column, and by a body being buoyed up with a force exactly in proportion to the weight of water which it displaces. These important truths in hydrostatics teach the practical lesson, that if canals be made only as deep or wide as will afford water to surround the vessels placed upon them, they will be sufficiently large for all purposes of buoyancy and navigation. A ship floats no better on the face of a sheet of water miles in width, than it would do on a mill-pond, provided there be enough of water in the pond to keep it off the bottom.

Every solid body possesses a *centre of gravity*, which is the point upon or about which the body balances itself, and remains in a state of rest or equilibrium in any position. The equilibrium of floating bodies is regulated in the same manner. The floating body has a centre of gravity, about which the whole mass will balance itself in the liquid; the heaviest side will sink lowest, and the more light will be uppermost.

In reference to floating bodies, there is a point called the *centre of buoyancy;* this is the centre of gravity of the liquid which is displaced. If the floating body be of the same specific gravity as water, then the centre of buoyancy will be at the same point in the floating body, as it would have been in the water; but there is seldom this uniformity, at least not in vessels used for purposes of navigation. It is necessary that all such vessels should be of a less specific gravity than water, in order that a part of their weight may be composed of cargo, stores, passengers, &c. and that they may be sufficiently buoyant. Heavy materials, called ballast, are usually placed in the bottom of the holds of vessels, to insure a low centre of gravity. A ship of the largest capacity and burden, with its centre of gravity properly regulated, rests in the water with a stateliness and stability which cannot be destroyed, except by some extraordinary violence.

HYDROMETERS.

If a substance be weighed in two fluids, the weights which it loses in each are as the specific gravities of those fluids. Thus a cubic inch of lead loses 253 grains when weighed in water, and only 209 grains when weighed in rectified spirit; therefore a cubic inch of rectified spirit weighs 209 grains, an equal bulk of water weighing 253; and so the specific gravity of water is about a fourth greater than that of the spirit.

The instrument called a *hydrometer* is constructed upon this principle. Its name is derived from two Greek words, signifying *measure of water;* but it is of course used for ascertaining the density of all kinds of liquids. There are various kinds of hydrometers. One of them consists of a glass or copper ball with a stem, on which is marked a scale of equal parts or degrees. When immersed in any fluid, the stem sinks to a certain depth, which is indicated by the graduated scale. The depth to which it sinks in the standard of comparison being known, we can thus easily ascertain how much it is specifically heavier or lighter than the fluid.

Fig. 15.

Much in the same manner is constructed another hydrometer of great delicacy and exactness. It consists, fig. 15, of a ball of glass, *b*, about three inches diameter, with another, *c*, joined to it, and opening into it, of one inch diameter, and a brass neck *d*, into which is screwed a wire *ac*, divided into inches and tenths of an inch, about ten inches long and one-fortieth of an inch in diameter. The whole weight of the instrument is 4000 grains when loaded with small weights, such as shot, in the lower ball *c*. When plunged into water in the jar, this instrument is found to sink an inch if a single grain be laid upon the top *a*; hence a tenth of a grain sinks it a tenth of an inch. So great is the delicacy of this hydrometer, that the difference in specific gravity of one part in 40,000 can be detected. Its total weight of 4000 grains is convenient for comparing water; but the quantity of shot in the lower ball can be varied, so as to adapt the instrument to measure the specific gravities of fluids lighter or heavier than the standard of comparison.

There is another very simple hydrometer, which consists of a number of glass beads of different weights, but whose proportions are known, and the beads marked accordingly. These are dropped into the fluid under examination, until one is found which neither sinks to the bottom nor swims upon the surface, but remains at rest wherever it is placed in the liquid; and this bead being numbered, indicates the specific gravity.

In making calculations of the strength and specific gravity of spirits by the above or any other means, attention must be paid to the degree of temperature of the liquid. Heat expands the liquor, and renders it specifically lighter; all spirits are therefore more bulky, in proportion to their weight, in summer than in winter, and also *apparently* stronger, not really so.

HYDRAULICS.

Having detailed the laws and properties of water in a state of rest or equilibrium, we have now to mention some of the most important results of these laws, and also the effects which are produced upon liquids by the application of forces, whether natural or artificial.

WATER A MECHANICAL AGENT.

Water, as already explained in the LAWS OF MATTER AND MOTION, may be made a useful agent of power, merely by allowing it to act with the force of its own gravity, as in turning a mill; and in this manner it is extensively employed in all civilised countries possessing brooks which are sufficiently rapid in their descent. But water may be rendered otherwise useful as an agent of force in the arts. Although subtile in substance, and eluding the grasp of those who desire to handle and hold it, it can, without alteration of temperature, be made to act as a *mechanical power*, as conveniently and usefully as if it were a solid substance like iron, stone, or wood. The lever, the screw, the inclined plane, or any of the ordinary mechanical powers, are not more remarkable as instruments of force than water, a single gallon of which may be made to perform what cannot be accomplished (except at enormous cost and labour) by the strongest metal.

To render water serviceable as an instrument of force, it must be confined, and an attempt then made to compress it into less than its natural bulk. In making this attempt, the impressed force is freely communicated through the mass, and in the endeavour to avoid compression, the liquid will repel whatever movable object is presented to it. The force with which water may be squirted from a boy's syringe, gives but a feeble idea of the power of liquids when subjected, in a state of confinement, to the impression of external force.

The mechanical force of water is exemplified by the hydraulic press. This is an engine employed by paper-makers, printers, and manufacturers of various kinds of goods, for the purpose of giving a high degree of pressure or smooth glazed finish to their respective articles. It has generally superseded the screw press, on account of its much greater power, with a less degree of trouble and risk of injury to the mechanism. Fig. 16 represents the outline of a hydraulic press. AB is the frame, consisting of four upright pillars supporting a cross top of great strength, and against which the pressure takes place in an upward direction. C, the material to be pressed, is forced upward by D, a round iron piston. This piston is very nicely fitted into an iron case E, which has a cavity F for receiving the water; the neck of the case grasps the piston so tightly, that no water can escape. A small pipe G conveys water into the hollow cavity from a forcing-pump H, which stands in a trough of water T. All that part of the apparatus below the base of the pillars is sunk out of sight in the ground. The pump apparatus is here represented as exceedingly simple, but in real machines it is very complex, and of great power. The pump, on being wrought, forces the water into the cavity. There the water, in endeavouring to escape, operates upon the movable piston, which it causes slowly to rise with its burden. The pressure thus exerted by the liquid almost exceeds belief: unless the case for the water be of enormous strength, it will be rent in an instant, as if made of the weakest material. When the weight has been raised to the required height, a stopcock is turned upon the pipe, and the apparatus remains at rest. The opening of the cock allows the water to gush out, and the weight accordingly sinks.

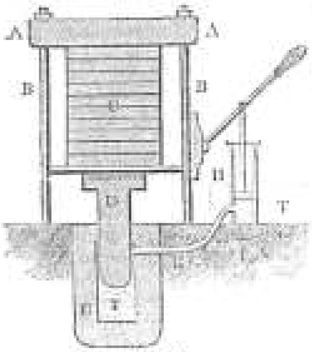

Fig. 16.

The mode of calculating the power of the hydraulic press is analogous to that for calculating lever powers. Thus the proportion is estimated between the small bore of the pump and the large bore of the cavity or barrel for the piston. Suppose that the pump has only one thousandth of the area of the barrel, and if a man, by means of its lever handle, press its rod down with a force of five hundred pounds, the piston of the barrel will rise with a force of one thousand times five hundred pounds, or more than two hundred tons. A boy working the pump by a long handle or lever, and taking a sufficiency of time, will raise a pressure of thousands of tons.

In the hydraulic press, a force-pump is employed for the sake of convenience; the same end could be attained by a small column of water of a great elevation, on the principle of pressure in liquids being as vertical height.

AQUEDUCTS—FOUNTAINS.

The tendency in a liquid to find its level, has permitted the construction of apparatus, consisting of pipes and cisterns, for supplying towns with water. No species of hydraulic machine has been of such great use to mankind as this apparatus.

In ancient times, the fact of water rising to a uniform level in every part of its volume, was either not perfectly understood, or there was a deficiency of materials wherewith to construct the apparatus required for carrying water a great distance. From whatever cause, towns were in these times supplied with water by means of open canals, either cut in the level ground, or supported on the top of arches built for the purpose. These structures, with their elevated channels, were called aqueducts. In Italy, and some other countries in the south of Europe, the remains of stupendous aqueducts, miles in length, still exist.

By a knowledge of the laws of fluids, and by possessing an abundance of lead and iron, we are enabled, in the present day, to construct apparatus for supplying towns with water in a manner the most effectual and simple; causing a cheap iron or leaden tube, sunk in the ground, to perform the office of the most expensive and magnificent aqueduct. The method of supplying towns with water consists in leading a pipe, of sufficient diameter, from a lake, river, or fountain of fresh and pure water, to the place where the supply is required. The iron pipes used for this purpose are composed of a number of short pieces soldered together, and extending to any length, or in any direction. From these main pipes smaller tubes of lead are led into the houses requiring the supply of water; and by means of these minor tubes, the water may be carried to any point which is not of a higher level than the original fountain affording the supply.

Fig. 17 is a representation of the mode of supplying towns with water in this convenient manner. A pipe is observed to proceed from a lake on the top of a hill down into a valley, and thence to supply a house situated on the opposite rising ground. From the pipe, in its passage across the valley, a small tube is carried to supply an ornamental fountain or jet d'eau. The water spouts from this jet d'eau with a force corresponding to the height of the lake above.

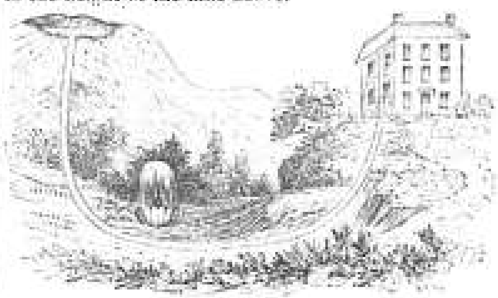

Fig. 17.

In towns not commanding a supply of water from a sufficient height, the water is forced by an apparatus of pumps to an elevated reservoir, and from that the pipes are laid. When the water is impure, or loaded with muddy particles, it is usual to purify it by filtration at the reservoir; it is made to filter or ooze through a mass of fine sand, in which the particles of mud are deposited.

Springs in the ground are natural hydraulic operations, and are accounted for on principles connected with the laws of fluids. One kind of springs is caused by capillary attraction, or natural attractive force by which liquids rise in small tubes, porous substances, or between flat bodies closely laid towards each other. This species of power is a remarkable variety of the mutual attraction of matter, and is as unaccountable as the attraction of gravitation, or the attraction exercised by the loadstone. Springs from capillary attraction are believed to be less common, and of smaller importance, than springs which originate from the obvious cause of water finding its level. The water which falls in the form of rain sinks into the ground in high situations, and finds an outlet at a lower level, though perhaps at a considerable distance.

Some springs are also accounted for by a reference to atmospheric action, but these will form a subject of notice under the head PNEUMATICS.

FRICTION BETWEEN FLUIDS AND SOLIDS.

The flowing of water through pipes, or in natural channels, is liable to be materially affected by friction. Water flows smoothly, and with least retardation from friction, when the channel is perfectly smooth and straight. Every little inequality which is presented to the liquid helps to retard it, and so likewise does every bend or angle in its path. A smooth leaden pipe will thus convey more water than a wooden pipe of the same capacity. Practically, an allowance is made in the magnitude of pipes for the loss of speed by friction. Where the length of the tube is considerable, and there are several bendings, it is not unusual to allow a third of the capacity for retardation. By increasing the capacity of pipes, a prodigious gain is secured in the transmission of water. The loss from friction on a small tube of an inch diameter of bore is so great, that one of twice the capacity will deliver five times as much water.

The rate at which water flows from an orifice in a reservoir, or containing vessel, is affected by the situation and the shape of the orifice. The most favourable situation for the orifice is at the bottom of the vessel; but the velocity of the emission is not in the ratio of the height of the liquid, or of a perpendicular column of particles; for as the water presses in all directions alike, there is from all parts of the vessel a general rush, as it were, to the outlet, thus putting the whole mass in motion.

Although the rush of water at the outlet is not as the ratio of the depth, it depends upon the depth. Thus if a vessel ten feet high be penetrated at the side on a level with the bottom, and the water stand at two feet and a half within, it will issue outwards with a certain degree of velocity. If the height of the water be quadrupled—that is, if the vessel be filled—the velocity will be doubled. In order to obtain a threefold velocity, a ninefold depth is necessary; for a fourfold velocity, sixteen times the depth is required; and so on. In fact, in whatever proportion the velocity of efflux is increased, the quantity of liquid discharged in a given time must be also increased in the same proportion; hence the quantity of water discharged conjointly with its degree of velocity will be increased in proportion to the pressure. There is here a striking coincidence between the descent of water and the relation which exists between the height from which a body falls and the velocity acquired at the end of the fall.

It has been ascertained that water rushes with most advantage from an orifice, when the orifice is in the form of a short round tube inserted into the vessel, and of a length equal to twice its diameter.

It has also been found that if the pipe, instead of being flush or level with the bottom of the reservoir, entered into it to some distance, it had the effect of making the flow of water even less than that which issued through the simple hole without any pipe. The singular fact of a pipe and hole of the same diameter discharging different quantities of water under different circumstances, whilst the head or pressure remains the same, must be accounted for by cross or opposing currents being created by the rush which all fluids make to the orifice. Currents will thus form from the top and sides of the containing vessel, and by their inertia they will cross each other, and thus impede the descent of the perpendicular column, causing the water which issues to run in a screw-like form; this, however, is in a great measure obviated by the application of a short tube from the aperture. That the projection of the tube too far into the interior of the vessel should make the flow less than if there were no pipe at all, may be thus explained:—The columns which descend from near the outside of the vessel, by turning up again to reach the discharging orifice, come into more direct opposition to the motion of the central descending columns, whilst they are at the same time themselves compelled to turn suddenly, in opposition to their own inertia, before they can enter the pipe. Thus the discharge is more effectually impeded than if it were proceeding from a simple opening in the bottom of the vessel.

The tube for the discharge of water should not only be short and round, but also trumpet-mouthed or funnel-shaped, both internally and externally, that being the form which admits the flow of liquid with the least possible retardation.

The effects of friction between liquids and solids are nowhere so conspicuous as in the flowing of rivers. The natural tendency in the water to descend at a certain speed, is limited by the roughness of the bottom, bends in the course of the stream, and small projections on the banks. From these causes, the water in a river flows with different velocities at different parts in any vertical section across the current. It flows at a slower rate of speed at and near the bottom than at the surface, and also slower at the sides than at the middle.

The resistance which a body moving in liquid meets with when it comes in contact with a solid, is as the square of the velocity of the moving body; in other words, the resistance is not twice, but four times, with a double rate of speed. This is easily explained:—A vessel moving at the rate of one mile per hour displaces a certain quantity of water, and with a certain velocity; if it move twice as fast, it of course displaces twice as many particles in the same time, and requires to be moved by twice the force on that account; but it also displaces every particle with a double velocity, and requires another doubling of the power on this account; the power thus twice doubled becomes a power of four. When the body is moved with a speed of three or four, a force of nine or sixteen is wanted, and so on. Thus the resistance increases as the square of the speed.

This important law suggests practical hints of considerable importance. For instance, in steam navigation, if an engine of fifty-horse power impel a vessel at the rate of seven miles an hour, it would require two of the same power to drive her ten miles an hour, and three such to drive her twelve miles an hour; hence the enormous expense of fuel attending the gaining of a high degree of velocity.

REACTION FROM THE EFFLUX OF FLUIDS.

If we suppose a vessel filled with water, the mass will be at rest, as every lateral pressure is counteracted by a perfectly equal but opposite one. But if an opening or orifice is made in any of the sides of the containing vessel, then the water will rush forth, and the pressure will evidently be removed at this spot, whilst the portion of the side diametrically opposite to the orifice continues to be pressed upon as strongly as ever. The consequence will be, that the whole vessel and its contents, if left free and unobstructed by friction, will move in a direction opposed to the direction in which the stream of water rushes out. This result may be compared to the recoil experienced in firearms, and has been taken advantage of as a motive force, though as yet with little practical benefit. The wheels or machines moved by this curious force are generally known as 'Barker's or Segner's water-mills,' and are variously constructed. In the accompanying diagram, fig. 18, the apparatus consists of a vertical tube AB, moving freely on a pivot C, and receiving a supply of water from a stream D. This water is discharged by two opposite horizontal arms ee', the jets issuing in contrary directions, and by their reaction causing a rapid rotatory motion of the whole machine. In practice, it is found more advantageous to reverse the apparatus, and compel the water to enter from below, by which means the friction occasioned by the weight of the main tube and its contained water is avoided.

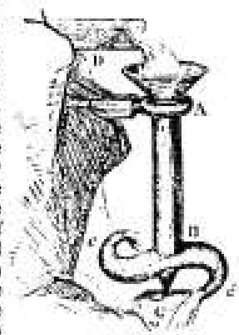

Fig. 18.

ACTION OF WATER IN RIVERS.

In cases where it is desirable to preserve the banks of rivers from injury, either from the regular action of the current or from floods, the water ought to be allowed a free open channel, with banks of a very gradual descent. The utmost violence of water in a state of motion may be rendered comparatively harmless, by allowing the flood or torrent to expand itself on a sloping or shelving shore. Inattention to this simple fact in hydraulics frequently causes much destruction to property on the banks of rivers.

A very small fixed obstacle, such as a stone or pebble, may partially impede and turn aside a brook of a slow current. The water, by striking on a stone at one side, is bent aside to the opposite bank, a little farther down; there it strikes upon the bank, and is returned to the side it formerly struck. Thus proceeding in currents from side to side, the banks become worn down at particular places, and in time a new and serpentine course is given to the stream. In the case of rivers flowing with considerable velocity, impediments of this kind are usually overcome, and the stream pursues its straight onward course, dashing down all obstacles to its progress. Thus rivers are generally winding in their course in flat countries, and straight in mountainous regions. (See GEOLOGY, p. 18.)

It sometimes happens that the water at the surface of a river may be moving in one direction, while the water at the bottom is flowing in an opposite direction. This is an exceedingly interesting phenomenon, which is observed to occur in certain rivers communicating with the sea, and is caused by the action of the tides, and the difference of specific gravity in salt and fresh water. When the tide is flowing inwards, the salt water rushes up the channel of the river, but not in such a manner as to stem the current of fresh water, which, being lighter, floats on the top of the salt water, and pursues its downward course to the ocean. In those instances in which there is no great disturbance of the two liquids, the fresh water, by its specific lightness, floats on the surface of the sea to a distance of many miles from the land.

WAVES.

Waves are the risings and fallings of the water, caused by some power, such as the blowing of the wind. The power, whatever it happen to be, communicates a force to the mass of liquid, and a series of undulations is the consequence.

These undulations or waves exhibit the transmission of the communicated force. The force does not advance or alter the lateral position of the water at any given point; it only alters the water in its vertical position, or in relation to its depth. When, therefore, waves advance, the water does not advance with them: the water but rises and falls, and assumes the figure of undulations on its surface. When the undulations approach the shore, the water then acquires a progressive motion, where it is shallow; and by friction on the bottom, or impulsion against the shore, the communicated force is exhausted. The shaking of a carpet affords an exact representation of the action of waves or undulations.

Waves are comparatively superficial; they seldom, even in the greatest storms, rise to a height of more than twelve feet above the level of calm water, and make an equal descent beneath, making altogether an appearance of twenty-four feet: at eight or ten feet below the intervening hollow or trough of the waves, the water is tranquil. Waves 'mountains high' is only a figure of speech.

ALTERATION OF TEMPERATURE.

By altering the temperature of liquid bodies, they become liable to peculiar laws, and exhibit peculiar phenomena.

At a temperature of 40 degrees of Fahrenheit's thermometer, water is at the point of greatest density. When the temperature is reduced below this point, the liquid gradually increases in volume till it reaches 32, when it freezes. When the temperature is raised above 40, the volume increases till it reaches the boiling-point, at which it has expanded to the extent of 1-23d additional to its bulk.

In consequence of this expansibility in heating, hot or warm water is specifically lighter than cold water; therefore, in heating any mass of water in a vessel over a fire, the lighter or warmed particles rise to the top, while the cold and heavy particles sink to the bottom, to be heated and to rise in their turn. In this manner the process of heating proceeds, until all the particles are of a uniform temperature, which is at the boiling point, when the liquid gradually flies off in steam.

If water be heated by the action of fire or the sun's rays on its upper surface, the mass is longer in attaining the vaporific point than when heated below, because water is a bad conductor of heat, and therefore the heat penetrates with difficulty through the upper stratum of warmed liquid to reach that which is beneath; and if the mass be very large—as, for instance, the ocean—no intensity of heat applied above can warm it throughout, or to any considerable depth.

Certain currents or sets of the ocean are known to be produced by the effort to attain an equability of temperature throughout. The power of the sun's rays at and near the equator heats the sea in that part of its volume to the depth of two or three hundred feet. This upper stratum of heated water flows in currents towards the north and south poles, and there, to a certain extent, tempers the severity of the cold. The waters of the northern and southern tracts of ocean, displaced by these currents, necessarily sink below them, and push on towards the equator, to supply the deficiency caused by the departure of the waters above. Thus in the economy of nature, we see a process in constant action precisely the same in principle as that upon which the artificial hot-water apparatus has been established.

PNEUMATICS.

Pneumatics, from the Greek word *pneuma*, breath or air, is the name of the department of science which relates to the weight, pressure, or motion of air, or of any aëriform or gaseous fluid.

It was anciently supposed that the air of the atmosphere was an element or simple substance in nature. It is now satisfactorily established that air is not an elementary body, but is composed of certain gases (almost wholly of nitrogen and oxygen, as explained under METEOROLOGY) in intimate union, and these gases can be separated from each other by a simple chemical process.

Air, in its common condition, is a thin transparent fluid, so subtile, that it cannot be handled, and when at rest, it cannot be felt. That it is a body, however, is quite obvious, because we feel its impression or force when agitated as wind, or when we wave our hand quickly through it. In the quick motion of the hand, we feel that it is partially opposed by something; and in inhaling breath into the lungs, we feel that we are drawing something through the mouth—that *something* is atmospheric air.

Air, like every other substance, whether solid or fluid, possesses a certain gravity or weight. The weight of air certainly, bulk for bulk, is much less than that of water; still the weight may be accurately computed. A bottle full of air weighs heavier in a balance than a bottle of the same capacity from which the air has been extracted. A cubic foot of water, as has been mentioned, weighs 1000 ounces. A cubic foot of air weighs only 523 grains, being a little more than one ounce; water, therefore, is about 840 times heavier than the air of our atmosphere. Inasmuch as water is a standard for comparing the gravities of liquids, air is a standard in the same respect for all aërial substances.

The specific gravity of air being denominated 1000, oxygen gas is 1111; nitrogen gas 972; hydrogen gas 69; and carbonic acid gas 1529. The lightest of these kinds of gas, therefore, is hydrogen, and the heaviest carbonic acid. Hence, if indefinite quantities of these aëriform bodies were placed in a vessel, or in an apartment, we should find that, after certain portions had gone into intimate union, according to the laws by which they combine, the surplus portions of each would assume relative positions according to their respective weights—the heaviest to the bottom, and the lightest to the top. Such an experiment would resemble that previously noticed of the mixture of mercury, oil, water, and spirits.

Air, and all kinds of gases, are rendered lighter by the application of heat, for then the particles in the mass are repelled from each other, and occupy a greater space; this process of lightening or thinning is called rarefaction. Rarefied air, being specifically lightest, mounts above that of a common density. The warmest air is always at the top of a room, and the coldest at the bottom.

Air is distinguished from water not only by its extreme comparative lightness, but by the property of elasticity; it is a compressible and elastic fluid. When any quantity of air is compressed into a smaller space than it naturally occupies, it will return to its natural bulk on the pressure being withdrawn. A small bladder of air may be squeezed between the hands so as to be considerably reduced in size; and on opening the hands again, and withdrawing the pressure, it will instantly resume its former bulk. If a metallic tube or barrel be fitted with a movable plug or piston, which is made to work in it perfectly air-tight, the air which occupies the space between the top and the bottom of this barrel when the piston enters, can be compressed to a hundredth part, or even less, of its usual bulk. If the force, however, by which the piston is pushed down be withdrawn, the air, by its elasticity, will force it up again with a power equal to that by which its descent was resisted. In proportion as any given volume of air is diminished by pressure, its elastic force is increased; in other words, the elastic force or elasticity of air is proportional to its density.

THE ATMOSPHERE.

The air, as formerly explained, is a great ocean wrapped round the earth to a depth of from forty to forty-five miles above the highest mountains, and forms a menstruum which is essential to the existence of all animals and plants. This ocean of air penetrates into all unoccupied places, in the same manner as water flows into all crevices and holes beneath the level of its surface; and it also finds a place in the bodies of animals, plants, and liquid substances: hardly anything, indeed, that we see in nature or art is free from air, unless force has been employed to extract it.

The height of the atmosphere, though usually estimated at forty or forty-five miles, is in reality unknown. The highest point above the level of the sea which has ever been reached by any human being, is 21,000 feet, which has been attained in a balloon. It is only conjectured, from the refraction of the sun's rays and other circumstances, that the height of the atmosphere is about forty-five miles. At and near the level of the ocean it is most dense, in the same manner as water at the bottom of the sea is more dense than it is at the surface, on account of the incumbent pressure. As we ascend mountains, or in any other way penetrate upwards into the atmosphere, the air becomes gradually less dense; and so thin is it at the height of three miles on the summit of Mont Blanc, that breathing is there performed with some difficulty. Beyond this limited height the density of the air continues to diminish, and at the elevation of about forty-five miles it is believed to terminate. (See Nos. 3 and 4.)

The extreme height of the atmosphere is not observable from the situation in which we are placed on the earth. Our eye, on being cast upwards, perceives only a vast expanded vault, tinted with a deep but delicate blue colour; and this, in common language, is called the sky. The blueness so apparent to our sense of sight is the action of the rays of light upon the thin fluid of the upper atmosphere, and the brightness is in proportion to the absence of clouds and other watery vapours. In proportion as the spectator rises above the surface of the earth, and has less air above him, and that very rare, the blue tint gradually disappears; and if he could attain a height at which there is no air, say at above fifty miles in height, the sky would appear perfectly dark or black. Travellers who have ascended to great heights on lofty mountains, describe the appearance of the sky from these elevated stations as dark, or of a blackish hue.

The atmosphere possesses the capacity of absorbing and sustaining moisture, but only to a limited extent. When saturated to a certain degree, it is relieved by the falling of the moisture in the form of rain. It is calculated that the whole atmosphere round the globe could not retain at one time more moisture than would produce about six or seven inches of rain.

By an elevation of temperature, the capacity of the atmosphere to absorb and sustain moisture is increased, and by a lowering of temperature, decreased. Cold breezes, by lowering the temperature of the air, cause the aeriform moisture to assume the appearance of clouds, and then to fall as rain.

LAWS OF AIR.

First—The pressure of the air is equal in all directions: *Second*—Its degree of pressure depends on the vertical height or depth, and at any place is proportional to its density: *Third*—Its surface is level in all parts of its volume: *Fourth*—It affords support according to its density and to the weight of the fluid displaced.

That air presses equally in all directions, may be rendered evident by filling a bladder with that fluid, and then pressing upon it so as almost to make it burst. The pressure is freely communicated through the mass, as in the case of the bag of water, and it will be observed that the confined air will rush out with equal impetuosity at whatever part the bladder is punctured.

The level of surface of air is less perfect than the uniform level of water, on account of the greater elasticity of the substance. In a series of strata of air of different densities, one above the other, a small portion of each mingles with those which immediately adjoin it—the particles of one commingle to a certain extent with those of another. There is thus, as respects aërial bodies, a modification of the law of uniform levelness of surface in all parts of the volume of fluid.

PRESSURE OF AIR.

The pressure depending on the vertical height or depth of air is an important property in the atmosphere, and on it depends the explanation of numerous phenomena. Air being a substance possessing gravity, it must of necessity press downwards in the direction of the centre of the earth, and therefore the degree of pressure on any given point will be equal to the weight of the column of air above the point, and proportional to the density of the air at that point.

The idea of the atmosphere possessing the property of gravity or pressure is of comparatively modern date. No such notion was entertained by the ancients, in consequence of living animals being observed to move with perfect ease in all directions, and because there was no other appearance in nature calculated to suggest it to their minds. It was, however, remarked, that when the air was sucked out of a small glass tube, the lower end of which was immersed in water, the water rushed up into the tube, and occupied the situation of the displaced air. In consequence of this and similar phenomena, it was alleged as a doctrine in physics, that 'nature abhors a vacuum.' A vacuum is a space destitute of air or any other kind of matter; and the notion was, that whenever by any chance such an empty space was found, nature interposed, with all imaginable haste, to fill it. With this very rude idea, pumps were formed to raise water—the rising of the water in these instruments being ascribed simply to nature's abhorrence of a vacuum. At length it was discovered that water could not be drawn up by a pump above a height of about thirty-two feet, and that a vacuum above that elevation remained unfilled; whereupon the terms of the doctrine were changed, and it was said that nature abhorred a vacuum only to a height of thirty-two feet, but no further.

This explanation was seemingly unphilosophical, and men's minds being carefully turned to the subject, various experiments were performed, and the important truth became manifest, that the atmosphere possessed gravity or pressure; also that that pressure was the sole cause of the rushing of liquids into tubes exhausted of air—the height of the ascending liquids being in every case limited by the degree of pressure of the incumbent atmosphere. Thus the discovery of a simple truth in science at once abolished the fantastic doctrine of nature's abhorrence of a vacuum, and all the laboured sophistry with which it was supported.* Nature has no dislike to a vacuum; a vacuum will occur in all situations from which solids or fluids are accidentally or artificially excluded.

The degree of pressure imposed by the atmosphere on any given spot on the earth's surface, as already noticed, is equal to the weight of the column of air above that spot, and is also proportional to the density of the air at the place. The atmosphere is deepest, or of greatest vertical height, at the level of the ocean, and there it exerts the greatest pressure. The pressure of the air at the level of the sea is usually reckoned to be about 15 lbs. on every square inch, or more accurately 14·6 lbs.

The pressure of 15 lbs. to the square inch refers to every shape of surface at or near the sea's level. The pressure is sideways, upward, oblique, and in every other direction, as well as downward, because fluids press equally in all directions. Thus in every crevice, nook, or vessel in which air happens to be, the pressure is equally intense. The human being, for example, sustains the pressure of 15 lbs. to the square inch all over his person, and this is a load (about 31,500 lbs. on an average-sized man) under which he could not possibly move, unless the pressure was also exerted in the interior of his body, or through his whole system of muscles, viscera, and bones, by which means the external pressure is counteracted, and he feels no pressure whatever.

If, however, the air by any means be withdrawn from the interior of any object, that object becomes immediately susceptible of the external atmospheric pressure. There are many familiar examples of this pressure around us. One of the most common consists in causing a thimble to adhere to the hand by sucking the air from beneath it: the adhesion is the result of the pressure of the atmosphere on the exhausted space on the hand. Another consists in lifting a stone by means of a sucker, formed of a string and a wetted piece of leather, as in the accompanying figure. The wetted leather is in this case pressed down upon the stone, and the string is then pulled: if air were admitted under the end of the string, the sucker would come off; but none being admitted, the atmosphere presses on the sucker, a rigid adhesion of the sucker to the stone is produced, and the stone, if not too heavy, is lifted.

Fig. 19.

The surgical process of cupping is upon the same principle. A small glass cup is held with its mouth near the part to be operated on, and the air being consumed within it by a lighted taper, it is instantly applied, and adheres with great force. The part having been previously lanced, the blood rushes from the wounds to fill the partial vacuum.

The feet of flies and some other insects are formed on the principle of the sucker, by which means they are enabled to walk and run with security on the ceiling of an apartment, back downwards, or on an upright and smooth pane of glass. At each step in advance, they procure a hold by the formation of a vacuum or air-tight space beneath their feet. The rapidity with which these vacuums or air-tightnesses are formed and destroyed, is an exceedingly interesting phenomenon in the economy of the animal, and cannot be rivalled by the utmost efforts of human skill. On a very moderate computation, a fly, in travelling six feet in the space of a minute, creates and destroys as many as 10,000 vacuums. When deprived of the outer extremities of its legs, on which the apparatus for adhesion is situated, a fly can walk without any apparent difficulty on a horizontal surface, such as a table, but is quite incapable of adhering to the roof, or of climbing any upright surface.

Limpets, snails, and some other testaceous animals, adhere to rocks and stones by causing a vacuum within their shells, which they accomplish by shrinking into a smaller bulk; by this simple contrivance, nature has effectually provided for their safe adhesion to their appropriate places of residence.

THE AIR-PUMP.

Air may be artificially withdrawn from a containing vessel by means of an apparatus called the air-pump. This apparatus is usually small, for standing on a table, and consists chiefly of a glass jar called a receiver, placed mouth downwards, over a flat surface, and with a small brass pump to draw the air from it. The annexed cut, fig. 20, represents an outline section of an air-pump, the working of which may be described. R is the glass receiver standing on a flat and smooth plate SS, and fitting so exactly, that no air can penetrate between the edges of the receiver and the plate. In the plate SS, there is a channel AB issuing into the barrel of a pump. P is the piston of the pump, with its rod C above, which is moved upwards and downwards by a handle and winch. The rod C works in a tight collar D. At the bottom of the pump there is a valve V, by which the air escapes, and is prevented from again entering. On depressing the piston, a portion of the contained air is expelled by the valve, and on raising the piston again to its position at the top, another column of air is admitted from the receiver into the pump, which is expelled in its turn. Thus, by a process of expulsion, the air in the receiver becomes at every stroke downwards more rare, till at length a vacuum sufficient for all practical purposes is established. The valve V, which opens outwards, is kept forcibly shut at every rising of the piston by external pressure of the atmosphere.

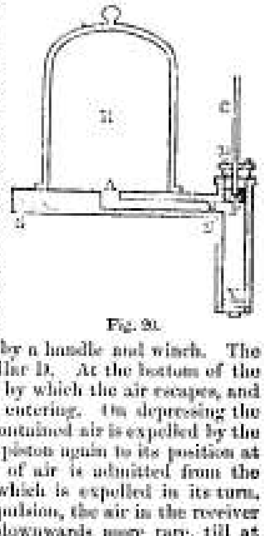

Fig. 20.

By means of the air-pump, a number of interesting experiments in pneumatics may be performed. For example, if a bladder, half full of air, and tightly tied at the neck, be placed under the receiver, and a vacuum then produced, the air in the bladder will expand by the removal of the external pressure, and seem as if ready to burst. Dried raisins, during a similar operation, will expand, and have all the plumpness of new fruit; and an egg, by the expansion of its confined air, will explode. Small animals, such as mice, placed below the receiver, and deprived of air, will immediately die, both from want of breath and the expansion of their bodies.

The atmosphere serves to retard the falling of bodies of a light and porous nature; and therefore, in the exhausted receiver of an air-pump, all such bodies descend with the same velocity as bodies of a heavy compact nature. A piece of coin and a feather let fall at the same instant of time from a hook within the top of an exhausted receiver, will strike the bottom at the same moment. (See LAWS OF MATTER.)

That atmospheric air is useful for the transmission of sound, in the absence of other media, is also exemplified by the air-pump. If we place a small bell in a

* This great discovery in physical science was made by Torricelli, an eminent Italian mathematician, about the year 1644. It was suggested by an ineffectual attempt to raise water from a deep well near Florence, by means of a pump of a greater height than thirty-two feet.

receiver, in such a manner as to admit of being rung easily from the outside without admitting air into the inside, whilst the receiver is full of air, the sound of the bell will be distinctly heard; but after the receiver has been exhausted, and although the bell be struck with the same force, the sound will be inaudible, or nearly so. If a small portion of air be admitted, it will be faintly heard, and it will gradually increase according to the quantity of air which is allowed to enter the receiver. Thus we are indebted to the air as a medium for conveying to us the sound of each other's voices, and all the melodious notes which constitute music.

The act of inspiring and expiring air resembles the alternating action of an air-pump. The air, on being drawn in through the appropriate tubes, fills the lungs, and the chest is expanded; having performed its office, the air is expelled in an impure condition, leaving a partial vacuum within, until another inspiration causes another expansion.

A machine, called a condensing-pump or syringe, is formed for the purpose of showing experiments with air more dense than that of the common atmosphere. The apparatus, which is represented in fig. 21, consists of a close glass jar or receiver fixed in a frame. A wire and hook serve to communicate with the interior during the performance of experiments. The syringe *i* is wrought by a piston with the handle *k*. From the bottom of the syringe there is a tube communicating with the interior of the receiver. When the piston is raised, a valve beneath opening inwards admits air into the cylinder of the syringe, and when it is depressed, this quantity of air is forced into the receiver; by the alternate raising and depressing of the piston, an immense quantity of air is forced into the receiver.

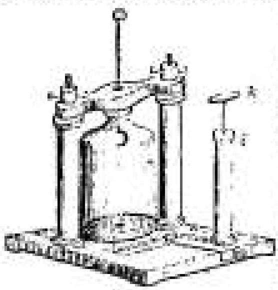

Fig. 21.

The elastic force of air so condensed is very great, and is employed for the projection of balls from an instrument called an air-gun. A certain quantity of compressed air is confined in a chamber at the inner end of the barrel, and when allowed to escape by touching a valve, a ballet is projected with a force resembling that of gunpowder.

PRESSURE OF AIR ON SOLIDS AND LIQUIDS.

The pressure of the atmosphere affects all liquids as well as solid bodies. The load of the incumbent air is as sensibly exerted within any given mass of water as on the surface. Thus atmospheric pressure keeps water and other liquids at the density they are commonly seen to possess.

If a glass be filled with water, and placed under the receiver of an air-pump, the abstraction of the air, by the removal of the atmospheric pressure, will cause the water to expand or become less dense, and it will overflow the vessel in which it is contained.

Water in its ordinary condition contains a certain quantity of particles of air mixed up with it. When the atmospheric pressure is lightened, these particles of air expand, and being of a less specific gravity than water, they mount to the top of the liquid in the form of small globules, and so fly off. The same effect is produced by expanding water by means of heat; the globules of air rise to the surface, and escape or remain attached to the inside of the vessel. Crystal bottles of water may be observed to be covered inside with small air-bells when the weather becomes suddenly light or warm. Water which has been boiled is comparatively free of air, and has an insipid flavour.

Certain gases are generated in some liquors, such as in porter, beer, and champagne wine, and unless the bottles in which they are contained be of sufficient strength to endure the expansive tendency, they will burst. On drawing the cork from a bottle of one of these liquors, the confined gas or air is suffered to expand, and the contents gush forth, a mixture of froth and liquid. If the liquid remain in an open glass for a short time, a large portion of the long-confined gases escapes into the atmosphere, and the liquor seems flat or dead. A portion of confined air, however, still remains, in consequence of the atmospheric pressure. If we take a glass of ginger-beer which seems quite dead, and place it under the exhausted receiver of an air-pump, it will again froth and appear brisk.

Some mineral waters, on springing from the ground, sparkle like beer. These most likely rise from great depths, where the incumbent pressure is considerable, and on attaining the surface of the earth, they expand, and give forth the gases pent up in their mass.

If a bladder full of air be carried from a low situation to a great height, the contained air will expand, and the bladder will burst, the same as if placed under the exhausted receiver of an air-pump. And, conversely, if a bladder be filled with air at a great height, where the fluid is rare, and brought to a low situation, the contained air will be compressed by the more dense fluid without, and the bladder will appear as if only half or partially filled.

The fluids in the animal and vegetable system are similarly affected by atmospheric pressure. Our bodies, for instance, would expand, and our blood-vessels probably be ruptured, if placed for a short time in a vacuum. On the same principle, any change in the density of the atmosphere has an effect, though not always perceptible, on the animal frame.

The atmospheric pressure, in ordinary conditions of the air, and at the level of the sea, as already stated, is equal to 15 lbs. to the square inch. If by any means, such as digging into the earth, we should go below the sea's level, the weight will be found to increase. In deep coal mines, for instance, the pressure of the atmosphere is something more than 15 lbs. to the square inch. This effect, however, is generally counteracted in mines and other deep excavations by an increase of temperature, which has the effect of rendering the air even lighter than it is at the normal surface.

The pressure diminishes, in a similar degree, as we ascend into the atmosphere. At every step upwards from the shore, the burden of the superincumbent mass lightens. At the height of three miles, one-half of the weight is lost; or, in other words, at that height the air is only half the density of air at the sea's level.

The breathing apparatus of animals is suited to an atmospheric density and pressure such as is found at the sea's level, or at a moderate elevation above it. By ascending in the atmosphere, as in climbing hills, we are deprived of the quantity of air to which we have been accustomed; and when we reach a height of three miles, we in reality inhale only one-half of the weight of air into the lungs that we use at the sea's level. Consequently, those who ascend to great elevations experience difficulty in breathing, and feel an expansion in their blood-vessels and muscles by the removal of a portion of the ordinary pressure. All the joints in our bodies, particularly those of the knee and shoulder, are in a great measure held together by the external pressure of the atmosphere; and thus a principle in pneumatics compensates for a binding of muscular ligaments.

A consideration of the effects of atmospheric pressure, and its variability at different elevations, also the alterations in pressure caused by the expansion or lightening of the air by heat, and its increased density by cold and moisture, tends to explain the remarkable influence which change of climate has upon the human constitution. Thus the inhabitants of countries possessing a light dry atmosphere, are usually more lively than those of countries with a heavy moist climate.

THE BAROMETER.

The pressure of the atmospheric column, at any given point, may be weighed with considerable exactness, by balancing it against an opposite column of mercury, water, or other liquid.

The pressure of 15 lbs. to the square inch at the ocean's level, is found by experiment to be equal to the weight of a column of mercury of 30 inches in height, a column of water 33 feet in height, or a column of oil 37 feet in height. In other words, the burden of the whole of our atmosphere is equivalent to an ocean of mercury covering the earth to a height of 30 inches, an ocean of water to a height of 33 feet, or an ocean of oil to a height of 37 feet.

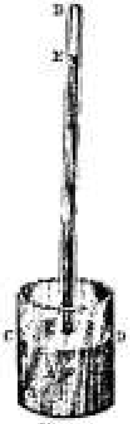

Fig. 22.

The fact of such being the degree of atmospheric pressure admits of easy proof, by means of a glass tube upwards of thirty-two inches in length, and a cup half filled with mercury, as represented in fig. 22. The tube is close at its upper end at B, but open at its lower extremity, which is immersed in the mercury below the surface level C P D. The tube having in the first place been filled with pure mercury, a finger is placed on its open end to prevent the egress of the liquid; and thus held, the lower end of the tube is turned downwards, and plunged into the vessel of mercury, when the finger is removed from the orifice. The mercury in the tube will now be observed to fall to E, or the height of about thirty inches above the surface C P D, and there it will remain.

The question now arises, Why the mercury in the tube does not run out altogether into the cup, instead of standing to a height of thirty inches in the tube? The explanation of the phenomenon is, that from E to B in the tube is a vacuum, and therefore the mercury at its upper extremity is entirely free of atmospheric pressure—there is no superincumbent weight to push it out. The column of mercury E P presses with nothing but its own weight on the mercury of the cup. This weight of thirty inches of mercury is counterbalanced by the pressure of air on the surface of the mercury in the cup; and thus it is evident that the weight of the atmosphere is equivalent to the weight of thirty inches of mercury. If by any means we remove the atmospheric pressure from the mercury in the cup, the mercury in the tube will immediately sink into the cup.

The circumstance of the column of mercury in the tube being narrow, and the surface of the mercury in the cup being broad, makes no difference in the experiment, because the pressure of elastic fluids is as their density, not as width of volume. The same result would occur if the surface of the mercury presented to the atmospheric pressure were only the width of the tube. The height at which mercury stands in a tube of this kind always bears reference to the incumbent weight of the atmosphere on the open and lower extremity of the column. If we increase the external pressure by artificial means, or by descending below the sea's level, the mercury rises; if, on the other hand, we decrease it by artificial means, or by ascending into the atmosphere, or if the atmosphere is rarefied by heat, the mercury falls.

This very obvious connection between the rising and falling of mercury in a tube and the atmosphere, has suggested the construction of an instrument called the *barometer* (a word from the Greek, signifying *weight* and *measure*), by which the effects of atmospheric pressure may be accurately known. The barometer in common use consists of a narrow glass tube upwards of thirty inches in length, and bent upwards at its lower extremity, as represented in fig. 23. The mercury is introduced into the tube with great care, so that a perfect vacuum exists at the upper extremity. The surface of the mercury in the bent part is open to the action of the atmosphere, and buoys up a small plummet or float F, to which a thread is attached; the thread proceeds upwards to a small pulley G, over which it goes, and terminates in a small ball W. The friction of the thread on the pulley turns a small index H, which points to figures on the surrounding dial. Commonly, the whole apparatus, except the dial-plate, is concealed in an ornamental frame. Barometers of this description are adjusted in such a manner, that the smallest rising or falling of the mercury from atmospheric action affects the index on the dial, and shows the degree of pressure.

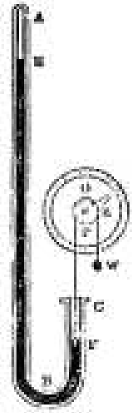

Fig. 23.

In common circumstances, the mercury ranges from 29 to 30 inches. It seldom sinks so low as 28, or rises to 31. When it falls, an indication is given of diminished pressure, and as diminished pressure causes the air to expand, and consequently to be sensibly cooled, moisture is liable to be precipitated in the form of rain; hence a fall in the mercury of the barometer is considered a prognostic of rain or wet weather, and a rise the reverse. The dial of the barometer is marked accordingly.

The barometer, besides being a weather-glass, is used as an instrument for measuring the heights of mountains, or heights attained in balloons, above the level of the sea. As the entire atmosphere sustains thirty inches of mercury in the tube, it follows that at every step as we ascend, the pressure will become less, and a less body of mercury be sustained. It is found that at the height of five hundred feet the mercury has sunk half an inch. But the fall does not proceed in this ratio as we go upwards, because a half of the whole atmosphere is within about three miles, and the other half expanded to an altitude of about fifty miles; hence, on gaining a height of three miles, the mercury is found to have sunk to fifteen inches, or one-half; and on gaining a height of four miles, to twelve inches.

Barometers for measuring heights are constructed with a determined scale, marked along the tube of mercury, and by consulting it as we ascend, we learn the height of any spot that we may reach. Perfect exactness, however, is not to be expected in this mode of measurement, because the atmospheric pressure is liable to variation from temperature, and the mercury is liable to contraction or expansion from the same cause. To guard against error, a thermometer, as well as a barometer is consulted in ascending heights, and the indications of both instruments, according to a scale established by experiment, determine the degree of elevation. Thus for a diminution of one degree of temperature between 0 and 32 degrees, the mercury in the barometer falls 0·0034 of an inch, and between 32 and 52 degrees it rises 0·0033 of an inch.

PUMPS.

The effect of atmospheric pressure on water is observable in various contrivances in the arts.

Fill a glass to the brim with water, and lay a piece of paper over the whole surface of the liquid: then turn the glass carefully upside down, holding on the paper by the hand; the water will now remain in the glass, being upheld by the pressure of the atmosphere against the paper. Glass fountains of water for bird-cages, ink-holders, and reservoirs of oil for lamps, are constructed on the principle of the liquid being upheld by atmospheric pressure.

The apparatus for lifting water from wells, forming the common sucking-pump, acts on the principle of removing the atmospheric pressure from a column of the liquid, thus causing a vacuum in the pump, and allowing the atmospheric pressure on the surface of the liquid in the well to force up and balance the column of liquid. Fig. 24 represents the outline of a common sucking-pump. It consists of a cylinder, furnished with a piston A, made to fit air-tight. In this piston there is a valve opening upwards, but here indicated as closed. When the piston is raised, the air is rarefied more and more at each stroke in that portion of the cylinder through which it has moved upwards, and the pressure of the air upon the surface of the water on the outside of the tube forces the fluid into it. The valve B is at the same time opened upwards, and the water, after several strokes, rushes in above it. When the upward stroke of the piston is complete, it is again depressed—the water passes through the valve in the piston, and on the next stroke it is discharged at the spout. It is evident that when the piston is sunk downwards, the water cannot be again forced out of the pump, because the valve at the bottom is pressed down, and prevents its escape.

Fig. 24.

Water may in this manner be lifted by a pump to any height, but in each case the lower or fixed valve in the pump must be less than 34 feet from the surface of the water. It is, however, disadvantageous to lift water from great depths by this means. In such cases it is usual to employ a succession of pumps, one above another.

It is customary to call pumps hydraulic machines; properly speaking, they are both hydraulic and pneumatic machines, for water is raised by them in a great measure through the agency of atmospheric pressure.

The form of pump used for forcing water to a height above the ground, as in the case of fire-engines or portable forcing-pumps for gardens, is different from the common suction-pump. The object in the forcing-pump is to lift water to a certain height by the formation of a vacuum, and then to inject it with violence into the air. The action of this kind of pump apparatus is represented in fig. 25. The piston A sucks the water by its upward motion; but on depressing it, the valve B is closed, and the water is consequently forced through the pipe C.

Fig. 25.

In the case of supplying water to the boiler of a steam-engine, it is necessary to employ a forcing-pump, to overcome the pressure of steam within the boiler. The force with which the water is injected overcomes the tendency which the steam has to rush out.

Cold or moderately warm water can only be lifted by a pump. If the water be above a certain temperature, about 150 degrees at the utmost, the sucker cannot form a perfect vacuum, because, in the attempt to do so, the water yields a steam or vapour which fills the space; in other words, by removing the atmospheric pressure by the piston, the water begins to vaporise, as if about to boil. When a pump is made to operate upon hot water, it labours in vain to raise the liquid. This circumstance limits the heat of water injected into the boilers of steam-engines; or if the water is injected at a high temperature, it must receive its heat between the pump and the boiler. This is sometimes done by causing the tube from the pump to pass through a vessel of waste steam.

SYPHONS.

Atmospheric pressure is very conspicuous in the case of the *syphon*.

A syphon is a tube bent in a particular manner, and is used for drawing off liquors from casks, or water from reservoirs. One kind is represented in fig. 26, and consists of a tube bent into two equal limbs, each open at the extremity. If such a syphon be filled with water, and inverted, so as to turn the two orifices downwards, the liquid will not run out, but remain suspended in the tube, because the pressure of the column of water within is not so great as the pressure of the air without, and thus its escape outwards is prevented. If one end be put into a vessel of water, the vessel will be emptied down to a level with the orifice. It is evident that, when one end of the syphon is inserted in water, the pressure of the atmosphere upon the surface of the water impels the liquid through the tube, and it could be forced upwards to an elevation of above thirty feet, or the height to which water rises in a vacuum. The diagram represents an instrument of this kind furnished with two cups, firmly attached to the ends, which, by retaining a portion of the liquid, keeps the syphon always full and ready for use.

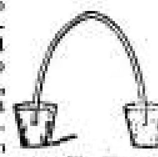

Fig. 26.

Syphons are more commonly made with a long and short limb, as in fig. 27. On inserting the short limb into a vessel of liquid, and drawing the air out of the tube at the mouth A, the liquid will rush out in a stream, and continue flowing till the vessel is emptied. The pressure upwards into the tube at A is the excess of the atmospheric pressure above the vertical pressure of the column of fluid AB; and the similar pressure at C is the excess of the atmospheric pressure above the vertical pressure of the column of fluid BC; but the latter excess is evidently the greater, and hence the liquid in the vessel is necessarily forced upwards through the tube from C to B; and thus the vessel is drained of its contents. By placing a stopcock on the tube above A, the stream can be checked, and permitted to flow at pleasure. There are instances of towns being supplied with water by means of large syphons of this kind. In these cases the syphon is brought over a rising ground from a lake or fountain at some distance. Certain kinds of springs are accounted for on the principle of the syphon; they act from the combined effects of a vacuum and atmospheric pressure.

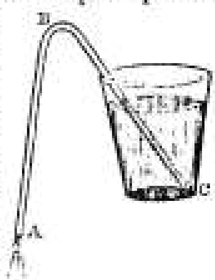

Fig. 27.

APPLICATION OF HEAT TO WATER.

The pressure of the atmosphere affects the boiling of water. At the common pressure of about 15 lbs. to the square inch, water will boil, or attain the vaporific point, at 212 degrees Fahrenheit. If we remove the atmospheric pressure by an air-pump, as is done in the boiling of sugar, we can produce the phenomenon of boiling at a much lower temperature. At the summit of Mont Blanc, where the atmospheric pressure is light, water is found to boil at 187 degrees.

Steam produced from boiling water is a transparent, colourless, and invisible substance, like air. If we could look into the boiler of a steam-engine, we should see nothing but the water in a state of ebullition. The white cloudy-looking matter which is emitted in the form of vapour, is moisture produced by the partial condensation of the steam in the atmosphere—taking the form of vapour is a step towards becoming liquid again. A cubic inch of water produces exactly a cubic foot, or 1728 cubic inches, of steam, at 212 degrees of temperature; in other words, when water is transformed into steam, it occupies 1728 times its former bulk. In this expanded condition, steam is of a less specific gravity than air. Its density is expressed by 0·625, that of air being 1.

The elastic force of steam in the process of heating —that is, the force with which it seeks to expand—differs at different temperatures. At first the force is inconsiderable, but it rapidly increases as the temperature is raised. At a temperature of 212 degrees, the elastic force is 15 lbs. on the square inch of the containing vessel, or equal to the external pressure of the atmosphere; at 250 degrees, it is 30 lbs.; at 272 degrees, it is 45 lbs.; and at 290 degrees, it is 66 lbs.

BUOYANT PROPERTY OF AERIFORM FLUIDS.

The atmosphere, as has been stated, possesses the property of buoying up bodies which, bulk for bulk, are lighter than itself. The law governing buoyancy in liquids is precisely the same as that governing buoyancy in aeriform fluids, and may here be repeated in reference to air.

1st, Any solid body immersed in a fluid displaces exactly its own bulk of fluid, and the force with which the body is buoyed up is equal to the weight of the fluid which is displaced. This refers to bodies of less density than air. *2d*, Any solid body of a greater density than air, when wholly immersed in that fluid, loses exactly as much of its weight as the weight of an equal bulk of air—that is, of the air which it displaces.

The support afforded to bodies in the atmospheric fluid by its resistance, is very evident from many appearances in nature—as the support of vapours or clouds, the rising of smoke and fine particles of dust, and the flying of birds; in art, it is exemplified by the flying of a boy's paper kite, the rising of soap-bubbles, and its buoyant property by the floating of balloons.

The flight of birds is not accomplished altogether by the buoyant property in the air. These animals support themselves by striking their wings against the fluid through which they are passing; and this friction, along with the property of buoyancy in the atmosphere, sustains them at any height to which they are pleased to ascend. Birds do not generally fly above half a mile in height, and seldom above a few hundred yards. At considerable elevations, the air is so specifically light, as to be unsuitable for their easy support. Those which rise to the higher regions of the atmosphere, as, for instance, the eagle, are provided with large wings, which enable them to support themselves in the comparatively thin fluid in which they move. A small bird, when let out from a balloon at the height of three miles, drops almost like a plummet, till it arrive at an aërial stratum against which its little wings can take effect.

The buoyant property of the air thus obviously diminishes in proportion as it becomes less dense; and there is a point above which the lightest imaginable body or particle of matter would inevitably sink. By this means, independently of terrestrial attraction, an effectual limit has been set to the distance attainable by substances from the surface of our planet. Not an atom of matter, since the period of the creation, has been suffered to escape beyond the higher regions of the atmosphere, or which has not, in making the attempt, been brought back to the earth.

The support given to bodies by the atmosphere diminishes their apparent weight, in the same manner as the apparent weight of bodies is diminished in water. A stone is moved more easily in water than in air, and so likewise is it moved more easily in air than in a vacuum. The diminution in weight of a body in air, as already stated, is equal to the weight of the bulk of air displaced. Thus, if an object which displaces one grain of air weigh a pound in a vacuum, it will weigh one grain less than a pound in air, and therefore one grain will require to be added to it to make up the apparent deficiency. The weight of air displaced by any marketable commodity is so exceedingly trifling, as not to be worth reckoning in ordinary circumstances. Strictly speaking, however, this weight of air has an influence in the value of the transaction. In all cases in which the object weighed is more bulky than the weight employed to balance it, a certain quantity must be added to overcome the force with which it is buoyed up by the atmospheric fluid.

The light heated air which escapes from a fire ascends, and is buoyed up by the more dense air beneath. Hydrogen, or any other gas of a less specific gravity than air, in the same manner ascends and floats in the atmosphere at the height at which it finds air of its own specific gravity. On the same principle, if heated air or any light gas be enclosed in a large silk bag, it will ascend in the atmosphere till it reach a region of air which is incapable of supporting it. Thus a soap-bubble enclosing warm air readily ascends to the ceiling of an apartment. If the bubble be made with cold water, it will sink instead of rising.

A *balloon* is a bag made of fine varnished silk, and of such a magnitude, that the difference betwixt the weight of its contents and that of the displaced air is sufficient to support the weight of the silk and the other parts of the apparatus. Balloons were originally made to rise by being filled with heated air from a fire hung beneath them; but this dangerous and inconvenient practice was in course of time superseded by the use of hydrogen gas, one of the lightest airs which can be prepared. Hydrogen gas has latterly been succeeded by carburetted hydrogen, which, though not so light, is more easily obtained, being the gas with which towns are now generally lighted. Employing a moderately pure and light gas, the contents of a balloon may be estimated to weigh only an eighth of the weight of the atmosphere, bulk for bulk; and hence, after adding another eighth for weight of apparatus, it will ascend with a force of six-eighths; in other words, if the gas and apparatus weigh two pounds, the balloon will lift from the ground a weight of other six pounds. The force with which a balloon will ascend is therefore to be calculated by measuring its capacity in cubic feet, and comparing the result with an equal bulk of atmospheric air: the difference of weight is the buoyant force of the balloon.

Balloon.

Of *aërostation*, or the art of moving through the air in balloons, great expectations were originally entertained; but the experience of half a century has proved that it is of no practical value. Its only use is the exhibition of an interesting principle in pneumatics. A balloon constructed in the best-known manner, and moving upwards with a powerful force, is subject to the following drawbacks:—As the balloon ascends, its contents expand, in consequence of the increasing rarefaction of the atmosphere; if, therefore, it has been entirely filled when on the ground, a portion of the gas must be allowed to escape as it rises, otherwise it will burst. Discharges of ballast are also required, in consequence of the absorption of moisture from clouds; and there being no means of recovering the lost ballast, the balloon, on the return of heat, rapidly rises in the air, its contents expanding in the ascent, and rendering further liberations of gas necessary to prevent explosion. These alternations continuing to operate more or less frequently, it is evident that they must soon put an end to the buoyant power, however great originally, and, along with the contending effects of winds, forcibly terminate any aërial excursion.

OPTICS—ACOUSTICS.

OPTICS.

The term *Optics* is derived from a Greek word which signifies *seeing*, and applies to that branch of natural philosophy which treats of the phenomena of *light* and vision. Of the precise character of light there are various theories, but none which admits of actual demonstration or proof. By some it has been described as consisting of very minute particles or molecules, which are thrown off from what are called luminous bodies in all directions, and with immense velocity; while others consider it as the effect of an undulation or vibration produced by luminous bodies in the thin and elastic medium which is interposed between them and the seat of our vision—this vibration producing an effect upon our organs, which we recognise as light, in a manner analogous to the impression of sound on the ear caused by vibrations of the atmosphere. The latter is called the *undulatory* theory of light; and the former, in which light is supposed to consist of *material* particles, the theory of *emission*.* Whatever may be the cause or absolute nature of light, we know it is a property of luminous bodies which enables us to see the luminous objects themselves, as well as others in their vicinity, and that its absence produces darkness.

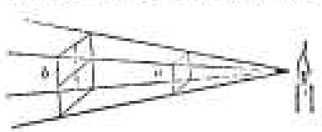
All visible bodies may be divided into two classes—*self-luminous* and *non-luminous*. Under the first head are comprised all those bodies which possess in themselves the property of exciting the sensation of light or vision, such as the heavenly luminaries, terrestrial flames of all kinds, phosphorescent bodies, and those bodies which shine by friction or by being heated. Under the second class we recognise such bodies as have not of themselves the power of throwing off particles or undulations of light, but which possess the property of reflecting the light which is cast upon them from self-luminous bodies. A non-luminous body may thus, by reflection, receive light from another non-luminous body, communicate it to a third; and so on. All reflected light, however, is inferior in brilliancy to that which comes direct from a self-luminous body.

Anciently, it was believed that light was propagated from the sun, and other luminous bodies, instantaneously; but the observations of modern inquirers have shown that this was an erroneous hypothesis, and that light, like sound, requires a certain time to pass from one part of space to another, though the velocity of its motion is truly astonishing, as has been manifested in various ways. Astronomers have proved, by observing the eclipses of Jupiter's satellites, when that planet is nearest and when it is farthest from the earth, that light moves from the sun to the earth, a distance of 95,000,000 miles, in seven and a half minutes, or about 200,000 miles during a single vibration of a pendulum. So prodigiously great is this velocity, that, as far as any common observation is concerned, light may be regarded as perfectly instantaneous in its action.

* The theory of emission was devised by Newton, and for a long time it was thought to explain the facts better than any other. It is not necessary to suppose that the particles succeed each other closely, so as to crowd the whole of space with a luminous stream. It is found that a single impression of light will remain on the eye for the eighth of a second, and therefore if eight particles fell upon it every second, there would be a permanent impression produced. But in the eighth of a second a ray passes through 25,000 miles, so that if one particle followed another at this distance, constant light would be maintained, and the shower would be so thin and scattered, as to allow room enough for all the innumerable crossings of luminous rays. At present, however, there are many phenomena which cannot be explained by this theory, and are found more consistent with the undulatory hypothesis.

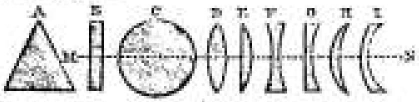
Light proceeds in a straight direction from the luminous body which produces it, towards the part or situation against which it is permitted to act. In consequence of this directness, a shadow or darkened spot is observable behind any opaque object presented to the light. During night, we are in the earth's shadow; and this shadow reaches so far beyond us into space, that when the moon plunges into it in her course, she undergoes an eclipse. The direct shining of the sun, or any other luminous body, is in the form of rays, or thin ethereal lines, each acting independently of the other; no such separation of parts, however, is observable in common circumstances, in consequence of the diffusive properties of the atmosphere. Seeing is simply the reception of the direct or reflected ray from an object by our eye. Until the rays of the sun reach the spot on which we are placed, we are neither conscious of light nor of the presence of the sun as an object. In the same manner, a candle being lighted and exposed in the open country in a dark night, all who are able to see it are within the influence of its rays; but beyond a given distance these rays are too weak to produce vision, and all who are in this remote situation cannot see the faintest appearance of the candle. It will therefore be understood that the seeing of any luminous object is equivalent to being within the influence of rays of sufficient intensity proceeding from it. The number of rays which proceed from even a common candle is so vast, as to be beyond our conception; for if such a light is visible within a range of four miles, it follows that if the whole of that space were surrounded with eyes, each eye would receive the impression of a ray of light.

In proportion as light advances from its seat of production, it diminishes in intensity. The ratio of diminution is agreeable to that which governs physical forces—that is, the intensity of the light will diminish as the square of the distance increases, or at the rate of 1, 4, 16, &c. But in proportion as we lose in intensity, we gain in volume; the light is the weaker the farther it is from the candle, but it is filling a wider space. Thus if a board, *a*, a foot square be placed at the distance of one foot from a candle, it will be found to hide the light from another board, *b*, of two feet square, at the distance of two feet from the candle. Now a board of two feet square is just four times as large as one of one foot square, and therefore the light at double the distance being spread over four times the surface, has only one-fourth the intensity.



Preliminary to any farther exposition of the nature and action of light, we offer the following definitions of terms:—Any parcel of rays passing from a point is called a *pencil* of rays. By an optical *medium* is meant any pellucid or transparent body—as, for example, air, water, or glass, which suffers light to pass through it. *Parallel rays* are such as move always at the same distance from each other. If rays continually recede from each other, they are said to *diverge*; if they continually approach each other, they are said to *converge*. The point at which converging rays meet is called the *focus*; the point towards which they tend, but which they are prevented from coming to by some obstacle, is called the *imaginary focus*. When rays, after passing through one medium, on entering another medium of different density, are bent out of their former course, and made to change their direction, they are said to be *refracted*;

when they strike against a surface, and are sent back again from the surface, they are said to be *reflected*. A *lens* is a glass ground into such a form as to collect or disperse the rays of light which pass through it. These are of different shapes, and thence receive different names. The following figures individually represent sections of the variously-shaped lenses and other glasses used in optics:—



A is a triangular stalk of pure glass, of which we have here a cross sectional or end view, and which is called a *prism*; each side of the prism is smooth. B is a section of a piece of plane glass, with sides parallel to each other. C is a sphere or ball of glass, and consequently is convex on all parts of its surface. D is a piece of glass convex, or bulging on its two sides, and is called a *double convex lens*. It is this kind of lens which is used for magnifying objects, in spectacles, telescopes, and other instruments. E is a *plano-convex lens*, flat, or planed on one side, and convex on the other. F is a *double concave lens*, or glass hollowed on each side. G is a *plano-concave lens*, or planed on one side, and concave on the other. H is a *meniscus*, or lens convex on one side, and concave on the other, both surfaces meeting, and of which we have an example in watch-glasses. I is an example of the *concavo-convex lens*, in which the surfaces disagree, or do not meet when continued. In all these lenses an imaginary line, represented by M N, and passing through the centres of the surfaces, is called the *axis*. Thus the line said to pass through the centre of any lens, in a direction perpendicular to its surface, is called its axis.

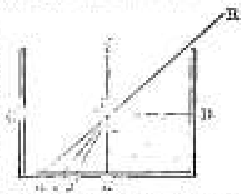
In treatises on optics, it is customary to divide the subject into two sections, under the heads Dioptrics and Catoptrics. The term *dioptrics* is compounded of two Greek words signifying *to see through*, and refers to the transmission of rays of light through transparent bodies, as well as the laws by which they are produced. *Catoptrics* is also from the Greek, and signifies *to see from or against*: it refers to the reflection of light from surfaces, and the formation of images by means of mirrors and other objects.

REFRACTION OF LIGHT.

Refraction, as already mentioned, is the bending of rays of light from the course they formerly pursued. If the rays, after passing through a medium, enter another of a different density, perpendicular to its surface, they are not refracted, but proceed through this medium in their original direction. For instance, if the sun's rays were to strike upon the surface of a river at right angles, or perpendicularly, to its surface, they would go straight to the bottom, and the line they observed in the air would be continued in the water. But if they enter obliquely to the surface of a medium either denser or rarer than what they moved in before, they are made to change their direction in passing through that medium; that is, they are refracted.

The mode of the refraction depends on the comparative density or rarity of the respective media. If the medium which the rays enter be denser, they move through it in a direction nearer to the perpendicular drawn to its surface. On the contrary, when light passes out of a denser into a rarer medium, it moves in a direction farther from the perpendicular. This refraction is greater or less—that is, the rays are more or less bent, or turned aside from their course—as the second medium through which they pass is more or less dense than the first. To prove this in a satisfactory way, take an upright empty vessel into a darkened room, which admits but a single beam of light obliquely through a hole in a window-shutter. Let the empty vessel stand on the floor, a few feet in advance of the window which admits the light, and let it be so arranged that, as the beam of light descends towards the floor, it just passes over the top of the side of the vessel next the window, and strikes the bottom on the side farthest from the window. Let the spot where it falls be marked. Now, on filling the vessel with water, the ray, instead of striking the original spot, will fall considerably nearer the side towards the window. And if we add a quantity of salt to the vessel of water, so as to form a dense solution, the point where the ray strikes the bottom will move nearer to the window. In like manner, if we draw off the salt water, and supply its place with alcohol, the beam of light will be still more highly refracted; and oil will refract yet more than alcohol.

The property of refraction may also be observable in the following experiment:—Let the annexed oblong figure represent a vessel half filled with water, and R the ray of light which may be expected to pass through it to the bottom at *d*. The direction of the ray is perfectly straight until it enters the water at *j*, when, instead of proceeding in a straight line to *d*, it is bent from its course, and compelled to strike the bottom of the vessel at *e*. If oil instead of water had been used, the ray would have been still more bent, and have reached the bottom at *f*. If the ray had been sent directly downwards, as from *i* to the surface of the water at *j*, it would not have been refracted, but have proceeded straight to the bottom at *k*.



The following simple experiments are well known:—Take an empty basin and place it on a table, then lay a shilling at the bottom of the basin, in such a position that the eye of the observer will not see it. Now fill the basin with water, and the shilling, though lying unmoved, will come completely into sight. The explanation of this phenomenon is, that the ray of light producing vision in the eye is bent on emerging from the water, and has all the effect of conveying our sight round a corner. In like manner the refractive power of water is observable when we thrust a straight stick or instrument into it, on aiming at any object. We see that the stick seems to be bent, and fails in reaching the point which we desired it should. On this account, the aim by a person not directly over a fish must be made at a point apparently below it, otherwise the weapon will miss by flying too high. Persons who spear salmon in rivers require to calculate upon this refractive power in taking their aim.

With regard to the refractive power of transparent substances or media, the general rule, with certain limitations, is, that it is in proportion to the densities of the bodies. It increases, for instance, from the most perfect vacuum which can be formed, through air, fresh water, salt water, glass; and so on. But those substances which contain the most inflammable matter, have the greatest refractive power. It was from the great refractive powers of the diamond and water, that Newton, with admirable sagacity, predicted that they contained inflammable principles. This fact future discoveries in chemistry verified. Tables of the refractive powers of substances most interesting in optics will be found in Brewster's 'Optics.' From these it would appear that substances which contain fluoric acid have the least refractive power, as inflammable ones have the greatest. With regard to the cause of refraction, on the theory of emission, the refracting medium would attract the particles of light, and increase their velocity during their transmission, and would alter the direction of their motion, thus causing refraction; but the intensity of the attractive force would require to be different for light of different colours; and on the undulatory theory, the ether within the refracting medium would be condensed by the attraction of its particles on the ether, and the velocity of transmission of the wave of light through this condensed ether would be less than in free space, and from this cause the direction of the motion would be altered, or refraction would take place; and from the different lengths of the waves of different colours, the velocity of their transmission would be different, thus causing different degrees of refrangibility according to the difference of colour.

The refraction of rays of light is observable in the case of common window-glass. The two sides of a pane not being perfectly parallel to each other, bodies seen through it appear as if distorted; and as the obliquities in the glass are very various, the distortions are equally grotesque and numerous. Some windows are purposely ground on the surface, to produce universal and minute refraction; and thus so great a confusion is introduced among the rays, that objects are not distinguishable through the glass. When the obliquities on the surface of one side of a piece of glass stand distinct from each other, so as to admit of refraction in a clear and distinguishable manner, then each obliquity affords a separate view of an object on the opposite side, and thus an object seems to be multiplied as many times as there are obliquities.

The refraction of light is observable on a great scale in relation to our atmosphere. The rays of the sun, on reaching the confines of the atmospheric fluid which envelops the earth, enter a medium of greater density than that which they have previously been pursuing, and consequently are refracted or bent. One obvious effect of this is, that we never see the sun in the actual position which he occupies. He is always less or more, in relation to our eyes, what the shilling is said to be in the above experiment with the basin of water. This is peculiarly the case in the morning, when his earliest rays reach our eyes; entering a denser medium, these rays bend round to meet our vision, and we actually see the body of the sun a few minutes before he has risen above the horizon—like the shilling in the basin, we see him round a corner. In proportion as the sun approaches the zenith, the refraction diminishes; and as he recedes towards setting, it increases. So considerable is it in the hazy atmosphere of the evening, that we retain a sight of his disk after he has set.

From these explanations, it will appear that the directness of our vision is at all times liable to be disturbed by atmospheric conditions. So long as the atmosphere betwixt our person and the object we are looking at is of the same density, we may be said to see in a straight line to the object; but if by any cause a portion of that atmosphere is rendered less or more dense, the line of vision is at once refracted or bent from its course. A thorough comprehension of this simple truth in science has banished a mass of superstition. It has been found that, by means of powerful refraction, objects at a great distance, and round the back of a hill, or considerably beneath the horizon, are brought into sight. In some countries this phenomenon is called the *mirage*. The following is one of the most interesting and best authenticated examples:—In a voyage performed by Captain Scoresby in 1822, he was able to recognise his father's ship, when below the horizon, from the inverted image of it which appeared in the air. 'It was,' says he, 'so well defined, that I could distinguish by a telescope every sail, the general rig of the ship, and its particular character; insomuch that I confidently pronounced it to be my father's ship the *Fame*, which it afterwards proved to be; though, on comparing notes with my father, I found that our relative position at the time gave our distance from one another very nearly thirty miles, being about seventeen miles beyond the horizon, and some leagues beyond the limit of direct vision. I was so struck by the peculiarity of the circumstance, that I mentioned it to the officer of the watch, stating my full conviction that the *Fame* was then cruising in the neighbouring inlet.'

A curious phenomenon of this kind was seen by Dr Vince, on the 6th of August 1806, at seven P.M. To an observer at Ramsgate, the tops of the four turrets of Dover Castle are usually seen over a hill between Ramsgate and Dover. Dr Vince, however, when at Ramsgate, saw the whole of Dover Castle, as if it had been brought over and placed on the Ramsgate side of the hill. The image of the castle was so vivid, that the hill itself did not appear through the image.

In the sandy plains of Egypt, the mirage is seen to great advantage. These plains are often interrupted by small eminences, upon which the inhabitants have built their villages, to escape the inundations of the Nile. In the morning and evening, objects are seen in their natural form and position; but when the surface of the sandy ground is heated by the sun, the land seems terminated at a particular distance by a general inundation: the villages which are beyond it appear like so many islands in a great lake, and between each village an inverted image of it is seen.

That the phenomena of the mirage are produced by variations in the refractive power of the atmosphere, can be proved by experiment. If the variation of the refractive power of the air takes place in a horizontal line perpendicular to the line of vision—that is, from right to left—then we have the lateral mirage; that is, an image of a ship may be seen on the right or left hand of the real ship, or on both, if the variation of refractive power is the same on each side of the line of vision. If there should happen at the same time both a vertical and a lateral variation of refractive power in the air, and if the variation should be such as to expand or elongate the object in both directions, then the object would be magnified as if observed through a telescope, and might be seen and recognised at a distance at which it would not otherwise have been visible. If the refractive power, on the contrary, varied so as to contract the object in both directions, the image of it would be diminished as if seen through a concave lens.

In order to represent artificially the effects of the mirage, Dr Wollaston suggested the viewing of an object through a stratum of spirit of wine lying above water in a crystal jar, or a stratum of water lying above one of syrup. These substances, by their gradual incorporation, produce a refractive power diminishing from the spirit of wine to the water, or from the syrup to the water: so that, by looking through the mixed or intermediate stratum at a word or object held behind the bottle which contains the fluids, an inverted image will be seen. The same effect, it has been shown, may be produced by looking along the side of a red-hot poker at a word or object ten or twelve feet distant. At a distance less than three-eighths of an inch from the line of the poker, an inverted image is seen, and within and without that an erect image.

The method employed by Sir David Brewster to illustrate these phenomena, consists in holding a heated iron above a mass of water bounded by parallel plates of glass; as the heat descends slowly through the fluid, we have a regular variation of density, which gradually diminishes from the bottom to the surface. If we now withdraw the heated iron, and put a cold body in its place, or even allow the air to act alone, the superficial stratum of water will give out its heat, so as to produce a decrease of density from the surface to a certain depth below it. Through the medium thus constituted, the phenomena of the mirage may be seen in the most interesting manner.

Double Refraction.

In the preceding part of this section, we have considered a single ray of light, reflected or transmitted through the substance of a transparent body, as leaving it in the same way in which it came into contact with it—namely, in a single pencil or ray. But there are a great many bodies which have the power of breaking the pencil of light incident upon their surfaces into two separate parts or pencils, more or less inclined to one another, according to the nature and state of the body, and according to the direction of the incident pencil. This is called *double refraction*, and the bodies which produce it are called doubly refracting bodies or crystals. They are very numerous, and include all salts and crystallized minerals not having the primitive forms of the cube, the regular octohedron, and the rhomboidal dodecahedron. Of all known bodies, the Iceland spar, or rhomboidal carbonate of lime, shows the fact with the greatest certainty; and as it is a mineral easily procured, it has been generally used in experiments upon this subject. Its crystals are of a rhomboidal form, having six acute solid angles, and two obtuse. Double refraction of light is employed to advantage in some kinds of lighthouses; and those who wish to investigate its nature and properties, may be referred to advanced treatises on the subject.

With respect to the *polarisation of light*—which is the separation of a ray of light into two rays, having different properties from each other, among which properties is that of producing colour in a variety of ways, although the original ray may be common or white light—we must also refer to works of higher scope than the present.

Colour by Refraction.

One of the most remarkable phenomena attending refraction is, that the rays of light, which seem to us to be white, may be separated into rays of various colours. It will be obvious that light has the effect of representing colours, where no colour substantially exists, by noticing the glancing and varied hues on irregular surfaces of glass, ice, or other crystallised substances.

The proper method of analysing the rays of light, and discovering into what colours they may be resolved, is to procure a prism, and perform the following experiment in a darkened chamber:—In the window-

shutter, E, of a darkened room, make a small hole, H, through which admit a beam of the sun's light, S, which, when nothing is interposed, will proceed in a straight line to P, and form a luminous white spot. If we now interpose a prism B A C, whose refracting angle is B a C, so that the beam of light may fall on its surface C A, and emerge at the same angle from its second surface B A, in the direction *g* G, and if we receive the refracted beam on the opposite wall, or on a white screen M N, 'we should expect,' says Sir David Brewster, 'from the principles already laid down, that the white beam which previously fell upon P would suffer only a change in its direction, and fall somewhere upon M N, forming there a round white spot exactly similar to that at P. But this is not the case. Instead of a white spot, there will be formed upon the screen M N an oblong image K L of the sun, containing seven colours—namely, red, orange, yellow, green, blue, indigo, and violet—the whole beam of light diverging from its emergence out of the prism at *g*, and being bounded by the lines *g* K, *g* L. This lengthened image of the sun is called the *solar* or *prismatic spectrum*. If the aperture H is small, and the distance *g* G considerable, the colours of the spectrum will be very bright. The lowest portion of it at L is a brilliant red. This red shades off by imperceptible gradations into orange, the orange into yellow, the yellow into green, the green into blue, the blue into a pure indigo, and the indigo into a violet. No lines are seen across the spectrum thus produced; and it is extremely difficult for the sharpest eye to point out the boundary of the different colours. Sir Isaac Newton, however, by many trials, found the lengths of the colours to be as follow, in the kind of glass of which his prism was made:—Red, 45; orange, 27; yellow, 40; green, 60; blue, 60; indigo, 48; violet, 80—Total length, 360.'

These colours are not equally brilliant. At the lower end, L, of the spectrum, the red is comparatively faint, but grows brighter as it approaches the orange. The light increases gradually to the middle of the yellow, where it is brightest; and from this it gradually declines to the upper or violet end, K, of the spectrum, where it is extremely faint.

From the phenomena which we have now described, Sir Isaac Newton concluded that the beam of white light is compounded of light of seven different colours, and that for each of these different kinds of light, the glass of which his prism was made had different indices—that is, measures of refraction; the index of refraction for the red light being the least, and that of the violet the greatest.

By means of a second prism placed behind a hole in the screen M N, opposite the centre of each coloured space, Sir Isaac Newton refracted the light a second time. In this case it was not drawn out into an oblong image as before, and was not refracted into any other colour than that which formerly belonged to each particular ray. Hence this great philosopher concluded that the light of each particular colour possessed the same index of refraction; and he termed such light homogeneous—that is, of the same kind, or simple; white light being regarded as heterogeneous—that is, of different kinds, or compound.

By various experiments, Sir Isaac proved that all the colours, when again combined, formed or recomposed white light. Indeed the doctrine may be illustrated by mixing together, in proper proportions, seven colours as like those of the spectrum as can possibly be got. By their union a grayish white is formed, for powders of the exact tint as those of the spectrum cannot be obtained. It may also be proved in this manner:—Let a circle of paper be divided into sections of the same size, and coloured like the spaces in the spectrum, and placed upon a humming-top, which is made to revolve rapidly; the effect of all the colours, when combined, is to produce a grayish white.

'All transparent substances, in bending light,' observes Dr Arnott, 'produce more or less of the separation of colour; but it is an important fact, that the quality of merely bending a beam, or of *refraction*, and that of dividing it into coloured beams, or of *dispersion*, are distinct qualities, and not having the same proportion to each other in different substances. Newton, from not discovering this, concluded that a perfect telescope of refraction could never be made; he supposed that the bent light would always become coloured, and so render the object indistinct. We now know, however, that by combining two or more media, we may obtain bending of light without dispersion—thus, by opposing a glass which bends five degrees and disperses one degree, to another glass which bends three degrees and disperses one, the opposing dispersions will just counterbalance each other, while the two degrees of excess of bending will remain to be applied to use.'

It having been found, by the experiments of Newton and others, that none of the seven colours of the solar spectrum could be broken by the prism into new colours, the theory was in some measure established that there were *seven* primitive colours. In time, however, practical men discovered that there were only *three* simple or homogeneous colours, and that all others resulted from them. These three primitive colours were *red*, *blue*, and *yellow*. That this was the true doctrine of colours, has been completely set at rest by the experiments of Mr D. R. Hay (Edinburgh), author of a treatise on the 'Laws of Harmonious Colouring.' We extract the following account of Mr Hay's experiments from the work in question:—

'Although this theory (that of there being only three primitive colours) was not set up in opposition to that of the natural philosophers, but seemed only to be established in a practical point of view, neither was it supported by any scientific experiments; yet it appeared to me more consistent with the general simplicity of nature, and I could not believe that she required seven homogeneous parts to produce what art could do by three. For instance, an artist can make all the colours, and indeed a correct representation of the prismatic spectrum (so far as the purity of his materials will allow), with three colours only; while, according to the theory of Sir Isaac Newton, seven simple or homogeneous colours were employed to produce the real one.

'The following discovery, made by Buffon, and illustrated by succeeding philosophers, helped to strengthen me in the conviction that the scientific theory might, like that of the practical artist, be reducible to three simple or homogeneous parts. If we look steadily for a considerable time upon a spot of any given colour, placed on a white or black ground, it will appear surrounded by a border of another colour. And this colour will uniformly be found to be that which makes up the triad: for if the spot be red, the border will be green, which is composed of blue and yellow; if blue, the border will be orange, composed of yellow and red; and if yellow, the border will be purple—making in all cases a tri-unity of the three colours called by artists homogeneous.

'With a view to throw such light upon the subject as my limited opportunities would permit, I went over the experiments by which Sir Isaac Newton established his theory, and the same results occurred: I could not separate any one colour of the solar spectrum into two. The imperceptible manner in which the colours were blended together upon the spectrum, however, and the circumstance of the colours which practical people call compound being always placed at the adjunct of the two of which they say it is composed, with my previous conviction, induced me to continue my experiments; and although I could not, by analysis, prove that there were only three colours, I succeeded in proving it to my own satisfaction, synthetically, in the following manner:—

'After having tried every colour in succession, and finding that none of them could be separated into two, I next made a hole in the first screen in the centre of the blue of the spectrum, and another in that of the red. I had thereby a spot of each of these colours upon a second screen. I then, by means of another prism, directed the blue spot to the same part of the second screen on which the red appeared, where they united, and produced a violet as pure and intense as that upon the spectrum. I did the same with the blue and yellow, and produced the prismatic green; as also with the red and yellow, and orange was the result. I tried, in the same manner, to mix a simple with what I thought a compound colour, but they did not unite; for no sooner was the red spot thrown upon the green, than it disappeared.

I tried the same experiment with two spectra, the one behind, and of course a little above the other, and passed a spot of each colour successively over the spectrum which was farthest from the window, and the same result occurred. It therefore appeared to me that these three colours had an affinity to one another that did not exist in the others, and that they could not be the same in every respect, except colour and refrangibility, as had hitherto been taught.

'These opinions, the result of my experiments, I published in 1828, as being a necessary part of a treatise of this nature; and I did so with great diffidence, well knowing that I was soaring far above my own element in making an attempt to throw light upon such a subject. I had, however, the gratification to learn that these facts were afterwards proved in a communication read to the Royal Society of Edinburgh by Sir David Brewster, on the 21st of March 1831, in which he also showed that white light consists of the three primary colours—red, yellow, and blue; and that the other colours shown by the prism are composed of these.

'The three homogeneous colours—yellow, red, and blue—have been proved by Field, in the most satisfactory manner, to be in numerical proportional power as follows—yellow, three; red, five; and blue, eight.

'When these three colours are reflected from any opaque body in these proportions, white is produced. They are then in an active state, but each is neutralised by the relative effect that the others have upon it. When they are absorbed in the same proportions, they are in a passive state, and black is the result. When transmitted through any transparent body, the effect is the same; but in the first case they are material or inherent, and in the second impalpable or transient. Colour therefore depends entirely on the reflective or refractive power of bodies, as the transmission or reflection of sound does upon their vibratory powers.'

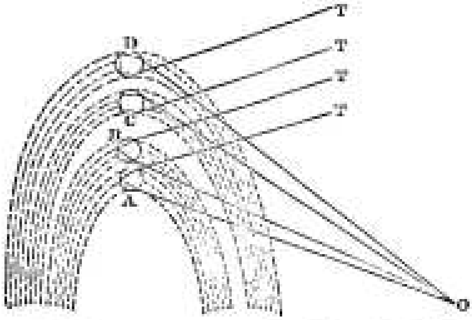
THE RAINBOW.

Every one knows that the rainbow is that brilliant and many-coloured arch occasionally seen spanning the sky opposite to the sun. Rainbows are only visible when rain is falling between the spectator and that part of the sky which is opposite to the sun, which is in its centre, as if at the end of a straight line, drawn from the sun through the eye of the spectator towards the opposite horizon; and being always under the horizon, the bow is less than a semicircle. It consists of two bows or arches—the one inner or primary, the other outer or secondary; and within the primary rainbow, and in contact with it, and without the secondary one, there have been seen supernumerary bows.

The primary or inner rainbow, which is commonly seen alone, is part of a circle whose radius is 41°. It consists of seven differently-coloured bows—namely, violet, which is the innermost, indigo, blue, green, yellow, orange, and red, which is the outermost. These colours have the same proportional breadth as the spaces in the prismatic spectrum. This bow is therefore only an infinite number of prismatic spectra, arranged in the circumference of a circle; and it would be easy, by a circular arrangement of prisms, or by covering up all the central part of a large lens, to produce a small arch of exactly the same colours. All that we require, therefore, to form a rainbow, is a great number of transparent bodies capable of forming a great number of prismatic spectra from the light of the sun.

Sir David Brewster thus explains the cause of the arc of the sky:—As the rainbow is never seen unless when rain is actually falling between the spectator and the sky opposite to the sun, we are led to believe that the transparent bodies required are drops of rain, which we know to be small spheres. If we look into a globe of glass or water held above the head, and opposite to the sun, we shall actually see a prismatic spectrum reflected from the farther side of the globe. In this spectrum the violet rays will be innermost, and the spectrum vertical. If we hold the globe horizontal, on a level with the eye, so as to see the sun's light reflected in a horizontal plane, we shall see a horizontal spectrum, with the violet rays innermost. In like manner, if we hold a globe in a position intermediate between these two, so as to see the sun's light reflected in a plane inclined 45° to the horizon, we shall perceive a spectrum inclined 45° to the horizon, with the violet innermost. Now, since in a shower of rain there are drops in all positions relative to the eye, the eye will receive spectra inclined at all angles to the horizon, so that, when combined, they will form the large circular spectrum which constitutes the rainbow.

To explain this more clearly—let A B be drops of rain exposed in the sun's rays, incident upon them in the direction T A, T B, out of the whole beam of light which falls upon the drop; those rays which pass through or near the axis of the drop will be refracted to a focus behind it; but those which fall on the upper side of the drop will be refracted, the red rays least, and the violet most, and will fall upon the back of the drop with such sufficient obliquity that many of them will be reflected, as shown in the figure. These rays will be again refracted, and will meet the eye at O, which will perceive a spectrum or prismatic image of the sun, with the red space uppermost, and the violet undermost. If the sun, the eye, and the drops A B, are all in the same



vertical plane, the spectrum produced by A B will form the colours at the very summit of the bow, as in the figure. Let us now suppose a drop to be near the horizon, so that the eye, the drop, and the sun, are in a plane inclined to the horizon, a ray of the sun's light will be reflected in the same manner as at A B, with this difference only, that the plane of reflection will be inclined to the horizon, and will form part of the bow distant from the summit. Hence it is manifest that the drops of rain immediately above the line joining the eye, and the upper part of the rainbow, and in the plane passing through the eye and the sun, will form the upper part of the bow; and the drops to the right and left hand of the observer, and without the line joining the eye and the lowest part of the bow, will form the lowest part of the bow on each hand. Not a single drop, therefore, between the eye and the space within the bow is concerned in its production; so that, if a shower were to fall regularly from a cloud, the rainbow would appear before a single drop of rain had reached the ground.

If we compute the inclination of the red ray and the violet ray to the incident rays T A, T B, we shall find it to be 42° 2′ for the red, and 40° 17′ for the violet, so that the breadth of the rainbow will be the difference of these numbers, or 1° 45′, or nearly three times and a half the sun's diameter. These results coincide so accurately with observation, as to leave no doubt that the primary rainbow is produced by two refractions and one intermediate reflection of the rays that fall on the upper sides of the drops of rain.

It is obvious that some of the rays will suffer a second reflection at the points where they are represented as quitting the drop; but these reflected rays will go up into the sky, and cannot possibly reach the eye at O. But though this is the case with rays that enter the upper side of the drop, as at A B, or the side farthest from the eye, yet those which enter it on the under side, or the side nearest the eye, may after two reflections reach the eye, as shown in the drops D C, where the rays T T enter the drops below. The red and violet rays will be refracted in different directions, and after being twice reflected, will be finally refracted to the eye at O; the violet forming the upper part, and the red the under part of the spectrum. If we now compute the inclination of these rays to the incident rays T T, we shall find them to be 50° 58′ for the red ray, and 54° 10′ for the violet ray; the difference of which, or 3° 12′ will be the breadth of the bow, and the distance between the bows will be 8° 15′. Hence it is clear that a secondary bow will be formed without the primary bow, and with its colours reversed, in consequence of their being produced by two reflections and two refractions. The breadth of the secondary bow is nearly twice as great as that of the primary one, and its colours must be much fainter, because it consists of light that has suffered two reflections in place of one.

Many peculiar kinds of rainbows have been observed, such as lunar ones, in which, however, the colours are faint and barely perceptible. Supernumerary rainbows are sometimes seen. 'On the 5th of July 1828,' says Sir David Brewster, 'I observed three supernumerary bows within the primary bow, each consisting of green and red arches, and in contact with the violet arch of the primary bow. On the outside of the outer or secondary bow, I saw distinctly a red arch, and beyond it a very faint green one, constituting a supernumerary bow, analogous to those within the primary rainbow.'

Red rainbows, distorted rainbows, and inverted rainbows on the grass, have been observed. The latter are formed by the drops of rain suspended on the spiders' webs in the fields. It is only necessary to mention that the iris, so frequently seen overarching a cataract, is produced by the refraction of light in passing through the misty vapour generated by the falling water.

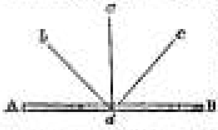
REFLECTION OF LIGHT.

Light, as has been mentioned, is diffused around us by the refractive power of the atmosphere, and therefore objects are quite visible though the rays of the sun do not strike directly upon them; in plainer terms, the atmosphere may be compared to the thick piece of glass called a *bull's eye* fixed in the deck of a ship, by which rays of light are collected and dispersed into all corners of the apartment beneath. The atmosphere being thus a vehicle of light, it may be supposed that, if we were to ascend to a great height above the level of the earth, or beyond the sphere of the atmosphere, we should be almost in darkness, although we were in reality nearer the sun. There is reason to believe that such would be the case; for travellers who have ascended to the summit of Mont Blanc, or about 15,000 feet above the level of the sea, mention that at that height the sky appears to be of an exceedingly dark blue colour, or almost black, and the light so faint that the stars are visible. We may understand from this, that the rays of the sun travel through immense regions of darkness before they reach our atmosphere, and are diffused into that universal soft light which we observe around us.

But besides being diffused by a pure atmospheric medium, light is greatly increased in brilliancy by *reflection*. If all the objects on the surface of our planet were to be black, which is a negation of all colour, the sun's light would be absorbed, or at least return no part of the rays which fell upon them; and we should, even while the sun shone, possess much less light than we now enjoy. Nature has avoided this calamity, and by producing all varieties of colours in objects, the sun's rays which fall upon them are less or more reflected, or sent back into the general mass of light. We now, then, understand that every object we see reflects rays of light, and that these rays travel from the object to our eye, as soon as we bend our vision upon it; inasmuch, however, as a thousand or more individuals may see the same object at the same instant of time, it is evident that the rays proceed at all points, and fall upon eyes at every variety of angle.

If the object be clear or polished in its surface, it will possess the power of representing the image of any object within reach of its rays. Thus the surface of a smooth lake will represent the image of the sky above, or the neighbouring hills, or of any object floating on its surface. This natural property in clear surfaces has suggested the formation of mirrors or looking-glasses. A mirror, or *speculum*, as it is scientifically called, is any instrument of a regular form, employed for the purpose of reflecting light or forming images of objects. Mirrors usually consist of metal or glass, having a highly polished surface. Those which are constructed of glass are coated upon the back with quicksilver, or rather with tinfoil mixed with a little mercury, for the purpose of reflecting more light; were this not the case, so little light would be thrown back, on account of glass transmitting it to a considerable extent, that a very indistinct image would be formed. The word speculum is generally confined to metallic mirrors, and they are either plane, concave, or convex. The plane ones are perfectly flat, like a looking-glass; and a common watch-glass conveys a very good idea of the other two species of mirrors. Coat the hollow surface with mercury, and place it before a candle, it forms a convex mirror; coat it upon the other side, and employ it as before, it becomes a concave mirror.

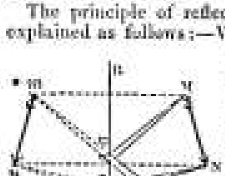
If a plane mirror, A B, be placed exactly in a horizontal position, a ray of light, c, darting downwards in an exactly perpendicular direction, and striking it at d, will be thrown back in the exact path which it traversed in its descent, without any deviation. If, however, it descends in an oblique manner, as is shown at e—a point midway between the perpendicular c and the horizontal A B—it will not return, as in the former instance, to the place whence it came, but will be reflected from the mirror at an angle exactly equal to that at which it descended upon it. The ray e d is called the *incident* ray, and d b the *reflected* ray. In the figure, c d e is called the *angle of incidence*, and b d c the *angle of reflection*; and they are both, as we have observed, exactly equal to each other. This being the fact, we have afforded us a method of universal application by which, when once the angle of incidence, or that at which the ray falls upon a body, is found, that of reflection is easily obtained. This holds true whatever shape the mirror may be of—plane, concave, or convex—and whatever number of rays may fall upon it.



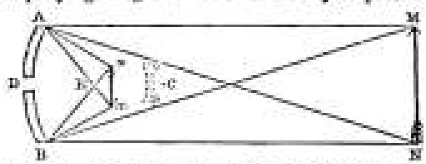
Let us apply the principle here mentioned to the simple phenomenon of seeing ourselves in a plane looking-glass. When we stand directly in front of a mirror, we see our image represented in it; and as we move, so does the image appear to move also, but with a peculiarity in its motion: if, for example, we walk towards the mirror, the image is seen to approach in a similar manner, but the approach is with double the velocity, because the two motions are equal and contrary. Suppose, however, while we stand at the glass, another person walks up behind us, his image will appear to us to move at the same rate as he walks, though to him the velocity will seem double, because, with regard to us, there will be but one motion, and with regard to him there will be two equal and contrary motions.

In the case of standing directly in front of the mirror, the image is necessarily before us, for the rays proceeding from our eye to the mirror are sent back from the surface without any angle of incidence. The case is otherwise when we stand so far at a side that we cannot see ourselves in the glass, though we can see the image of another person equally far off on the opposite side. Two persons so situated will see each other though they cannot see themselves, because the line of rays from the first person striking on the glass form an angle of reflection, and dart off in the direction of the second person, while the rays from the second person are similarly reflected towards the first. Such is a practical exemplification of the angle of reflection in mirrors.

The principle of reflection may be more minutely explained as follows:—We suppose R R to be the surface of a plane mirror, the arrow M N any object placed in front of it, and E the eye of an observer placed at i k. Of the rays which shoot in a rectilinear direction from the points M N of the object, and are reflected from the mirror, those which enter the eye are few in number, and must be reflected from portions D F and G H of the mirror, so situated with reference to the eye and the object, that the angles of incidence of the rays which fall on these portions must be equal to the angles of reflection of those which enter the eye between i and k. For instance, the ray M D is reflected in the direction D i, and the ray M F in the direction F k. In the same manner, the rays N G and N H will be reflected severally in the directions G i and H k. If the rays i D and k F be continued backwards, they will meet at a point m, whence they will appear to have come to the eye. For the same reason, the rays G i and H k, if continued in the same manner, will seem to meet at the point n as their focus, and m n will be the virtual image of the object M N. It is called *virtual*, because it is not formed by the actual union of rays in a focus, and cannot be received upon paper. The virtual image m n is as far behind the mirror as the object M N is before it; consequently, if we join m n, it will be of the same dimensions as M N, and have the same position behind the mirror as the object has before it. If we join the points M m and N n, the lines M m and N n will be perpendicular to the mirror R R, and consequently parallel. In every position of the eye the image is seen in the same spot; its absolute size is always the same, and its apparent size is also the same when seen at equal distances from the eye. If the object M N is an individual surveying himself in the mirror, he will see his perfect image as if at m n.



The manner in which rays are reflected from a concave mirror, next deserves our attention. It will have been frequently observed by the reader, that when he looked at himself in the hollow of a polished metal spoon, his face and bust appeared to be inverted, or upside down. We explain this by referring to the accompanying diagram. M N is an object placed at



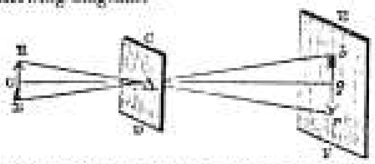
some distance from a concave mirror A B, whose centre is C, and whose principal focus is E. The rays from M fall diverging upon the mirror, and are reflected to a focus at m (a little without the principal focus), where they form an image of the extremity M. In the same way, a representation of the extremity N will be painted at n, so that a complete but inverted image of N M will thus be formed; and it is evident that it will be very bright, though small, because a great number of rays are concentrated, and concur in forming each point of the image. The size of the image thus formed corresponds to the distance of the object from the mirror. If the latter be large, and the former very bright, a series of beautiful experiments may be made by varying the distance of the object, and observing the variations in the size and place of the image. As the object recedes from the mirror, the picture approaches E, and gradually decreases in size.

If we consider m n as a small object, a magnified representation of it will be formed at M N, which, when viewed by a convex lens, such as will be afterwards described, constitutes a *reflecting microscope*. If we place a small concave mirror o p behind it, so as to enlarge the image, and reflect the rays through an opening D in the large mirror A B, then this second image may be magnified still more by means of a lens, in which case it constitutes a Gregorian reflecting telescope. If instead of a concave we employ a convex mirror o p, and place it between E and n m, so as to reflect the rays which would otherwise have met at n m, then an enlarged image would in this case also be painted at D, where it can be magnified as in the former instance.

An image formed by a concave mirror is always highly magnified when the object is near the focus; but as it passes that point, and approaches the mirror, the image gradually decreases in size, and becomes equal to the object when the latter touches the mirror. Indeed, when the object is placed between the principal focus and the mirror, the image is a virtual one apparently formed behind the mirror, or would be so formed behind it if the substance of the mirror permitted. Concave mirrors, from their property of converging rays into a focus, may be used as burning-glasses; practically, mirrors of this shape are used to gather the rays from lamps, and reflect them, with increased brilliancy, into the darkness. The lamps of coaches, lighthouses, &c. are fitted up with these reflectors.

With respect to convex mirrors, they always form images of a diminished size, because the rays which form them become convergent in their passage to the eye of the spectator; in other words, the rays from the object proceed to a virtual or imaginary focus behind the mirror, and thence the image, in a miniature form, seems to be reflected to the eye. In this, as in all cases of reflection from concave mirrors, the size of the image represented is exactly what it might be expected to be if we could see through the glass, and observe the dimensions at the virtual focus.

It is perhaps not generally known that images may be formed upon a piece of paper, by placing a small hole between the object and the paper, and excluding all extraneous light. This will be best understood by the following diagram:—

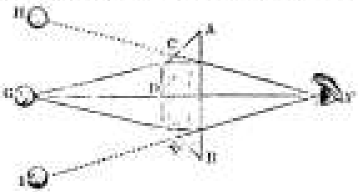


Let C D be a window-shutter having a small aperture A, and E F a piece of paper placed in a dark chamber. Then if an illuminated object, R G B, is placed on the outside of the shutter, we shall observe an inverted image of this object painted on the paper at *r g b*. In order to understand how this takes place, let us suppose the object R G B to have three distinct colours—*red* at R, *green* at G, and *blue* at B; then it is plain that the *red* light from R will pass in straight lines through the aperture A, and fall upon the paper E F at *r*. In like manner the *green* from G, and the *blue* light from B, will severally fall upon the paper at *g* and *b*, and an inverted image *r g b* of the object R G B will be painted upon it. Every coloured point in the object R G B having a coloured point corresponding to it, and opposite to it, on the paper E F, the image *b g r* will be an accurate picture of the object R G B, provided the aperture A is very small. If it be increased in size, indistinctness in the image will ensue; for with a large aperture, two adjacent points of the object will throw their light on the same point of the paper, and thus create confusion in the picture. It is perfectly clear that if the paper E F be moved to a further distance from the hole A, the size of the image will be increased; and if it be brought nearer to it, it will be diminished.

LENSES.

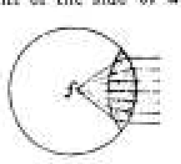
Lenses, as already mentioned, are of different forms, and consequently possess different refractive powers. A lens may be composed of any transparent substance—as glass, diamond, a globule of water, &c.; in the arts, a lens is made of glass, as pure and colourless as possible. The design in forming lenses is to procure a medium through which the rays of light from any object may pass, and converge to a corresponding point beyond. The manner in which the rays proceed through the glass, and then centre in a focal point, will depend on the form of the lens, its capacity for refraction, and the distance of the object.

If we take a piece of glass, flat on one side, and cut into different faces on the other, and then look through it from the flat side at any object—for instance, a pea, we shall see as many peas as there are faces receiving the rays from the single pea. We may exemplify this principle of multiplication by the following figure, in which A B is a lens flat on one side, and cut into three faces on the other *c d e*. F is the eye of the spectator, and G the pea to be looked at. The eye receives a pencil of rays direct through the lens at *d*, and sees the object without refraction. A pencil also proceeds from

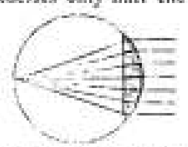


G to the face *c*, and another pencil to the face *e*, and in both cases the rays are bent and refracted to the eye. This eye, however, does not recognise the path of either of these oblique rays, but perceives the image of a pea at H and at I; and thus three peas seem to be seen in place of only one.

In smoothly ground lenses, in which there are no distinct faces to multiply the images of an object, the rays bend, as we have said, so as to meet in a corresponding point beyond them. A lens may consist of a perfect globe of glass, or globe filled with pure water, in which case the refractive power will be considerable; a double convex lens, which is the more common kind, may be viewed as a portion cut out of the side of a sphere, as seen in the annexed fig.

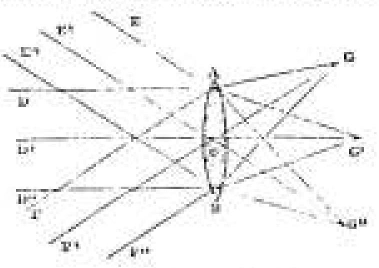


Here, as in all such cases of convexity, the focus of the parallel rays passing through the lens is at *f*, which is the centre of the sphere of which the farther or anterior side is a portion, or a point at half the diameter, or *radius*, of the sphere from it. Should we take a plano-convex lens, the focal point would be considerably different. In the next figure we have an example of this kind of lens, which evidently possesses only half the refractive power of the double convex glass.



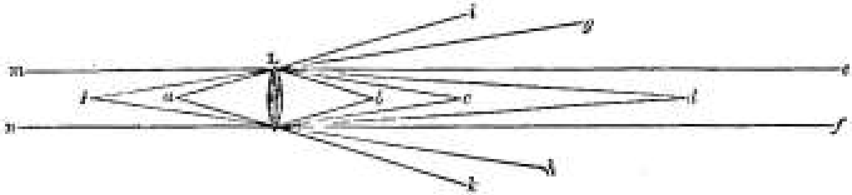
Here the parallel rays, falling on the convex side of the lens, are seen to converge at the distance of the whole diameter of the sphere. Thus the focal point at which the rays of light fall, is always regulated by the degree of curvature of the lens. We shall illustrate this by various diagrams, to which we ask the reader's careful attention, for the subject is somewhat difficult, and cannot be comprehended by a superficial glance.

We take a double convex lens represented by A B, the axis of which is the line G' C D'. The ray D' G', being straight through the centre, suffers no refraction;



but the rays D A and D'' B are refracted so as to meet at the focal point G'. We now observe that the parallel rays E A, E' C, and E'' B, and also F A, F' C, and F'' B, falling obliquely on the lens, will in a similar manner be refracted, and have their foci at G and G'', at the same distance from the lens. Those lines which pass through the centre—as E' C G'' and F' C G—do not alter their direction, not being refracted. Thus in whatever way parallel rays pass through a lens, we have a focal point beyond it, be it straight forward or in an oblique direction.

The distance at which the rays meet beyond the lens is exemplified in the next diagram, given by Dr Arnott in his treatise on Physics, and whose definition of the focal point we beg leave to offer :—' Rays falling from *a* on a comparatively flat or weak lens at L, might meet only at *d*, or even farther off; while with a stronger or more convex lens, they might meet at *c* or at *b*. A lens weaker still might only destroy the divergence of the rays, without being able to give them any convergence, or to bend them enough to bring them to a point at all, and then they would proceed all parallel to each other, as seen at *e* and *f*; and if the lens were yet weaker, it might only destroy a part of the divergence, causing the rays from *a* to go to *g* and *h*, after passing through, instead of to, *i* and *k*, in their original direction.



In an analogous manner, light coming to the lens in the contrary direction from *b c d*, &c. might, according to the strength of the lens, be all made to come to a focus at *a* or at *l*, or in some more distant point; or the rays might become parallel, as *m* and *n*, and therefore never come to a focus, or they might remain divergent.

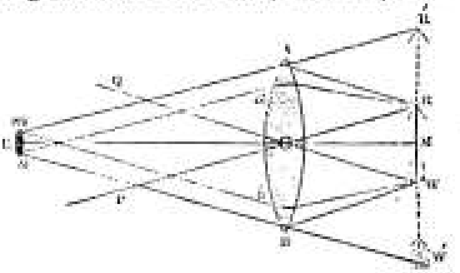
'It may be observed in the above figure that the farther an object is from the lens, the less divergent are the rays darting from it towards the lens, or the more nearly do they approach to being parallel. If the distance of the radiant point be very great, they really are so nearly parallel that a very nice test is required to detect the non-accordance. Rays, for instance, coming to the earth from the sun do not diverge the millionth of an inch in a thousand miles. Hence, when we wish to make experiments with parallel rays, we take those of the sun.

'Any two points so situated on the opposite sides of a lens, as that when either becomes the radiant point of light, the other is the focus of such light, are called *conjugate foci*. An object and its image formed by a lens must always be in *conjugate foci*; and when the one is nearer the lens, the other will be in a certain proportion more distant.

'What is called the *principal* focus of a lens, and by the distance of which from the glass we compare or classify lenses among themselves, is the point at which the sun's rays—that is, parallel rays—are made to meet; and thus, by holding the glass in the sun, and noting at what distance behind it the little luminous spot or image of the sun is formed, we can at once ascertain the focus of a glass, as at *a* for the rays *e* and *f*.'

From the preceding explanations, it will be understood that when an object is placed at any distance from a lens, an image of it will be formed in the corresponding conjugate focus; but to see this image distinctly, the eye must generally be placed at least six inches behind it—that is, farther from the lens. When, however, the object is placed in the principal focus, the rays are refracted parallel, and the image in this case is distinct when seen at any distance. But the most remarkable quality of a double convex lens remains to be noticed; we allude to its magnifying power. This quality is entirely a result of the refractive powers of the glass: embraced within the sphere of the rays from the lens, the object is apparently expanded in size, and seems brought nearer to the eye. This may be elucidated, for small objects seen near, by a reference to the succeeding diagram:—

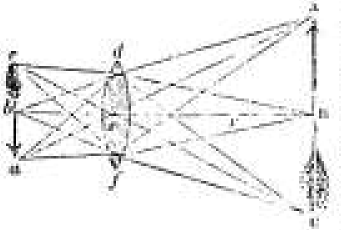
Let E be the eye, and *m n* the diameter of its pupil, R W a small object placed at the least distance of distinct vision (about six inches from the eye for small objects), and let R W be its apparent size when seen by the unaided eye. If a convex lens, A B, is now interposed between the eye and the object, so that the object, R W, shall be in the principal focus of the lens, an enlarged image, R′ W′, of the arrow will then be seen, its extremities R′ W′ lying in the directions E A, E B. The directions of these rays are determined thus :—From R and W draw the central rays R C P, W C Q, through the centre C of the lens; then the rays of the



conical pencil, proceeding from the point R to every point of the nearer surface of the lens, are refracted in such a manner by the lens, that they all emerge in directions parallel to the central ray R C P; but of the whole refracted pencil only a small portion enters the eye—namely, the pencil A *m n a*, limited by the size of the pupil *m n*; and the head A of the arrow, whence this pencil proceeds, appears to lie in the direction of the pencil E A R′ at R′. It is shown exactly in the same manner, that the point W will appear in the direction E B W′ at W′. The enlarged image of the small arrow, R W, is therefore R′ W′. The proportion in which the image is enlarged will be easily ascertained thus:—The triangles E R′ W′, C R W, are similar, and therefore the ratio of R′ W′ to R W, is that of E R′ to C R, or of E M to C M; that is, as the least distance E M of distinct vision, to the focal length C M of the lens. If, therefore, the least distance of distinct vision be divided by the focal length of the lens, the quotient will be its magnifying power. If E M be reckoned 6 inches for small objects, and if the focal length C M be 2 inches; then since 6, divided by 2, gives 3 for a quotient, the magnifying power is 3 times. If C M were one quarter of an inch, then 6, divided by $\frac{1}{4}$, gives 24 for a quotient, and the magnifying power would in this case be 24 times.

A more simple explanation may be attempted :—Turn to the figure in the preceding page, representing the lens with three faces on one side, and flat on the other. There it will be observed that the vision travels in the direction of the ray from the object, as it passes through the glass, and therefore sees an appearance of three objects. Now in the above case of a magnifying lens, the vision in the same manner travels from the eye at E in the direction of the angle of refraction; it goes on to R′ and W′, and thus the actual object being drawn out, as it were, to meet these points of vision, or seemingly expanded by the bent rays, we of necessity see an apparently larger object. If the glass were cut in faces, instead of being smooth, the object would not appear drawn out, but would be multiplied in as many points as there are faces.

The inversion of the image by a lens may be illustrated by the next diagram. A B C is an arrow, with the point uppermost, placed beyond the focus at F, of a double convex glass *d e f*. In virtue of the refractive power of the lens, the rays which proceed from A meet at *a*, and form an image of the arrow point inverted; while the rays from C meet at *c*, and form a similarly inverted image of the feather part of the arrow. The rays proceeding from B unite at *b*. Here only rays from A, B, and C, are represented for the sake of clearness; but in point of fact, rays from all parts of the object proceed through the lens; hence an entire image is



formed in an inverted position. Should the object A B C be brought nearer the lens, the image will be removed to a greater distance, because then the rays are rendered more divergent, and cannot so soon be collected into corresponding points beyond. To procure a distinct image, the object must be removed farther than the focal point F from the glass. In this exemplification the object seems to be diminished; but if we make the small arrow the object, the larger one will be the image of it magnified.

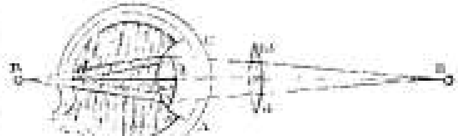
In order to explain the power of lenses in magnifying distant objects, and bringing them near us, let us suppose an object placed at one hundred feet distance from the eye of a spectator. Let us place a convex glass of twenty-five feet focal distance half way between the object and the eye; then, as has been previously observed, an inverted image of the object, and of the same size, will be formed fifty feet behind the lens. If this picture is looked at six or eight inches behind it, it will be very distinctly seen, and nearly as well as if the object itself had been brought to within six or eight inches of the eye of the spectator. If, however, instead of a lens of twenty-five feet focal length, a lens of a shorter focus is made use of, and so situated with respect to the eye and the object that its conjugate foci are at the distance of twenty and eighty feet from the lens—that is, the object is twenty feet before the lens, and its image eighty feet behind it—then the size of the image will be four times that of the object. If the eye, therefore, looks at this magnified image six inches behind it, it will be seen with great distinctness. In this case the image is magnified four times directly by the lens, and 200 times by being brought 200 times nearer the eye; so that its apparent magnitude is 800 times larger than before. At distances less than the preceding, the rule for finding the magnifying power of a lens, when the eye views the image which it forms at six inches' distance, is, according to Sir David Brewster, as follows:—'From the distance between the image and object in feet subtract the focal distance of the lens in feet, and divide the remainder by the same focal distance. By this quotient divide twice the distance of the object in feet, and the new quotient will be the magnifying power, or the number of times that the apparent magnitude of the object is increased. When the focal length of the lens is quite inconsiderable, compared with the distance of the object, as it is in most cases, the rule becomes this:—Divide the focal length of the lens by the distance at which the eye looks at the image; or, as the eye will generally look at it at the distance of six inches, in order to see it most distinctly, divide the focal length by six inches, or, what is the same thing, double the focal length in feet, and the result will be the magnifying power.'

THE EYE—VISION.

Having, in our Account of the Human Body, described the anatomical construction of the eye, we shall here confine ourselves to the actual process of vision. As mentioned in the article referred to, the eye, in front, consists of the *iris*, or variously coloured ring, which has the property of contracting or expanding to regulate the admission of light through the little dark spot in the centre called the *pupil*. Immediately behind the iris and pupil there is a transparent substance resembling in shape a double convex *glass*, which is thence called the *crystalline lens*. The use of this lens is to collect and refract the rays of light, so that they may converge to a point beyond; in other words, cause them to fall on the back part of the eye, called the *retina*. Such are the main instruments of vision; and the sense of seeing is produced by certain nerves which convey intelligence of the image on the retina to the brain. If these nerves be injured, the image will still be pictured on the retina, but the mind will possess no power of recognising their presence.

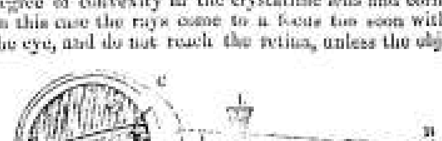
It will be understood from these explanations that the main instrument of vision is the crystalline lens, which collects the rays, and brings them to a focus on the retina. If the lens be perfectly transparent, and of the proper convexity, the light is enabled to act with due effect on the retina, and the representation of the object looked at will be correctly pictured to the mind. But if the transparent coating of the eye be dull, or the lens be either too flat or too convex, every object will appear dim.

Two kinds of defective vision are more common than any other, and they are known by the name of *long-sightedness* and *short-sightedness*. Long-sightedness, or the power of seeing objects best at a considerable distance, is caused by too great a flatness in the crystalline lens and outer coating of the eye; and the deficiency of vision in old persons is usually from a similar cause. To remedy this defect, as far as possible, artificial lenses of glass are employed. These lenses are called *spectacles*, and act in the manner we are now to describe. The annexed figure represents an eye in which the



crystalline lens is too flat. C A is the cornea or outer covering, *b* is the crystalline lens, and *d* is the retina behind; B is the object looked at. We may observe, that in consequence of the flatness of the lens *b*, the rays proceeding from the object are not sufficiently refracted, but proceed to a focus as far back as R; in other words, the focus would be at R, if the retina would permit; but as the retina is in the way, the rays, from not being focalised upon it, cause imperfection in the vision. To remedy this, we interpose an artificial convex lens, or glass of a pair of spectacles (*a a*), and by its aid the rays, represented by dotted lines in the figure, are brought to a focus on the retina at *d*. Thus by selecting spectacles of a proper focalising power in relation to the eye, one kind of imperfect vision is very happily remedied.

Short-sightedness arises from a cause the reverse of that just alluded to, being produced by too great a degree of convexity in the crystalline lens and cornea. In this case the rays come to a focus too soon within the eye, and do not reach the retina, unless the object



is brought quite close to the organs of vision. We here offer a representation of this condition. In consequence of the projecting globularity of the cornea, C A, and the too great refracting power of the crystalline lens, the rays from the object B fall short of the retina at R. To remedy this, we interpose a double concave lens, L L, by which the rays are rendered more divergent before they reach the eye, and are brought to a focus, where they should be, on the retina.

We have said above, that in short-sighted persons the rays do not reach the retina unless the object is held close to the eyes. The effect produced by this is similar to that of employing concave spectacles; because the nearer we hold an object to our sight, the angle of the rays from it is the wider; the rays are more expanded before they enter the eye—that is, more divergent. Thus the extreme rays from a point to the pupil of the eye make a

greater angle at o than those from a point of a more distant object make at a; that is, the rays from o are more divergent on entering the eye than the rays from a, and thus nearness of an object is equivalent to seeing it at a greater distance through a concave lens. So when the object a is farther distant than o, the rays from a have a less divergence, which is equivalent to viewing it at a nearer distance with a convex lens. These remarks, however, refer merely to the distinctness of the vision, and not to the apparent size of the object.

The apparent magnitude of the same object when viewed at different distances, depends on the size of what is called the *visual angle*—that is, the angle formed at the eye by the rays from the extremities of the object. We may exemplify this as follows:—

An eye, E, is looking at an object *a b*, and another object *c d*, at double the distance. It is evident that the rays from *a b* are more expanded, or cause a larger angle on the eye, than the rays from *c d*. Various familiar phenomena are explained from the law of the visual angle under which an object is seen; the apparent size being less always in proportion as the distance of an object is greater. Hence the principles of perspective in drawing, by which objects are made to appear at a great distance in the background of a picture, although in reality they are as far forward as the objects in front.—(See Drawing and Perspective.)

Another important circumstance connected with vision requires to be noticed. In consequence of the refractive power of the crystalline lens, the rays from an object fall upon the retina in such a manner that the image is there pictured upside down; and this inversion of the real appearance of things requires to be corrected by an act of the mind under the influence of experience. We beg leave to offer Dr Arnott's explanations on this somewhat puzzling point:—'Because the images formed on the retina are always inverted as respects the true position of the objects producing them—just as happens in a simple camera obscura—persons have wondered that things should appear upright, or in their true situations. The explanation is not difficult. It is known that a man with a wry neck judges as correctly of the position of the objects around him as any other person, never deeming them to be inclined or crooked, because their images are inclined in relation to the natural perpendicular of his retina; and that a bedridden person, obliged to keep his head upon his pillow, soon acquires the faculty of the person with wry neck; and that boys who at play bend themselves down to look backwards through their legs, although a little puzzled at first, because the usual position of the images on the retina is reversed, soon see as well in that way as in any other. It appears, therefore, that while the mind studies the form, colour, &c. of external objects in their images projected on the retina, it judges of their position, not by the accidental position of the images on the retina, but by the direction in which the light comes from the object towards the eye, no more deeming an object to be placed low because its image is low in the eye, than a man in a room into which a sunbeam enters by a hole in the window-shutter, deems the sun low because its image is on the floor. A candle carried past a keyhole throws its light on the opposite wall, so as to cause the luminous spot there to move in a direction the opposite of that in which the candle is carried; but a child is very young indeed who has not learned to judge at once of the true motion of the candle by the contrary apparent motion of the image. A boatman, who, being accustomed to his oar, can direct its point against any object with great certainty, has long ceased to reflect, that to move the point of the oar in some one direction, his hand must move in the contrary direction. Now the seeing things upright, by images which are inverted, is a phenomenon akin to those here reviewed.'

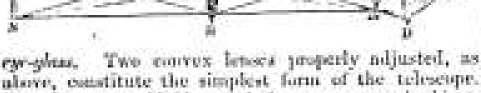
The same able writer on physics proceeds to a definition of another peculiarity in visual arrangements—namely, why, from having two eyes, the object does not appear to us to be double: 'In answer to this, we shall only state the simple facts of the case. As in two chess-boards there are corresponding squares, so in the two eyes there must be corresponding points, and when on those points a similar impression is made at the same time, the sensation or vision is single; but if the impression be made on points which do not correspond, owing to some disturbance of the natural position of the eyes, the vision becomes double. Healthy eyes are so wonderfully associated, that from earliest infancy they constantly move in perfect unison. By slightly pressing a finger on the ball of either eye, so as to prevent its following the motion of the other, there is immediately produced the double vision; and tumours about the eye often have the same effect. Persons who squint have always double vision, but they acquire the power of attending to the sensation in one eye at a time. Animals which have the eyes placed on opposite sides of the head, so that the two can never be directed to the same point, must possess this faculty in a more remarkable degree.

The corresponding points in the two eyes are equidistant, and in similar directions from the centres of the retinæ, which centres are called the *points of distinct vision*, and at them the imaginary lines named the axes of the eyes terminate; but it is worthy of remark that these points, in being both to the right or both to the left of the centres, must be one of them on the inside of the centre, as regards the nose, and the other on the outside—that is to say, a point of the left eye between the centre and nose has its corresponding point in the right eye between the centre and the cheek—and from this fact arise consequences meriting attention. When the two eyes are directed to any object, their axes meet at it, and the centres of the two retinæ are opposite to it, and all the other points of the eyes have perfect mutual correspondence as regards that object, giving the sensation of single vision; but the images formed at the same time, of an object nearer to or further from the eye than the first supposed, cannot fall on corresponding points; for an object nearer than where the axes meet, would have both its images on the outsides of the centres, and an object more distant would have both its images on the insides of the centres—and in either case the vision would be double. Thus if a person hold up one thumb before his nose, and the other in the same direction, but farther off, by then looking at the nearest, the more distant will appear double, and by looking at the more distant, the nearest will appear double. The reason for applying the term 'point of distinct vision' to the centre of the retina, is felt at once by looking at a printed page, and observing that only the one letter to which the axis of the eye is directed is distinctly seen; and consequently that, although the whole page be depicted on the retina at once, the eye, in reading, has to direct its centre successively to every part.'

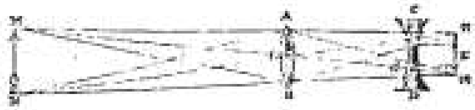
The retina of the eye possesses such exquisite sensibility, that it retains the impression of the image of any bright object presented to it for the space of the eighth of a second after the object has been withdrawn, or after the eye has been shut. Thus the burning end of a rapidly-whirled stick will appear to form hoops of fire; and a fiery meteor or skyrocket shooting rapidly through the air will appear as a long line of light. The mind is in these and similar instances deceived, as the eye, in reality, sees only one point of fire at precisely the same time. The retina, for the same reason, retains for a time an impression of any vivid colour. When we look at the sun, the retina is so strongly affected as to be incapable for a time of seeing other objects distinctly. The most remarkable circumstance connected with these phenomena is, that when the eye is shut after such impressions, a spot of colour, *different* from the colour looked at, is apparently seen. A spot of this nature is in optics called a *spectrum*; and works of an extended character on the science, embrace lengthened definitions of the various spectra with which the eye will be affected. We need here only refer to the experience of our readers on this interesting point, and mention generally, that no satisfactory explanation has ever been given of the reason why the colours in the spectra differ from those which were actually seen.

OPTICAL INSTRUMENTS.

Telescopes.—Telescopes, sometimes called spying-glasses, are instruments in the form of tubes, fitted up with lenses of different kinds and powers, and used for examining distant objects. The word telescope is from the Greek, and signifies *afar off*, and *to see*. A telescope, in its simplest construction, contains two lenses—one is used to create a picture of the object looked at, and therefore called the *object-glass*; the second to magnify that picture, or more properly to enable the eye to come very close to it, and yet have a distinct picture of it, and for this reason called the



eye-glass. Two convex lenses properly adjusted, as above, constitute the simplest form of the telescope. Let the arrow, M N, stand for any outward object, and let its rays fall upon a convex lens, A B, which is seen edgeways in the figure. The rays will be all bent, so that, at a certain distance on the other side of the lens, a new representation of the arrow, *n m*, will be made. The rays from the point of the arrow at M will be so acted on at the two surfaces of the lens, that they will all come together again, and make, as it were, an arrow point at *m*. The rays from the feather at N will fall into their places at *n*, in a new arrow head; and so on throughout, the whole being inverted. A second lens, C D, is used, not to form a second picture (as it would do if distance were allowed it), but to enable the eye at E to look closer at *n m* than it could otherwise do. What the eye sees, therefore, by the two lenses, is a near picture of the original arrow turned upside down. This picture is nearer and larger to the sight in proportion to the roundness of the magnifying lens. Suppose the image, *n m*, is 6 inches from the picturing or *object* lens, then if the eye look at it at a distance of 6 inches, the picture will have the same apparent size as the original, and nothing will be gained. But if the second lens, or *eye-piece*, enables the eye to come within 1 inch of the picture, and yet see it without confusion, it will be 36 times as large to appearance as the original—6 times each way. In fact the view is now improved as much as if a six-mile object were brought within 1 mile. Now the greater the distance of the picture from the object lens which forms it, the greater its focal distance; and the nearer that the eye can be brought to the picture by the eye lens, the larger the appearance will be, or the greater will be the magnifying power of the telescope. Two such lenses shut up in a tube make what is called the *astronomical telescope*. In looking at the heavens, the inversion of the picture causes no inconvenience. In the Galilean telescope, represented below—so called



from Galileo—a concave eye-piece is placed behind the position of the picture, which lodges it at once in the eye. There is no inversion in this telescope.

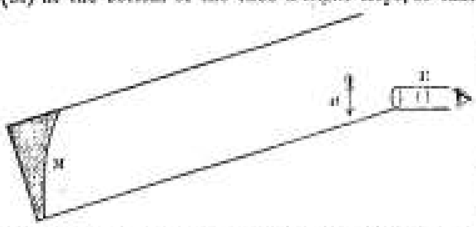
For land objects, which must appear erect, a telescope is formed with additional lenses, which make a second picture, as in next fig. The lens, A B, makes the first picture, and the two lenses, CD and EF, cross the rays

again, and make a second picture, which is upright. This is viewed by the eye-piece, G H. To increase the power of these telescopes, the object-glass, A B, is made with a very long focus, or so as to form its picture as far off from itself as possible. This requires its shape to be very much flattened, and still to preserve a perfect roundness—a matter difficult of execution. All lenses are more or less imperfect; that is, the picture they form is liable to be somewhat confused, which takes off from the advantage of the instrument. The greatest evil is one that cannot be cured by a single lens—that is, the fringing or colouring of the picture. But this action has been done away with by using a double lens, or two lenses of different kinds of glass joined together. The difference in the quality of the glasses to produce colour is so managed that they neutralise one another; and a picture free from coloured and indistinct edges is produced. This compound lens is called *achromatic*, or wanting in colour. With these lenses very perfect telescopes are made of 2, 3, 6, or 10 feet in length, and with eye-pieces of half or quarter of an inch, and under, of focal distance. A three-feet telescope—that is, a telescope where the picture is made 36 inches from the object-glass, and an eye-piece that lets the picture come within half an inch of the eye (a half-inch eye-piece)—would magnify 72 times each way, and have the same effect as if the distance of the original were divided by 72. This, and other instruments in which refracting lenses are employed, are called *refracting telescopes*, and they magnify or bring near in proportion as the focal distance of the object-glass is greater than the focal distance of the eye-glass.

Refracting telescopes require to be of considerable length where much power is required, and on that account reflecting telescopes are for many purposes preferred. The *reflecting telescope* was invented by Sir Isaac Newton, but has been much improved since his time. A view of the improved instrument is given beneath. The peculiarity of this instrument is, that the

image of the object is reflected from a concave mirror within the tube, and this image is again reflected from a small mirror to the eye. Referring to the figure, T is the tube, and A B the object to be represented. At the end opposite from the object, there is a small tube *t t*. At the main end of the wide tube, there is a concave mirror D F, with a hole in the middle at P. The principal focus of this mirror is at I K; here the image *m* is inverted, and the rays, crossing each other at *n*, go on to the small reflector L. From this they are reflected in parallel lines through the hole P. At P they enter the plano-convex lens R, which causes them to converge at *a b*; but here the image requires to be magnified, which is done by means of the plano-convex lens S; in other words, the object is seen under the angle *e f d*. In order to accommodate focal distances, the small mirror L can be removed to a greater distance or brought nearer, by the rods and screws communicating from X.

Sir William Herschel got over the difficulty of placing the observer out between the object and the mirror, by a simpler arrangement. He gave the mirror (M) at the bottom of the tube a slight slope, so that



it sends its image to *a*, at the edge of the tube's mouth, where it is viewed by the eye-piece E without bringing the observer's head between the thing viewed and the mirror. On this principle he constructed telescopes of gigantic dimensions and power. His greatest was 40 feet long, and the mirror 4 feet wide. The use of a large mirror is to take in more light, which is apt to fail in using high magnifying powers. With an eye-piece of an inch focus, the power of such a telescope would be 480 each way, which would magnify a surface nearly a quarter of a million of times. The moon would be seen by such a power as if she were brought within 500 miles of us, her real distance being 240,000.

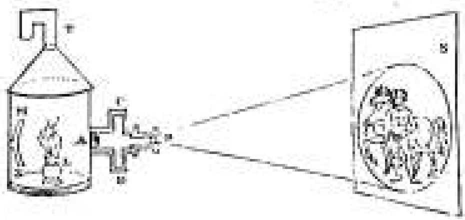
But Lord Rosse has surpassed Herschel in the construction of reflecting telescopes. The chief difficulty in making monster telescopes (apart from the stupendous machinery for supporting and moving them), is the forming of the mirror or speculum, which is of metal, and requires to have a surface of high polish and reflecting power, and at the same time to be ground into a perfectly spherical or rather parabolic form; the mixing of the ingredients to make a good shining metal, and the casting of an immense mass, like a millstone, of an even hardness throughout; and lastly, the grinding, shaping, and polishing of the surface, make a series of operations of the utmost difficulty. After succeeding in the manufacture of the speculum, Lord Rosse has gone on to construct two telescopes of immense power—the one 26 feet long; the other, 'the monster telescope,' 56 feet, the focal length of the mirror being 52 feet. The 56 feet tube is 7 feet wide; the mirror at the bottom is 6 feet wide, with a glittering polish all over the surface, and weighs three tons.

Microscope is a term compounded of two Greek words, signifying *to see what is small*, and denotes that instrument employed to examine minute objects. Those microscopes of greatest power, and termed compound, approach to the telescope in their form. The difference lies in this, that whilst in the telescope the object-glass forms the image of a distant object just as much smaller than itself as the distance of the image from the glass is less, in the microscope, conversely, a small object, placed near the focus of the object-glass, produces a more distant image, as much larger than itself as the image is more distant. In both cases an appropriate eye-glass is employed. The object-glass of a microscope is in general very small, that of a telescope large. An object-glass of a microscope having one-eighth of an inch of focal distance, and so placed as that the image of the object is formed at six inches, the image will be of a diameter forty-eight times as great as the object; and when viewed through an eye-glass of half an inch focus, it will appear magnified twelve times more, or will appear 30,000 times larger than the object. A single or one-lens microscope, magnifies chiefly by allowing the eye to see the object nearer than it could do without the glass.

A *Camera-Obscura*, or *Dark Chamber*, is formed by placing a convex lens in an aperture made in the window-shutter of a darkened room. A glass of proper size and focal distance is chosen, and a screen, or the wall of the chamber, is properly prepared to receive the light, and by this means there is painted on it an accurate picture of all the objects seen from the window, everything bearing an exact resemblance to the reality.

The *Camera-Lucida* is an instrument now frequently used in drawing landscapes, delineating objects of natural history, and copying and reducing drawings. The best form of the instrument consists of a piece of thick parallel glass, at one end of which there is a metallic mirror, having a highly-polished face. The rays from the object are made first to pass through the glass, when they are reflected back upon one of its sides by the mirror, and from that to the eye.

The Magic Lantern.—When a small object is placed close to a lens, and the image reflected upon the wall of a dark chamber, at, say, one hundred times farther from the lens than the object is, there will be a greatly magnified representation of the object. It will only be seen, however, under ordinary illumination; and it is therefore necessary to have a very strong light, concentrated by a suitable mirror or glass, and directed upon the object. When artificial light is employed, as of a lamp, the instrument then becomes a magic lantern. It consists of an argand burner placed in a dark lantern, on one side of which is a concave mirror, the vertex being opposite to the centre of the flame, which is placed in its focus. The lantern is made of tin japanned; and to



carry off the smoke from the flame, it is provided with a tube T at the top. L is the light, and M N a concave mirror to give strength to the light, and send the rays through the tube A B in front. At A in this tube is a hemispherical illuminating lens, and there is a convex lens at B. In the middle of the tube there is a wide part C D, open at the sides, for the reception of *slides*. These slides are slips of glass on which pictures are painted, and the principle of the apparatus consists in forming a representation of the picture, in a magnified size, on a distant white wall or screen S. The slide being placed in one of the conjugate foci of the lens B, the image is consequently enlarged. By bringing the lantern nearer the screen, we diminish the representation, because we cause the rays to strike the screen at a point where they are less divergent. It is an improvement in exhibiting the representations from the magic lantern, to cause the images to fall on a piece of distended and wetted muslin, behind which the spectators are placed. Lately, the mode of representing scenes has been further improved by using two lanterns, placed at equal distances; in this case, while the view in one is being withdrawn, the view in another is coming on, and the eye is charmed with seeing, for example, a scene in winter dissolve and assume the appearance of a similar scene in summer.

ACOUSTICS.

The term ACOUSTICS is derived from two Greek words, which signify *I hear*, and *an art*; and is applied to that branch of natural philosophy which treats of the nature of *sound*, and the laws which determine its production and propagation.

Atmospheric vibration is allowed to be the cause of sound. For instance, a bell is struck by its clapper, the body of the bell consequently vibrates, as we may sensibly assure ourselves by applying our nail lightly to the edge: in its agitation, it beats or makes impulses on the air, which, yielding under the stroke or pressure, is compressed or condensed to a certain distance around. The compressed air instantly expands, and in doing so, repeats the pressure on the air next in contact with it; and thus each one of the original strokes of the vibrating metal sends out a series of *shells* of compressed air, somewhat like the waves dispersed over a lake from the dropping of a stone into its placid bosom, and, like them, always lessening in bulk and force. These *shells* are from two inches to thirty feet in thickness. The air, thus agitated, finally reaches the ear, where it gives a similar impulse to a very fine nervous membrane, and the mind then receives the idea or impression which we call a *sound*.

With regard to the velocity with which the impulse of sound advances, it appears, from the most accurate experiments on the discharge of pieces of ordnance, and marking the interval between the flash and the report, at a distance carefully measured, that when the atmosphere is at the temperature indicated by 62° of Fahrenheit's thermometer, sound travels at the rate of 1125 feet per second, which is nearly equal to the velocity of a cannon-ball the moment it issues from the piece. The ball is very speedily retarded by the resistance of the air, but sound advances with undiminished velocity, though unequal intensity. It will travel a mile in little more than four seconds and a half, or twelve and three-fourth miles per minute. On this depends an easy method of determining in many cases our distance from objects, and which may often prove useful, particularly in thunder-storms. We have only to observe in seconds the interval between the flash and the report, and allow four seconds and a half to every mile, or 1125 feet to every second. It is remarkable, also, that all kinds of sounds, strong or weak, acute or grave, advance with the same velocity; and this arises from the circumstance, that all the oscillatory movements in the air, however minute, or however extended, are performed each in the very same interval of time. For every degree of Fahrenheit above 62°, the velocity of sound is increased one foot and about a seventh (strictly 1 14-100th foot), and for every degree below 62°, it is lessened in the same measure; so that, when the temperature is at the freezing-point, the rate is only 1090 feet per second.

That water is a vehicle of sound as well as the air, is proved by various circumstances, particularly by the fact, that a bell rung under water can be heard above; and if the head of the auditor be also under water, it will be still more distinctly heard. The sound which the sonorous body produces, however, is graver than that which it gives forth in the air. That the atmosphere is necessary for the transmission of sound is evident from the fact, that a bell rung in the exhausted receiver of an air-pump can scarcely be heard. Smooth bodies form favourable channels of sound, as, for example, the surface of ice, snow, water, or the hard ground. Savages, it is well known, are in the habit of putting their ear to the ground, in order to discover the approach of enemies or beasts of prey. Tubes convey sounds with great accuracy, and to great distances, and this property has been applied to various useful purposes. The speaking-trumpet used at sea is a familiar instance; as are also the tubes now generally laid between the galleries and apartments of warehouses, banks, and other public offices, by which the persons in the several apartments can communicate distinctly with each other without rising from their seats. Another valuable application of the tube principle is that of examining the chests of persons supposed to possess pulmonary affections. This is done by means of the *stethoscope*, an instrument invented by Dr Laennec of Paris, and which resembles a small trumpet. The wide end of the instrument is applied to the body, and the other is held to the ear of the physician, who then has a very clear perception of the sounds caused by the action of the lungs, and can judge whether they be healthy or the reverse. A person of skill can exactly describe the condition of the lungs from the nature of the sounds which thus reach his ear.

In consequence of sound requiring a certain length of time to travel, it is impossible for two sounds, at any distance from each other, to be heard at the same moment by persons who are not at equal distances from both. 'If two persons, A and B,' says an American writer, 'are standing at the distance of one mile from each other, and each fires a gun at the same moment, A will not hear B's gun until several seconds after he hears his own, because the sound will require that time to pass through the distance between them. And the same will be the case with B. One might at first suppose that if A should wait and fire at the moment he hears the report from B, the two sounds would then be heard together. A would hear them together, but the time that must elapse after B had fired, before the sound from A would come to *him*, would be greater than if they fired at the same moment: for he must wait till the sound of his own gun had gone to A, and then until the sound of A's discharge should return to him. It is thus evidently impossible for two persons, standing at a distance from each other, to produce a sound which shall be heard by both at the same time.

'It is on account of this principle, that in long ranks of soldiers, where two bands of music are placed at a considerable interval from each other, it is impossible for the two bands to keep time with each other. They may indeed play together, but each soldier will hear the nearest sounds quickest, and thus they will seem to be out of time. It is often noticed, too, that if from an eminence we look upon a long column which is marching to a band of music in front, the various ranks do not step exactly together. Those in the rear are in each step a little later than those before them. This produces a sort of undulation in the whole column, which is difficult to describe, but which all who have noticed it will understand. Each rank steps, not when the sound is *made*, but when, in its progress down the column at the rate of 1125 feet per second, it reaches their ears. Those who are near the music hear it as soon as it is produced, while the others must wait till sufficient time shall have elapsed for it to have passed through the air to them.

'Should a commander stand at the distance of a fifth of a mile from his army, and command them to fire, they might all obey at the moment when the word of command reaches them; but the officer will hear the report of the guns from those at the side nearest him first, then those a little farther off, and so on to the most remote. Thus, though all might obey with equal alacrity, the sounds will not, and cannot, appear simultaneous, for the reports of the distant guns must be delayed long enough for the command to pass from the officer to the men, and then for the sound to return. All attempts, therefore, to make the firing appear exactly simultaneous from a long line must be in vain.'

An *echo*, or duplication of sound, is one of the most interesting phenomena in acoustics. The cause of it is precisely analogous to the reaction of a wave of water. When a wave of water strikes the precipitous bank of a river, it is thrown back in a diagonal direction to the side whence it came, and there again strikes on the bank. In the same manner, the pulses or waves of sound are reflected or thrown back from flat surfaces which interrupt them, and, thus returning, produce what we call an echo. It is evident that the smoother the surface which reflects the sound, the more perfect will be the reverberation. An irregular surface, by throwing back the wave of sound at irregular intervals, will so confound and distract it, that no distinct or audible echo will be reflected. On the contrary, a regular concave surface will reflect sound in such a manner, that at a certain point the reflections from each part of the concave surface will be concentrated into a focus capable of producing a very powerful effect. The velocity with which an echo returns to the spot where the sound originates, depends of course upon the distance of the reflecting surface; and since sound travels at the rate of 1125 feet in a second, a rock situated at half that distance will return an echo in exactly one second. The number of syllables pronounced in a second will in such a case be repeated distinctly, while the end of a long sentence would blend with the commencement of the echo.

An echo may be double, triple, or even quadruple, according to the nature and number of the projecting surfaces from and to which the sound is allowed to play. Distinctly-marked echoes of this combined and planned order may sometimes be heard in the vaults of cathedrals, in which case the waves of sound are driven from side to side of a deeply-groined arch, and reverberate in protracted peals. One of the most interesting echoes of this kind in nature, is that which occurs on the banks of the Rhine at Lurley. If the weather be favourable, the report of a musket, fired on one side, is repeated from crag to crag, on opposite sides of the river alternately, as represented in the fig.

F is considered as the primary point of radiation for the sound, and crossing the river, it strikes at 1, then is sent off to 2, and so on to 3 and subsequent points, stopping, or faintly dying away, opposite E.

There are some remarkable echoes in ecclesiastical structures, arising from peculiarities in the construction. In erecting the baptistry of the church of Pisa, the architect, Giovanni Pisano, disposed the concavity of the cupola in such a manner, that any noise from below is followed with a very loud and long double echo. Two persons whispering, and standing opposite to each other, with their faces near the wall, can converse together without being overheard by the company between. This arises from the elliptical form of the cupola, each person being placed in the focus of the ellipse. In the cathedral church of Gloucester, there is, or was lately, a whispering gallery above the eastern extremity of the choir, which extends from one end of the church to the other. If two persons, placed at considerably distant points, speak to one another in the lowest voice, it is distinctly heard. A similar effect is produced in the vestibule of the Observatory of Paris, and in the cupola of St Paul's in London. A tourist has mentioned that in Italy, on the way to Naples, and two days' journey from Rome, he saw in an inn a square vault, where a whisper could easily be heard at the opposite corner, but not at all on the side corner that was near to you. This property was common to each corner of the room. He saw another on the way from Paris to Lyons, in the porch of an inn which had a round vault. When any one held his mouth to the side of the wall, his whisper could be heard on the opposite side.

The whispering gallery in St Paul's, London, is a great curiosity. It is 140 yards in circumference, and is just below the dome, which is 430 feet in circumference. A stone seat runs round the gallery along the front of the wall. On the side directly opposite the door by which visitors enter, several yards of the seat are covered with matting, on which the visitor being seated, the man who shows the gallery whispers with the mouth near the wall, at the distance of 140 feet from the visitor, who hears his words in a loud voice, seemingly at his ear. The mere shutting of the door produces a sound like a peal of thunder rolling among the mountains. The effect is not so perfect if the visitor sits down half way between the door and matted seat, and much less if he stands near the man who speaks, but on the other side of the door.

It is of great importance that buildings designed for large auditories should be constructed in such a manner, that the voice of the speaker will neither echo from the walls nor be lost to the hearers. The best known form of apartment for the proper distribution of sound, is that in which the length is from a third to a half more than the breadth, the height somewhat greater than the breadth, and having a roof bevelled off all round the sides. This species of ceiling, called technically a coved or *coach roof*, from its being lower at the sides than centre, is in all cases best suited for conveying sounds clearly to the ears of auditors.

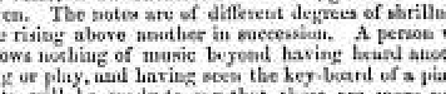
MUSICAL SOUNDS.

There is a peculiar character in sounds, depending on the character of the sounding body. A blow with a hammer, or the report of a pistol, produces only a noise. But if a body be of such a thinness and tightness as to produce a succession of impulses of a sufficient degree of quickness, a *tone* is the result—namely, a sound composed of a great number of noises, all so close upon each other, that they bring but one result to the ear. Wires and strings of metal and catgut, slips of metal, fine membranes, and columns of the air itself enclosed in tubes, are the most familiar means of producing sounds of this kind. Such sounds are said to be musical.

The study of musical sounds, as a branch of natural philosophy, is calculated, perhaps, to give as much pleasure to the man of science as music itself can convey to those who are gifted with what are called good ears. The natural character of these sounds, and their relations to each other, are very remarkable; while the relation of the whole to the human mind must be regarded as one of the most interesting proofs of creative design which the entire circle of nature presents.

The principal sounds of music may be said to be only seven in number. There are other five, which may be produced by the voice with some little difficulty; but the voice, in an untutored condition, gives forth only seven. The notes are of different degrees of shrillness, one rising above another in succession. A person who knows nothing of music beyond having heard another sing or play, and having seen the key-board of a pianoforte, will be ready to say that there are more notes than seven; but there are only seven that are, strictly speaking, various. The voice or an instrument may run up into other notes; but all of these are repetitions of the first seven, and identical respectively with them, in all respects except shrillness. In ordinary pianofortes, there are at least six repetitions of the seven notes, so that the uppermost keys are shriller than the voice of a child, while the lowest rumble like a drum.

The seven notes are named Do, Re, Mi, Fa, Sol, La, Si, or by the first seven letters of the alphabet in a peculiar arrangement—namely, C, D, E, F, G, A, B. They

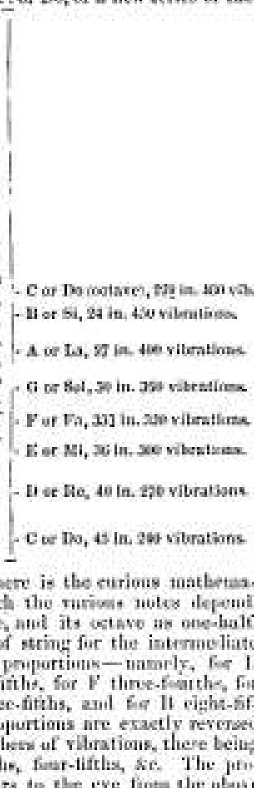


are here represented in the well-known language which musicians present to the eye (using the *treble clef*).

Let an ordinary piece of catgut or violin-string be extended between two points on a board, and screwed up. It may be made, according to its length and degree of tension, to vibrate, when struck, exactly two hundred and forty times in a second. The note which it thus produces is C, or Do; and a man, on trial, will find that this is the note with which he is most apt to begin a song, when he attempts to sing. The note in his voice will be perfectly in unison with the note produced by the string; that is to say, they will melt into and agree with each other, and the effect will be pleasant. This is because the membrane at the top of the singer's windpipe (the instrument of his voice) vibrates exactly the same number of times in a second, producing that note, as the string does. The equality in the number of vibrations is what makes the notes the same, and the effect harmonious and agreeable.

We shall suppose the string to be forty-five inches long that produces the note C of 240 vibrations in a second. Being extended between two pegs near the surface of a board, the experimenter may place his finger upon it right in the centre, and twang or strike either half, when he will find a much shriller note produced, being, in reality, the first C, or Do, of a new series of the seven notes. In this case, the vibrations are exactly double—namely, 480 in a second—these being always the more rapid the shorter the string or the greater its tightness. The second or upper C is called the *octave* of the first, being the eighth note above it.

We shall now suppose that the string is shortened only so far as to leave thirty inches, or two-thirds of its length, free for twanging. This shorter string will sound the note G, or Sol. In this case, as the length of string is two-thirds, so are the vibrations three-halves, or one and a half times those in the former instance; namely, 360. All the other notes are produced by different proportions of string and numbers of vibrations, as shown in the adjoining scale:—



What is remarkable here is the curious mathematical proportions on which the various notes depend. Taking the first C as one, and its octave as one-half, we have various lengths of string for the intermediate notes, in the following proportions—namely, for D eight-ninths, for E four-fifths, for F three-fourths, for G two-thirds, for A three-fifths, and for B eight-fifteenths; all of which proportions are exactly reversed with regard to the numbers of vibrations, there being in succession nine-eighths, four-fifths, &c. The proportions, as clearly appears to the eye from the above scale, are not regular: the string is first shortened five inches, then four, then two and a quarter, next three and three-quarters, and so on. Nevertheless, these are the musical notes which the voice naturally gives forth, and which the mind recognises as beautiful. The string twanged at lengths which would appear in more regular proportion, would give forth musical sounds, but not the seven notes of music—not those peculiar sounds which all nations recognise as such, and which nature has manifestly appointed to serve in that character.

Irregular as the proportions appear, there are some of the seven notes which are more proportioned to each other than the rest. They are said to be more in *harmony* with each other; and the effect when they are struck together is pleasing. It is to be observed in the first place, that a note always harmonises well with its octave, or the eighth or repeating note above it. This is supposed to be because the vibrations of the one note in that case are exactly two for one of the other. The first Do also harmonises well with Sol (G), which is called its *fifth*, being the fifth note above it; and this is, on the same supposition, because the vibrations are in that case as three to two, which is also a symmetrical proportion. Harmony is also produced when some other notes are sounded at the same moment with those which are third above them (their *thirds*); and this may be accounted for in a similar way. Thirds, fifths, and octaves, are therefore pleasing or harmonious sounds; while seconds, fourths, sixths, and sevenths are less so.

Experiments of a very curious nature have been made on this subject. It may readily be observed by the naked eye, that when one of the longer strings of the harp or pianoforte is struck, there is not only a vibration along the whole length, giving it an elliptical appearance, but there are also vibrations of shorter lengths of the same string going on at the same time. It has been found, when light pieces of paper are hung across the string, that they settle at certain places, showing that the principal subordinate vibrations correspond with octaves, fifths, and thirds. A drum, or a sonorous board, over which sand has been strewn, will, if beat, throw the sand into curious figures of a determinate and regularly-recurring character. There are even more curious facts connected with the harmonious notes. The *cries* of a city—that is, the scarcely articulate, but often very musical, sounds uttered by persons selling things on the streets—generally rise on thirds or fifths, sometimes on octaves; and this although few of these poor people have ever been taught music. The cry of oysters by women in Edinburgh is, for example, always on an octave.

With respect to the sounds produced by wind instruments, the effect is caused by the vibrations of a column of air confined at one end, and either open or shut at the other. The length of the sounding column determines the nature of the vibrations; but along with the fundamental tone, there are inferior and subordinate vibrations. The whole column divides itself into regular portions—equal to the half, the third, and so on, of the longitudinal extent—in the same manner as we showed was the case in stringed instruments. We may observe something similar to these vibrations in the contraction and expansion of a long and very elastic string, to one extremity of which a ball is attached. A spiral spring also shows, and perhaps more clearly, the repeated stretching and recoil. If suddenly struck at one end, it will exhibit not only a vibration throughout its whole extent, but likewise partial ones, which wind vermicularly along the chain of elastic rings. If the air be struck with great force, the subordinate vibrations sometimes predominate, and yield the clearest and loudest tones. This may be observed in the dying sounds of a bell, which rise one or two octaves, and expire in the acutest note. Upon the degree of force with which the instrument is blown, depends the performance of the bugle-horn, whose compass is very small, consisting only of the simplest notes. In other wind instruments, the nature of several notes produced depends upon the length and size of the tube, or the positions of the holes in its sides. In the organ, there is a pipe for each note, and wind is admitted from the bellows to the pipes by the action of keys similar to those of a pianoforte. The organ may be played also by a barrel made to turn slowly under the keys, and to lift them in passing, by means of pins projecting at certain determinate intervals from the surface of the barrel. In wind instruments which are furnished with reeds, the tone depends on the stiffness, weight, length, &c. of the vibrating plate or tongue of the reed, as well as on the dimensions of the tube or space with which it is connected.

For further information on the theory and practice of music, see Music and Musical Instruments.

ELECTRICITY—MAGNETISM—ELECTRO-MAGNETISM.

ELECTRICITY.

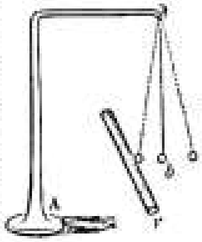
It was observed in ancient times, that when amber was rubbed, it acquired a power of attracting and repelling such light bodies as hair and feathers; and this power afterwards came to be called Electricity, from *electron*, the Greek word for amber. Although the ancients were thus familiar with some of the more obvious phenomena of electricity, they did not investigate the subject methodically, or attempt any generalisation of facts into a scientific theory. It was only in modern times, when close reasoning from truths, established by the evidence of the senses, began to be practised by philosophers, that the phenomena connected with electricity assumed the dignity of a science. Dr Gilbert, an English physician, made the first step towards generalisation in the year 1600. He published a valuable treatise, in which he observed that not only amber, but various other substances, can, by friction, be made to draw light bodies to them. Boyle, Guericke, Newton, and some other philosophers of that period, contributed to extend human knowledge upon this interesting subject; but the real science of electricity took its rise in a later age. About the middle of the eighteenth century, several very remarkable facts were ascertained, particularly by Benjamin Franklin, which identified lightning with electricity; but the extensive relations which connect it with so many other departments of physical science were not discovered until the present century, nor was their importance until then appreciated. In this short era a new science has arisen, founded on that modification of electricity which is known by the name of Voltaic Electricity. The voltaic battery (which will be afterwards described), as an instrument for analysing or decomposing chemical substances, has connected it with chemistry in the most intimate manner. Hence has sprung Electro-Chemistry, one of the connecting branches between remote divisions of the philosophy of nature. Electro-Magnetism is a still more recently-discovered province of science, and which identifies as one two powers which were previously regarded as distinct.

As the best method of conveying a clear, and at the same time philosophical view of this interesting science, we shall, in the first place, independently of all theory, state the most general and remarkable facts connected with it. After these have been enumerated, the reader will be prepared for a review of the theories which have been advanced for the purpose of explaining phenomena, and for connecting the various facts in the mind. The general facts relating to this subject may be classed under two heads—1st, The *Excitation* of Electricity; and, 2d, The *Distribution* of Electricity. Connected with each of these heads are various phenomena, which we shall notice as they occur during the gradual development of the subject.

EXCITATION OF ELECTRICITY.

If a stick of sealing-wax, a bit of amber, the glass of a watch, or any other smooth piece of glass, be rubbed upon dry flannel or woollen cloth, or even the sleeve of a cloth coat, it will be found to have acquired a new and very singular physical property. This property is exhibited by holding the body which has been subjected to friction over small and light substances, such as shreds of paper, gold leaf, feathers, straw, cork, &c. These will be first instantly *attracted* to it, some of them adhering to its surface, others falling back to the place whence they were withdrawn, whilst others are thrown off from the body, as if they were *repelled* from it. Here, then, is a distinct phenomenon—a process of attraction and repulsion at the same instant, which requires careful examination.

The phenomena of attraction and repulsion may be exemplified in a striking manner by a small apparatus, of which we adjoin a representation. A is a stand bent at its upper extremity, and having a hook to which a fine silk thread is attached, with a very small pith ball at its end *b*. Rub a dry rod of glass *r*, and, on presenting it to the ball *b*, the ball will be immediately attracted to the glass, and will remain in contact with it. After they remain in contact for a few seconds, if the glass be withdrawn without being touched by the fingers, and again presented to the ball, the latter will be *repelled*, instead of being attracted, as in the first instance. By being touched with the finger, the ball can be deprived of its electricity; and if, after this has been done, we present a piece of sealing-wax in place of the glass formerly employed, the very same phenomena will take place: on the first application, the ball will be attracted; and, on the second, repelled. It is clear, then, in the first place, that both these electrics—the glass and the wax—have the power of attracting another body before they have communicated to it any of their own electricity; and, secondly, that they repel the body after they have communicated to it a portion of their own electricity.



But a very remarkable circumstance takes place, if we, after having conveyed electricity to the ball *b*, by means of excited glass, which has been for a moment or two in contact with it, should present to it, after the former was withdrawn, excited sealing-wax: the ball, instead of being *repelled*, as it would be were the glass again applied, is *attracted* by the wax. If the experiment be reversed, and the excited wax first presented to the ball, and then the excited glass, the latter will be found to *repel* the ball. 'Hence it follows,' says Sir David Brewster, 'that excited glass *repels* a ball electrified by excited glass. Excited wax *repels* a ball electrified by excited wax. Excited glass *attracts* a ball electrified by excited wax. Excited wax *attracts* a ball electrified by excited glass. From which we conclude that there are two opposite electricities—namely, that produced by excited glass, to which the name of *vitreous* or *positive* electricity has been given; and that produced by excited wax, to which the name of *resinous* or *negative* electricity has been given.

'If, when the pith ball *b* is electrified, either with excited glass or wax, we touch it with a rod of glass, its property of being subsequently attracted or repelled by the excited glass or wax will suffer no change; but if we touch it with a rod of metal, it will lose the electricity which it had received, and will be attracted either by the excited glass or wax, as it was when they were first applied to it. Hence the rod of glass and the rod of metal possess different properties—the former being incapable, and the latter capable, of carrying off the electricity of the pith ball.'

In these experiments, electricity has been produced by *friction*; but there are other methods of obtaining it, which, however, will be afterwards explained.

With regard to attraction and repulsion, a few facts remain to be stated. Some substances remain longer in contact with the electric than others, and two bodies which have both been in contact with the same electric mutually repel each other. If electrics of considerable size are employed, the phenomena of course are better observed; and if the experiment be performed in a darkened chamber, flashes of bluish light will be seen to extend over the surface of the electric submitted to friction, which we shall suppose is a cylinder of sealing-wax, sulphur, or glass. Sparks, accompanied also with a sharp snapping sound, will be seen to dart round it in various directions. If a round body, as a metallic ball, be presented to it, and moved from one end to the other, a succession of sparks will be obtained as the ball passes along the surface; and if the knuckle be presented instead of the metallic ball, each spark will be accompanied by a pricking sensation. If a metallic globe be suspended in the air by silk threads, and in that situation rubbed by an electric, it will also become electrical, and exhibit the same properties as an electric. It is essential to the success of this experiment that it be *insulated;* that is, cut off, by means of a non-conductor, from all communication with any substance, except the air and the electric which sustains it. The instruments employed in experiments similar to those above described are termed *electroscopes.*

DISTRIBUTION AND TRANSFERENCE.

We have noticed that when the excited electric was brought near the pith ball *b*, the latter was first attracted, and then repelled. If we now remove the electric, and present to the ball which has thus touched it a second ball, which has had no previous communication with an electric, we find that these two balls attract one another, and come into contact. The same actions are repeated between this second ball and a third which may be presented to it; and so on in succession, but with a continued diminution of intensity. This diminution plainly indicates a diminished power, in consequence, as it would seem, of its being distributed amongst a number of bodies. It is clear, therefore, that the unknown power which we have called electricity, can, like heat, be transferred or communicated from one body to another, and that its intensity, like that of heat, is weakened by being diffused amongst a number of bodies. An electrified ball can be deprived of its electricity by being touched with a rod of metal of any kind; but if we touch it with glass or wax, it will not be carried off. Hence metals are said to be *conductors*, and glass and wax *non-conductors*, of electricity. Bodies differ greatly in their power of conduction, and many of them owe it to the water which they contain. The following lists show, in a general manner, the kind of substances that possess these properties:—

Conductors.—Silver, copper, lead, gold, brass, zinc, tin, platina, palladium, iron, and the metals in general, charcoal, plumbago, concentrated acids, diluted acids, saline solutions, metallic ores, animal fluids, water, living vegetables and animals, flame, smoke, soluble salts, alcohol, ether, moist earths.

Non-Conductors.—Shell-lac, amber, resins, sulphur, wax, glass, vitrifications, mica, various minerals, silk, wool, hair, feathers, dry paper, leather, air, and all dry gases, baked wood, dry vegetable bodies, porcelain, camphor, caoutchouc, dry chalk, lime, phosphorus, ice, ashes of animal and vegetable bodies, oils.

If electricity is excited on a body, it must either remain on it or pass away; in the former case, the body is a *non-conductor or an insulator;* in the latter case, it is a *conductor.* If the electricity pass along a surface instantaneously and entirely, that surface is a good conductor; if the excitement pass along more slowly, the surface is a conductor of an inferior kind. If the electricity remain altogether stationary at one part of the continuous surface of a body, that body is a perfect insulator; if it remain for a considerable time at one place, but yet have a tendency to move along slowly over the whole body, the insulation is not perfect; there is a degree of conducting power in the substance. Hence a bad conductor is the same as a good insulator, and a bad insulator the same as a good conductor. The metals are the best conductors: the excitement runs along their surface with the speed of light; hence wires and chains, and plates of some metal, such as copper, brass, &c. are used for the purposes of good conduction. Charcoal, in its pure forms, such as plumbago, or that from well-prepared wood, stands next to the metals. Strong acids and alkalies are also good conductors. Water ranks inferior to these, but is still very high; hence all bodies, of whatever material, if they are wet or moist, conduct well; so that to retain the excitement anywhere, dryness is an essential condition. Living animals and vegetables conduct well, in consequence of their containing a great body of water; when dried, both animal and vegetable substances insulate to a very considerable degree, especially the former. Dry silk, wool, feathers, skins, &c. which are all of animal origin, are ranked among insulators. Dry wood, and other vegetable substances, are more nearly allied to conductors than the animal tissues. The resinous bodies are among the best insulators. The most perfect of all insulators are the dry gases, or airs that have no moisture or watery vapour in them. Water, in its liquid state, is a good conductor, but it is an insulator when solidified into ice, or when boiled into steam. The presence of steam, however, is always to be avoided, on account of its liability to be deposited on surfaces, as water or dew; so that although the air were free from visible vapour, yet if it is highly charged with steam or invisible vapour, there is a great danger of the electrical excitement being dispersed by the surfaces of insulators becoming damp. So long, however, as the steam retains its perfectly elastic and gaseous state, like the gases in general, it has no conducting power. Sulphur and phosphorus are among the insulators, and stand perhaps next to wax and the resinous bodies. Some of the insulating solids, such as glass, are rendered conductors by being heated to redness, or to the verge of liquidity: so that the mechanical state of bodies has a great deal to do with their character as conductors or insulators. If all substances were ranked in one table, beginning with the best conductors, and ending with the worst, which are also the best insulators, the metals would be at the top, and the dry gases at the bottom. In the middle would be dry vegetable and animal bodies; between these the line would be drawn where conduction might be said, for all practical purposes, to end, and insulation to begin; but to have good insulation, we would have to descend to glass, sulphur, wax, and shell-lac. Such a table, read from the bottom upwards, would be a table of insulators. When we require strong insulating pillars to support great weight or pressure, glass is commonly used; but where strength is not necessary, wax and shell-lac are preferred. Conducting substances may be rendered non-conducting by being coated with wax or some resinous varnish.

A distinction was formerly made between *electrics* and *non-electrics*, or substances that could be electrified by rubbing, and substances that could not be so electrified; and it was further asserted that non-conductors or insulators were electrics, and that conductors were non-electrics. This was founded on the fact that sealing-wax, amber, and glass, the substances used for exciting electricity, are among the insulators; whereas if we take a good conductor, such as a rod of metal, and rub it ever so much, no excitement seems to be produced. But the whole supposition was founded in a mistake. It is not true that the insulators are the only substances that can be excited by friction; almost every body in nature becomes electric when rubbed with proper precautions. The reason why no electricity appears on a metallic rod or other conductor is, that the excitement is carried off as fast as it is produced; whereas on sealing-wax or glass, it remains stationary, and thus shows itself on the very spot that is rubbed. To electrify a good conductor, it must be carefully insulated. If we take a plate of metal, and attach it to a dry glass handle, and hold it in the hand by the glass, and then rub the surface, a most perceptible excitement is produced, and all the ordinary phenomena of attraction and repulsion can be observed by means of it: so that the metals, and all other conductors, are as good electrics as any of the insulators. In fact, on the electrical machine, a metallic compound is used as one of the rubbing surfaces, and is found preferable to all other rubbers. In this case glass, an insulating substance, is acted on by a conducting substance, showing that, in the actual excitement of the electricity, both kinds may be made available. The distinction of electrics and non-electrics is therefore now abandoned, because non-electrics do not exist, as was supposed. The only substances that have been found incapable of yielding electricity by friction are the gases. There seems to be some feature in the gaseous state of matter that prevents it from acting as an exciting body; probably the same reason that renders gases the most perfect of insulators. But this fact renders still more striking the mistake of calling insulators the only electrics; for the only substances that are absolutely non-electrics are the best insulators that exist. It has been lately proved by Faraday, that a stream of dry air, however violent and intense, rushing through an aperture in a solid body, has no power to excite electricity; although it is demonstrated that the friction, or agitation of the surface of the body, is very strong. But if the stream of air carry along with it particles of powder of any kind, or if it convey liquid drops, a very high excitement may be produced. This discovery was made in consequence of an observation of Mr Armstrong of Newcastle, that steam jets electrified the boiler that they rushed out from. A high *negative* or *resinous* charge is thus given to a metallic boiler, while the jet itself shows *positive* or *vitreous* electricity. The apparent inference from the fact was, that steam could act as a rubber upon metal, and that these two substances could generate electricity by their action, the same as a piece of sealing-wax rubbed with cloth. But when Faraday investigated the phenomenon, he found that what rubbed the cylinder, and created the excitement, was, not the steam, but the water-drops. Dry steam—that is, steam in its perfect invisible elastic state—yields no electricity; and no other dry gas can produce any; but if a certain amount of watery particles be carried out, action arises. And any gas whatever, if it is the medium for sustaining a rush of liquid or solid particles through an aperture, will thereby excite the two electricities—the one kind being made to arise on the body that the stream rushes out from, and the opposite kind appearing in the jet and on everything that it touches. It thus appears that though a stream of water rushing over a surface might evolve electricity, a current of dry air, however powerful, is incapable of the same effect.

THE TWO KINDS OF ELECTRICITY.

It will be understood, from the preceding explanations, that there are two kinds of electricity—namely, a *vitreous* or *positive* electricity, and a *resinous* or *negative* electricity. Although we have thus two electricities, there does not appear to be the smallest difference between them when they are taken individually. The distinction is only observable when brought in contact; they then display so marked a contrariety, or mutually opposive force, that they may be viewed as agents having opposite qualities, which completely neutralise one another by combination, just like an acid and an alkali. It is remarkable that the excitation of one species of electricity is always accompanied by the presence of the other, and both are produced to an equal extent. Thus, when a piece of glass is rubbed by silk, just as much resinous electricity is produced in the silk as there is vitreous electricity produced in the glass; and whatever electrified bodies are repelled by the one, are attracted by the other. Of course these two surfaces, having acquired opposite electricities, invariably attract each other. A white and a black ribbon rubbed against each other between the finger and thumb, exhibit electrical phenomena in a very marked manner. The black is resinously, and the white vitreously electrified; of course they attract each other; and if separated, the one attracts the light bodies which the other repels. When two pieces of the same ribbon of the same length are rubbed, the one being drawn lengthways, and at right angles, over a part of the other, the one which has been subjected to friction in its whole length acquires vitreous, and the other resinous electricity.

To know the species of electricity evolved, it is merely necessary to communicate beforehand, to the slips of gold leaf, a known electricity, either from excited glass, or sealing-wax. If they be divergent with the former, then the approach of a body similarly electrified will augment the divergence, but that of one oppositely electrified will cause their collapse.
